Introduction to the Proceedings of PLEA 2017

The question we all too often forget to ask is Why? Why, for instance did we in Edinburgh set out on the PLEA 2017 journey to give ourselves all the very hard work of creating a huge conference in which people from all over the world were invited to discuss and develop ideas of Passive and Low Energy Buildings (PLEA)? Well the answer is that we believe the issue of good building design, embraced for thirty five years by the PLEA movement is simply one of the most important there is in the evolution of a safer world in which people will be able to live comfortable and affordable lives in a rapidly changing world.

The PLEA organisation started in 1982 as a small group of international friends dedicated to the ideal of sharing knowledge on how to design and operate minimal and renewable energy buildings. The development of solar buildings lay at the core of its ethos in those early days and still does. PLEA now has a membership of several thousand professionals, academics and students from over forty countries (www.plea-arch.org). Having expected three to five hundred abstracts for the 2017 PLEA conference we were overwhelmed by more than fourteen hundred.

It is obvious that the time for PLEA thinking has come.

Where better to share these important ideas than in Edinburgh, the 18th Century capital of the European 'Age of Enlightenment'? It is here we set about creating our Team Scotland to organise the conference, held on the 2nd – 5th July 2017 and including 665 papers published in these Proceedings. The impressive list of people who helped us included: the Scottish schools of architecture and engineering, the City of Edinburgh, the Scottish Government, Historic Environment Scotland, the Royal Incorporation of Architects in Scotland, the Chartered Institution of Building Services Engineers and a host of related professional companies and organisations.

Reflecting the diverse interests of the team involved, the subject matter of the conference is separated in the following proceedings into papers sorted according to the thirty-one Forums in which they were presented at the conference. Readers should first review the contents lists to see which subject areas are of particular interest to them and then browse through the varied papers by selected Forums. Separation of the papers into these various fields enabled authors to present their ideas at the conference to smaller groups with whom they could expertly explore and discuss their own results while learning from other related studies that might lend light to their own thinking.

Introduction to the Proceedings of PLEA 2017

In discussions at one of our Forum Leader meetings we decided that in reality many of the the larger challenges we face could be distilled down into five different themes:

- Building Better, Safer Places for All (inclusion and resilience)
- Designing to Thrive in a Changing world (affordability and well-being in good buildings)
- Learning from, and building on, the Lessons of the Past (evidence based design evolution)
- Powering our Lives with Sustainable Energy (clear, durable and affordable futures)
- Empowering Current Generations (Education for change)

These themes run through in the pages of these proceedings, and were accompanied at the conference itself by a fascinating exchange of ideas, interpretations and assumptions and their attendant design solutions.

The conference was also accompanied by a simple Enlightenment message, presented in four flanking banners in the Ballroom of the Assembly Rooms where generations have deliberated since it was first opened at the height of the original Age of Enlightenmenttwo hundred and thirty ago:

Sun – Light – Wind – Natural Energy Buildings

Thermal assessment of different configurations of roof ponds for passive cooling

José Manuel Almodóvar[1], Pablo La Roche[2] and Dongwoo Yeom[3]

[1] School of Architecture, University of Seville, Spain, jmalmodovar@us.es

Abstract: This paper discusses the cooling potential of two pond roof prototypes built and tested in a hot-dry climate with mild winters. The first roof consists of a pond covered with a floating insulating panel with a spray system above it that operates at night. The second roof is composed of a flat aluminum plate separated from the water by an air gap. At night, the temperature of the aluminum sheet falls below the temperature of the water, and therefore, the water vapor inside the roof condenses and falls by gravity. The potential cooling of a Water to Air Heat Exchanger (WAHE) has also been tested by connecting the cells with the ponds by a pipe through which the cell's air is re-circulated by a fan. We ran multiple series and compared the results to a control cell that had an energy code compliant insulated roof. Results demonstrate that both pod roof variants have higher cooling potential than the code compliant control cell. The best performance is obtained in the insulated roof with WAHE operating all time. In this case, the indoor temperature can be kept below 24 ºC even with ambient temperatures above 35 ºC.

Keywords: pond roof, passive cooling, physical testing – mockups, cooling with water

Introduction

The roof is the most exposed building envelope element to the sky, providing a broad range of possibilities for passive cooling purposes. The concept of a roof pond was introduced by Hay and Yellot (1978), with the "skytherm" system, in which the cooling effect was obtained by nocturnal radiation. Givoni (1994) evaluated the performance of using fixed shade or floating insulation roof pond systems under different climatic conditions. In the last years, considerable resources have gone into the study of pond roofs and several authors have summarized the state of the art of pond roof variants (Spanaki et al., 2011).

This paper discusses two covered pond roofs coupled directly (conductively) with the indoor space for a hot-dry climate with mild winters. Particularly, a roof pond with a floating insulating panel and spray system operating at night and a roof with a sealed flat aluminum plate separated from the water by an air gap. In addition, the effect of a WAHE system on the performance of the pond roofs has been evaluated. A fan re-circulates the indoor air through a WAHE placed inside the pre-cooled pond roof's water that acts as an intermediate sink absorbing and dissipating energy through to the outside air that is the final heat sink.

The WAHE system was patented by Richard Bourne and David Springer (Bourne & Springer, 1992). Although earth to air heat exchangers (EAHE) that use the ground for heat storage and dissipation is being used increasingly (Peretti et al., 2013), WAHE have some advantages compared to EAHE (La Roche et al., 2016). The water dissipates more easily the heat exchanged with the pipe than soil and water has a higher thermal capacity than earth.

Experimental setup

To evaluate the benefits of adopting the different pond roof configurations, test cells were built and monitored at the Lyle Center for Regenerative Studies in Cal Poly Pomona. It is located in a hot-dry climate with mild winters about 40 km east of Los Angeles, in southern California (Figure 1).

Figure 1. Left: pond roof with floating insulation and spray system. Center: pond roof with a sealed aluminum plate. Right: details of the roof with aluminum plate

The test cells are 1.35 m x 1.35 m x 1.35 m, facing south, slightly to the west. The walls of the test cells are 178 mm thick, with drywall on the inside, 5.08 cm x 10.16 cm (2” x 4”) studs with glass wool insulation, OSB board, XPS insulation board, and plywood on the outside. The floor of the cell is made of OSB board and XPS insulation board. The U-value of the wall and floor is 0.308 W/m^2K and 0.299 W/m^2K respectively. The walls were painted white to reduce the heat gains. A double glazed window (610 mm x 610 mm) was installed in the south wall, and was tested with and without shade. A 10.16 cm (4”) exhaust fan and intake flap was installed separately for the ventilation, and 89 mm plastic wheels were installed under the cell to adjust direction and location of the cells. We have evaluated the different roof pond configurations in test cells with identical floor and walls, and we have compared the results with a control cell covered by a code compliant insulated roof with a U-value of 0.055 W/m^2K.

Data loggers were installed in multiple locations in the test cells to monitor the dry bulb temperature, mean radiant temperature, and relative humidity. The sensors were Onset models U12-012, UX 120-006M, and TMC6-HD respectively. Figure 2 shows their location in the test cells.

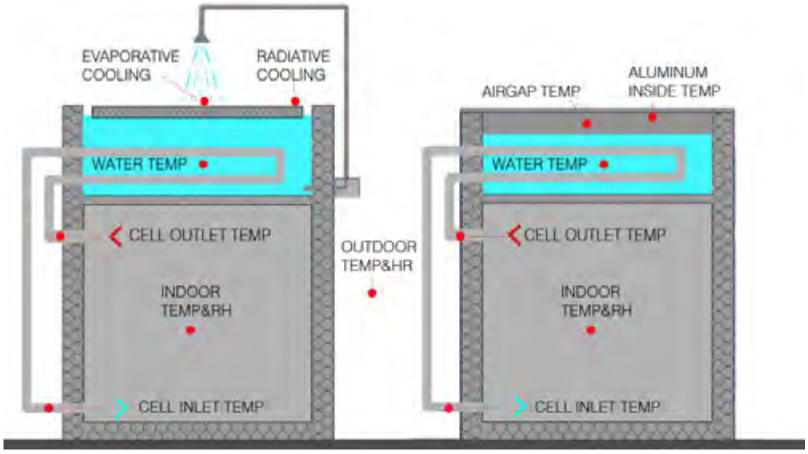

Figure 2. Sensors location

Experimental setup of the roof pond with floating insulation and sprayed at night

This roof is composed of a pond that is 0.35 m deep covered by a floating polystyrene insulation of 3 cm thick. A spray is placed over the pond roof to circulate the water over the insulation during the nighttime and, in turn, cool the water by radiation and evaporation (La Roche, 2012). The exterior surface of the insulating panel is white to reflect solar radiation and the paint provides some improvement in the re-radiation during the night. The spray is 0.5 m above the center of the water pond, the minimum height to provide some significant evaporative cooling (Yannas et al., 2000). The supporting roof is a metal deck that provides good thermal coupling with the space below. The U-value of the roof pond is 0.272 W/m^{2}K. The insulated roof pond was developed by Givoni and then tested with La Roche (La Roche and Givoni, 2000). The spray operation is limited to night hours (from 7 pm to 7 am) in order to improve efficiency and reduce the pond evaporation rate.

Experimental setup of the pond roof with an aluminum plate separated from the water by an air gap

This prototype is an evapo-reflective roof composed of a water pond of 20 cm deep covered with a flat aluminum plate separated from the water by and air gap of 10 cm. The system is properly sealed to prevent water vapor escaping outside. Therefore, no water waste by evaporation is produced. The upper surface of the aluminum sheet is painted white to enhance its reflective properties. At night, the temperature of the aluminum sheet falls below the temperature of the water, and therefore, the water vapor inside the roof condenses and falls by gravity. This way, heat is transferred outside the system. A previous dynamic mathematical model for other pond roof covered by an aluminum plate variant was developed for a hot and dry climate (Ben Cheikh and Bouchair, 2004). Subsequently, it was discussed and compared with other pond roofs by Sharifi and Yamagata (2015). The pond roof is supporting by a metal deck that provides good thermal coupling with the cell indoor air. The U-value is 1.311 W/m^{2}K.

Water to air heat exchanger (WAHE) system description

The cooled water of the pond roofs is used to cool the interior of the test cells by the use of a WAHE. A fan in the pipe connecting the test cells to the pond roofs circulates the indoor air of the experimental cells through a WAHE placed inside the pond's water. The air transfers heat by convection to the underwater pipe which exchanges by conduction heat with water. Finally, the pre-cooled air is introduced into the test cell to reduce overheating (Fig. 3).

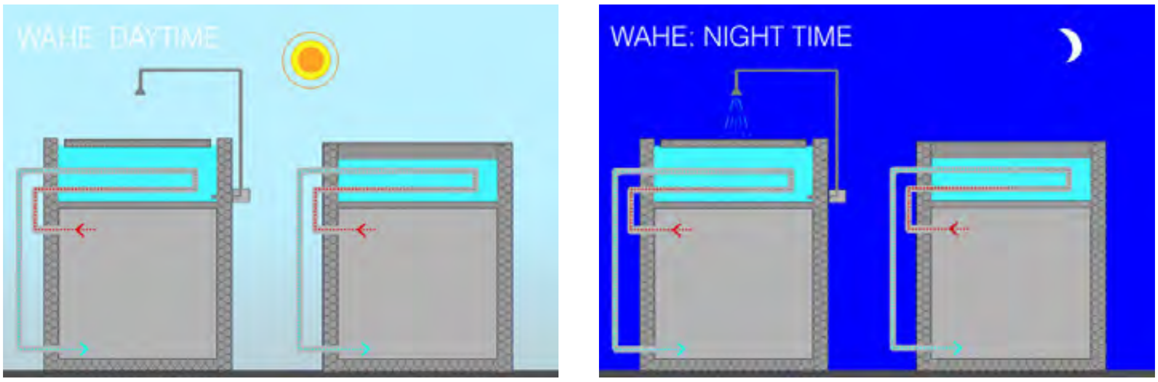

Figure 3. WAHE system operation

A PVC pipe wrapped with batt insulation, waterproofing and aluminum foil moves the air from inside the cells to the pond roofs. However, a flexible uninsulated aluminum pipe under the water increases the pipe's thermal conductivity and WAHE efficiency. Based in previous experimental evaluations for the dimensioning of WAHE in water ponds (Almodovar et al., 2016), we have selected an underwater aluminum pipe of 10.16 cm (4") diameter and 3.5 m length; 1.5 m/s flow velocity; and fan operating all the time (day and night) to continuously reduce the indoor air temperature.

Results

We ran multiple series from August to the beginning of October 2016 and compared the results of different pond roof configurations to a control cell that had a California energy code compliant insulated roof. Due to the space limitation only a few selected series are presented in this paper.

Results of the pond roof with a floating insulation and sprayed at night

Series 1 (Aug. 31 to Sep. 4)
The spray system operates at night (from 7 am to 7 pm) and the WAHE is not connected. The series evaluates the cooling effect of the night-time spray system above the insulating panel to cool the water by evaporation and radiation to the sky and also the effect in cooling the space coupled below by a metal plate.

Maximum temperatures are a good indicator of the cooling performance of the system. The higher the difference between the inside and outside maximum air temperature, assuming a lower temperature inside the test cell, the better the performance. Results show that even with outside temperatures above 35 ºC the cell air temperature can be kept below 27 ºC (8 ºC less than outside) while the control cell maximum temperature is around 29 ºC. Thus, the test cell has better performance than the control cell that reaches 2 ºC more (Fig. 4).

Series 2 (Aug. 21 to 26)
This series investigates the same roof configuration than series 1 but with the WAHE system operating all time (day and night). The results report that the system's performance is far better. The maximum indoor temperature is below 24 ºC while the ambient temperature is around 35 ºC. Hence, a difference of more than 10 ºC is recorded (Fig. 4).

The difference between the maximum pre-cooled air temperature at the pond outlet and the maximum water temperature is only around 1 ºC, while the rate of evaporation was 3.5 mm/day (so around 6.3 liters evaporated per day). On the other hand, results show that the air temperature is almost identical in the cell outlet and pond inlet, as well as the pond outlet and cell inlet. Therefore, the heat transfer when the air circulates through the pipes connecting the interior of the cell and the pond water is negligible.

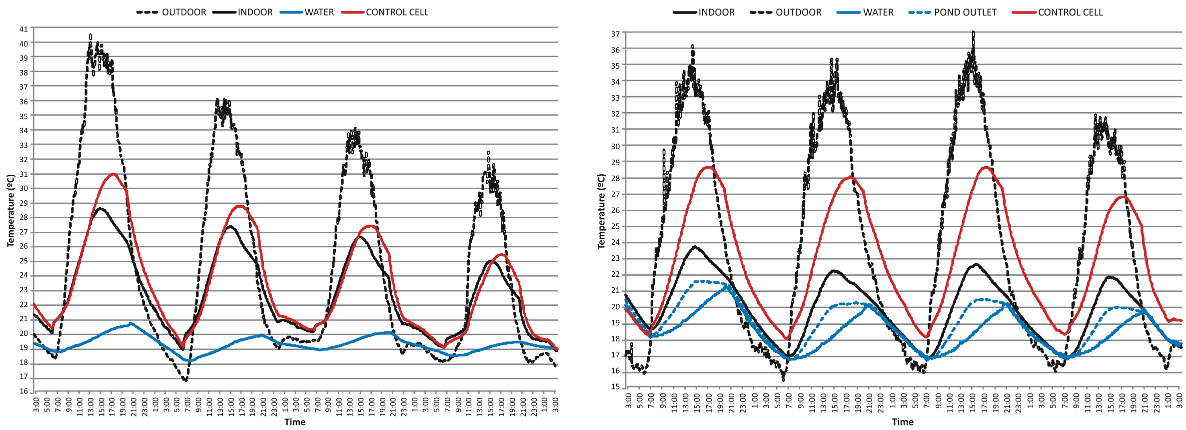

Figure 4. Temperature measured in the insulated pond roof with sprays working at night. Left: series 1, without WAHE. Right: series 2, with WAHE

Results of the pond roof with an aluminum plate separated from the water by an air gap

Series 3 (July 26 to 31)

The WAHE do not operate. Results show that the maximum water temperature is slightly higher than the insulated pond roof with sprays at night. However, the difference between the maximum outdoor and indoor temperature is still high, more than 6 ºC when the ambient temperature reaches 35 ºC. Moreover, the test cell performance is also better than the control cell, being its maximum temperature around 1 ºC lower (Fig. 5).

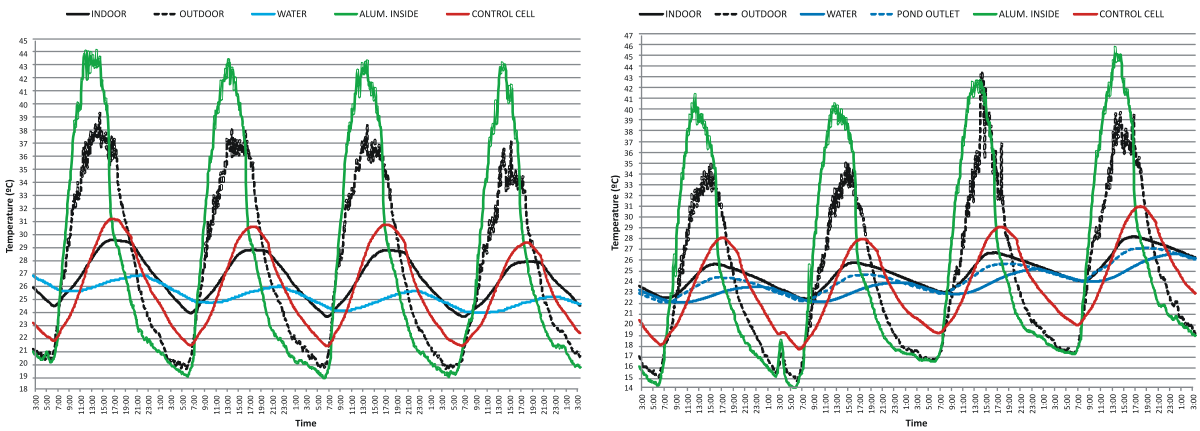

Figure 5. Temperature measured in the aluminum roof. Left: series 3, no WAHE. Right: series 4, with WAHE

Series 4 (Aug. 9 to 14)

This series is similar to series 3 but with the WAHE system operating all day. The test cell maximum indoor temperature can be kept more than 2 ºC below the control cell and the difference between the indoor and outdoor maximum temperature is more than 8 ºC when ambient temperature is over 35 ºC. Therefore, the WAHE considerably increases the cooling performance of the pond roof. On the other hand, the heat exchange in the WAHE is as efficient as in series 2. The difference between the maximum pre-cooled air temperature and the water is only around 1 ºC (Fig. 5).

Series 5 (Aug. 14 to 19)

We tested the same system that in series 4 but with a spray system placed over the water (below the aluminum sheet) that operates at night (from 7 pm to 7 am). Results show the cooling potential is lower than in series 4 (without sprays). When sprays operate at night the aluminum inner surface temperature increases an average of around 6 ºC, from a value close to the outside temperature to about 1 ºC below the water temperature. Due to the higher aluminum inner surface temperature, the condensation process decreases and then also the cooling performance of the whole system (Fig. 6).

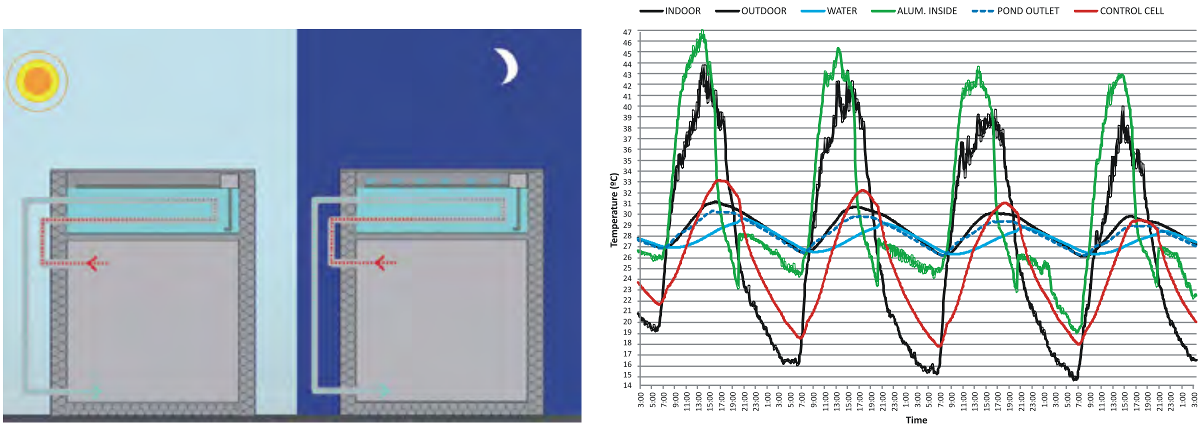

Figure 6. Temperature measured in series 5. Pond roof with aluminum plate, WAHE and spray system

Temperature Difference Ratio (TDR)

The temperature difference ratio (TDR) was proposed by Givoni and implemented by La Roche (2011) and used with good results to compare passive cooling systems with different configurations. TDR is determined by comparing the average reduction of the maximum temperature inside the cell with the average swing as expressed in the following equation:

$$TDR = (T_{max\text{-}out} - T_{max\text{-}in}) / (T_{max\text{-}out} - T_{min\text{-}out}) \quad (1)$$

Where: $T_{max\text{-}out}$ = maximum temperature outside; $T_{max\text{-}in}$ = maximum temperature inside; $T_{min\text{-}out}$ = minimum temperature inside.

The numerator is the difference between the indoor maximum temperature and the outside maximum, and the denominator is the outdoor swing. A higher value indicates that there is a larger temperature difference between outside and inside and there is more cooling. Using TDR we have compared results of the different pond roof configurations and the control cell as a function of the outdoor temperature swing.

Results show that the insulated roof with sprays + WAHE has the better performance, an average of 0.17 better than the roof covered with aluminum + WAHE and 0.23 than the control cell. The performance of the different pond roofs considerably decrease when the WAHE do not operate. More specifically, the insulated pond decreases around 0.12 and the pond roof covered with aluminum plate 0.04. Only the performance of the roof covered with aluminum with sprays working at night is worse than the control cell. Each point in figure 7 is one day’s data.

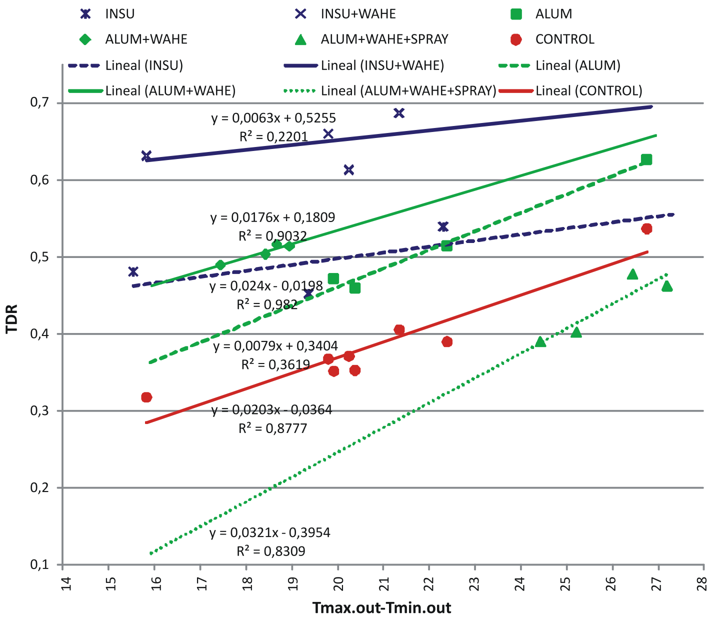

Figure 7: Correlation between the daily outdoor temperature swing and the daily TDR in pond the different pond roof configurations and the control cell

The equations that predict the TDR in each pond roof prototype are listed below:
Insulated pond roof with sprays (INSU):

$$TDR = 0.0024(T_{max\text{-}out}\text{-}T_{min\text{-}out}) – 0.0198 \quad (2)$$

Insulated pond roof with sprays and WAHE (INSU+WAHE):

$$TDR = 0.0063(T_{max\text{-}out}\text{-}T_{min\text{-}out}) – 0.5255 \quad (3)$$

Pond roof covered with aluminum plate (ALUM):

$$TDR = 0.0176(T_{max\text{-}out}\text{-}T_{min\text{-}out}) – 0.1809 \quad (4)$$

Pond roof covered with aluminum plate and WAHE (ALUM+WAHE):

$$TDR = 0.0203(T_{max\text{-}out}\text{-}T_{min\text{-}out}) – 0.0364 \quad (5)$$

After TDR is calculated for a building using Eqs. (2) to (5), it is possible to predict the indoor maximum temperature using equation (1) and solving for $T_{max\text{-}in.}$

$$T_{max\text{-}in} = T_{max\text{-}out} - [TDR * (T_{max\text{-}out}\text{-}T_{min\text{-}out})] \quad (6)$$

Where outdoor maximum and minimum temperatures, or daily temperature swing, must be known. These equations could be used in buildings with lightweight walls, south facing shaded windows and the selected pond roof prototype to predict maximum indoor temperatures.

Conclusion

Previous papers have demonstrated the cooling potential of different pond roofs coupled directly (conductively) with the indoor space for dissipating heat from the building, either by nocturnal long wave radiation to the sky, simple convection to exterior ambient air and evaporative cooling. This paper evaluates two pond roof configurations and demonstrates that their performance is better than a code compliant insulated roof. In addition, their cooling potential could be considerably improved by a WAHE system that re-circulates de indoor air between the cell and the pond roof.

Results show that the better performance is obtained by the insulated roof with sprays at night and WAHE system operating all time. This roof configuration, that is 0.23 better than a code compliant insulated roof (control cell), can keep the indoor temperature under 24 ºC even with outdoor temperature above 35 ºC. Therefore, a difference of more than 10 ºC is recorded. When the WAHE is not operating the system cooling potential decreases an average of 0.12. On the other hand, the efficiency of the pond roof covered with aluminum plate is an average of 0.09 better than the control cell. This percentage is improved to 0.12 when the WAHE system operates.

Future research should include more series to experimentally evaluate other pond roof configurations with a fan sensor that re-circulates the indoor air through the WAHE or provide natural ventilation as required according to seasonal variations.

Design to Thrive

Rethinking the market-driven urban block in Buenos

Camila Ines Della Bitta[1]

[1] MArch Sustainable Environmental Design 2012-2014, Architectural Association School of Architecture, London, UK, camiladb@gmail.com

Abstract: The paper focuses on the environmental design factors that should be considered in the process of urban densification taking place in Buenos Aires, Argentina's largest city and the second largest in South America after Sao Paulo. It follows from a recent study of a typical Buenos Aires urban block in the area of Palermo, a developing neighbourhood where finding land for the construction of new high-rise residential buildings has led to the demolition of much of the heritage tissue. The parameters affecting the environmental performance of the different building typologies that coexist within the city's urban blocks were studied to identify constraints and opportunities for improving indoor as well as outdoor conditions. The paper will present proposals concerned with improving environmental quality and minimizing energy consumption of the new developments, while being cognizant of the developer's capital cost limits. The proposals encompass improvements to the existing heritage houses to prevent their demolition, thus preserving their interesting spatiality which creates a sense of the house in the middle of a city. Finally, the proposals also encompass improvements to open spaces at the centre of the blocks and use of rooftops for communal activities.

Keywords: density, urban block, housing, open spaces, urban typologies

Introduction

In the last couples of decades cities around the world have been experiencing a significant increase in population, due to not only demographic growth but also migration from rural to urban areas. The city of Buenos Aires has been no exception. Buenos Aires is the main and biggest city in Argentina. The country's total population is approximately 40 million, unevenly distributed along the territory. Almost half of the population is concentrated in the province of Buenos Aires and 70% of these live in the City of Buenos Aires. The city of Buenos Aires is divided into two areas: Capital Federal (The city centre) and "Gran Buenos Aires," (The suburbs). Although the suburbs account for approximately 75% of the city's total population, the city centre has a considerably higher density: 14.000 Hab/Km^2 compared to 2000 Hab/Km^2 (INDEC, 2010).

Over the last decades the urban growth has been characterized by urban sprawl towards the peripheries, while the population in the city centre has remained constant. This type of growth incentives social division and increase carbon emissions and energy demand (Burdett and Rodde, 2011). The densification in Capital Federal should be encouraged as it is proven that dense, compact and mixed use urban tissues is energy and resource efficient (Burdett and Rodde, 2011). It is vital that cities provide diversity in a same area: working, residential, commercial, recreational spaces, public transport and services. The closeness to each other will allow inhabitants to walk from one place to the other without depending on the use of a car.

The paper addresses the issue of densification by focusing on a typical block in Capital Federal. The densification in the city has been done by destroying the existing heritage houses, losing the identity they provide to the city and their interesting indoor spatial qualities. The aim of the paper is to provide ways in which these heritage houses can be integrated into the densification process, and at the same time to address the issue of lack of outdoor public spaces in this area.

Climate analysis

The City of Buenos Aires (34°36'S, 58°26'W), is located in a warm template area (IRAM). Throughout the year, the temperature fluctuates between a maximum mean monthly temperature of 25 °C in December-January to 10 °C in June-July. Three seasons can be recognised: a warm period between November and March, with mean temperatures between 20-25 °C; a mild season in April, September and October, with mean temperatures between 15-20 °C; and a cool period between May and August with mean temperatures below 15 °C (Fig. 1).

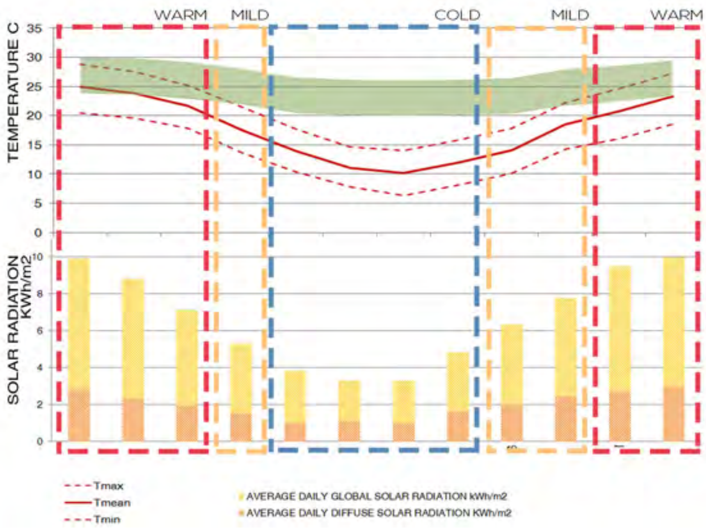

Fig.1: Annual mean temperatures and solar global radiation. Source: After Meteonorm 7.0.

Area of intervention

The paper focuses on Palermo neighbourhood. The main reasons are:

-Palermo registered the highest amount of constructed meter squares of new residential buildings during the last couple of years (Atlas, 2009).

-It is the neighbourhood with the largest and densest population, accounting for 8% of the total population of Capital Federal (INDEC, 2010).

-The distribution of public green outdoor spaces is not convenient in Palermo, as seen by the fact that it is the neighbourhood with the highest amount of population without access to a recreational public space in a 500m radius. The area present big expansions of public parks, but a considerable portion of the population resides far away from these areas (Fig. 2).

There is a need to create an acupuncture design of small and accessible parks for the area, in order to create a more homogeneous distribution of these spaces. These public spaces not only contribute to dissipate negative environmental conditions, but also contribute to social encounter.

Fig. 2: Distances to public green spaces. Source: After Atlas, 2010.

Once the area of intervention was selected, the criterion of selection of a block was based on identifying where it is allowed by the regulation to build the most. Once the block was chosen, the types of building which will be preserved were identified, which turned out to be two: the heritage buildings and the already new builds. It is taken into account that in the developers scenario everything would be demolished and the maximum volume allowed would be constructed in order to maximize the sellable square meters (Fig. 3). This will be following the existing building regulations, one regulate the general urban form (Maximum heights, amount of meter squares, footprint, uses, etc.), and another regulate the habitable conditions inside the dwellings (Minimum size of windows, minimum ventilation required, etc.) (Code, 1977).

Fig. 3: Comparison between the amounts of square meters constructed in each scenario.

The main challenges of the project are:

-How to make the heritage houses more competitive, in order for them not to be demolished?

-How should public space be introduced into the block?

Analytic work

The heritage buildings and new builds are analysed further, in order to determine how these thermally perform in relation to their construction type.

The thermal analysis was performed for the front unit in the heritage houses. A Base case, which assumes how the heritage houses are constructed, was analysed.

During the cool period the highest loses were experienced through the construction: windows, walls and roof. By improving the envelope by adding insulation and applying night shutters during the night, the heat loads were reduced drastically from 31 KWh/m^2 to 6 KWh/m^2. During the warm period (Fig. 4) the highest heat gains are from solar gains. Hence, by improving the envelope and applying shutters to avoid solar penetration inside the room, the cooling loads are reduced significantly. The free-running temperatures in the case of the improved unit stays within the comfort band almost all of the time, reducing peak temperatures from 34 °C to 30 °C.

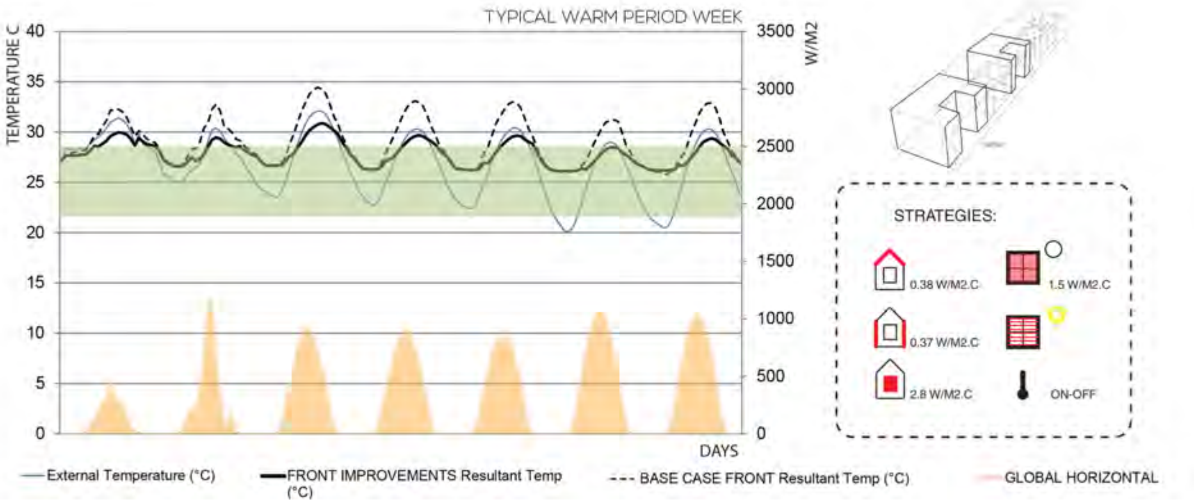

Fig. 4: Free-running temperatures inside the unit in a typical warm period week. Source: After TAS.

The thermal analysis was performed for a unit in the between party wall buildings located at 1st floor. The Base case was analysed, assuming they are constructed in the way currently implemented by developers.

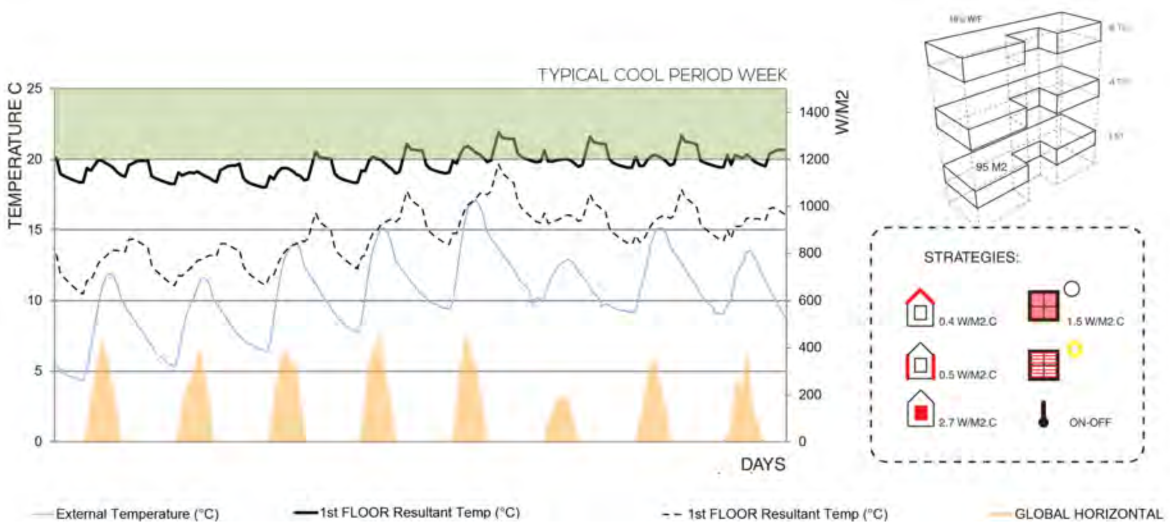

Fig. 5: Free-running temperatures inside the unit in a typical cool period week. Source: After TAS.

During the cool period (Fig.5) the highest loses were experienced through the construction: windows, walls and roof. By improving the envelope by adding insulation and applying night shutters during the night the heat loads were reduced drastically. The free-running temperatures of the improved unit mostly stay within the comfort band, presenting lower temperatures during the night. During the warm period the highest heat gains are from solar gains. Therefore, improving the envelope and applying a blind the cooling loads are reduced significantly. The free-running temperatures of the improved unit remains within the comfort band most of the time, assuming that independence of mechanical means of cooling could be achieved.

Design concept

As mentioned before, the city's growth leads to scarcity of public outdoor space, mainly because most of the investment in the city came from private developers. This project studies the possibility of providing more vitality on the Ground floor to promote social encounter. The block will be “perforated” at ground level in order to allow the people to access and share the central space of the block, allowing a network of public spaces which enhance the connectivity as an urban scale. The environmental conditions are analysed in order to optimize the type of program and activities that will be located there.

Fig. 6: Design brief of the project.

The urban block is currently planned to be constructed by private investors who, following the urban code for construction, destine the outer edge of the ground floor to residential buildings, while the private core is usually destined for private parking. The idea is to “crack” the volume of the block and allow access from the public to the central space. There will be two means of access: two main circulations through the new builds, and four secondary and more local accesses through the five heritage houses (Fig. 6). In this way, 2,400 m^2 of public outdoor space is provided to the neighbourhood. The removed parking area will be replaced by underground parking, providing the same number of parking spaces. Independent designer shops, bars and restaurants, will be located at ground level which will bring life to the ground floor with the added opportunity to enjoy the outdoors.

A mapping of the different microclimates was performed, tracing the percentage of hours of direct solar radiation and the incidence of NE wind speeds. This was done for the warm period and the cool period, in order to recognise the most desirable areas. Two distinct zones in the courtyard can be identified as the result of the mappings: the central area, with wider views to the sky resulting in more solar access, and the corner spaces, with less exposure to the sun. In the central area as the sun patch moves along the courtyard, an open plan was designed in order to allow the free movement along the park. The children’s playground was placed in the sunniest spot, which allows the opportunity to use it, in sunny days, even in the cool season. For the warm period, a line of deciduous trees were placed along the circulations to provide protection from the sun. In the corner spaces which are less exposed to the sun. The expansions of the cafeterias, restaurants, bars and kiosks were placed in this area. When the weather is not warm enough, people will stay indoors.

There are some moments during the cool season that the occupant will not find the environmental conditions on the ground floor adequate. This will be the opportunity to move to the rooftop, which will be unobstructed from the surrounding buildings throughout all the seasons. All the rooftops that are at the same level +26.50m will be connected introducing an additional 3,300 m^2 of communal space (Fig. 6) that could be enjoyed due to the good weather conditions in Buenos Aires.

Special attention is placed on the treatment of shading devices in the rooftop, in order for it to be enjoyed during the warm season. In addition, such as it is unobstructed to the sun, so it is from the wind as well. At this level the wind flows can reach 3-5 m/s. A wind of 5 m/s could represent a reduction of 14 °C in the feeling of the temperature (CIBSE, Guide A, 2006). This could present problems in the outdoor comfort during the cool period. A perimeter rail to be able to control the exposure to the wind in certain areas is studied.

In Fig. 7 the different combinations of pergolas and railing that were used are represented. Through this circulation there are some sitting areas where the user can stop and sit down to enjoy the view. The pergola has mainly two shapes: a “C” shape that allows views to the courtyard and frames a sitting area protected from the sun, or an “O” shape that encourages a simple circulation while still having views. The railing follows this main circulation and, depending on the chosen combination, different levels of protection or exposure to the wind are created.

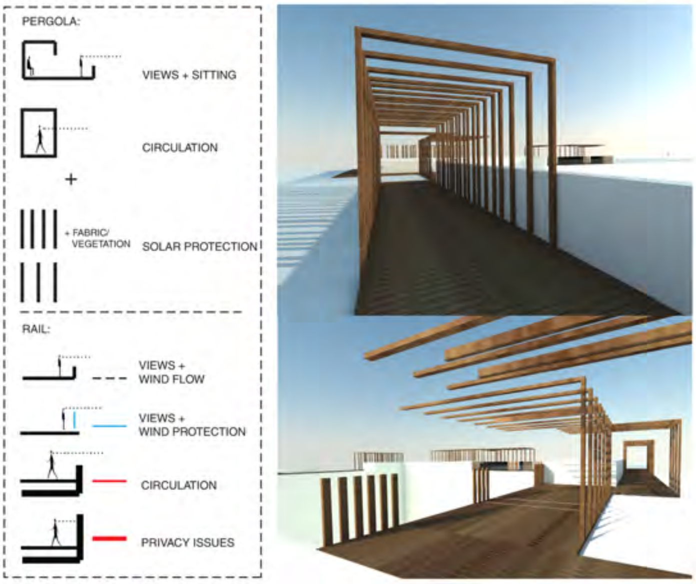

Fig. 7: Pergola and railing combinations.

Avoiding the demolition of the existing heritage tissue is the main challenge. The positive qualities and identity they provide to the urban scene is motivation enough to rethink them and propose a strategy to motivate an interest and investment in them. In a developer’s scenario the heritage houses would be demolished and as much square meters as possible would be built. This would involve 3400 m^2 of demolition works. This shows yet another advantage of preserving the heritage houses: avoiding demolition costs and savings in embodied energy from the materials. Refurbishment of existing buildings is considered one of the most successful sustainable measures: reduction of the use of materials, energy and contamination that a new construction would cause. (Brophy, V and J.O. Lewis, 2011).

In order to create interest in the heritage houses, a densification process is proposed. Due to its construction type (45 cm. brick wall), the existing structure allows the addition of 3 light well type construction levels.

The plots assigned for new developments currently contain buildings without any architectural value: houses constructed in the ‘80s and storage buildings. The proposal is to demolish these, and increase densification following the processes allowed by the code.

Final considerations

The paper studies the possibility of taking advantage of the solar radiation in order to cover some of the block’s electricity demand. In the case of Argentina, an emerging country, the electricity demand is constantly increasing. Electricity production is responsible for carbon emissions to the environment, as approximately 60% is generated from petrol and natural gas (Energy department, 2011). This, together with the electrical crisis that Argentina is experiencing right now (due to the high demand and lack of investment) makes the possibility of developing renewable energies interesting.

The current challenge is that the electricity costs in Argentina are extremely cheap, caused by high levels of state subsidies. This does not motivate neither the user nor the developer to invest in renewables energies. Although there is currently no stimulus from the government, we can assume that there will be. From the total roof surface 1360 m2 are available for placing photovoltaic ("PV") solar panels. The best inclination for these panels, in order to maximize the Global horizontal radiation, is 30° (Della Bitta, C., 2014). With this inclination the incident solar radiation would be 1900 KWh/m2/yr facing N.

Allocating 50% of the available area to Solar panels, 26% of the block's electricity demand (78880 KWh/yr) will be covered by internal generation, reducing the dependence on the national electricity grid. Furthermore, allocating the other 50 % of the available area to solar thermal would reduce the electricity used to heat water by 60% (183600 KWh/yr).

The Proposal's value added exceeds that of the Developers by almost US$ 10 million. This is mainly for two reasons: A 10% price premium on residential units (product of the enhanced design and access to green spaces), and the additional m^2 generated for commercial purposes (which can be sold at US$ 3300/m^2). These two factors increase the block's value by approximately US$ 13.5 million. On the cost side, the Proposal costs exceed that of the Developers by approximately US$ 3.5 million, mainly caused by the deployment of the underground parking lot. The development cost of the residential area is only slightly higher due to the addition of expanded polystyrene as insulation, which is a relatively inexpensive material (US$ 1 per m^2).

The proposal's flats are 30% more energy efficient as they do not rely on the use of the air conditioner and are dependent on heating during fewer hours. As explained if a renewable energy system is installed, this would result in significant reductions of the energy demands. Considering the block as a whole, the proposal would demand 62% less electricity than the block designed by the developers. However, as electricity prices are heavily subsidized in Argentina, the investment in renewable generation units is not economical for individuals, and hence should count with financial aid from the government.

The project proposes 2400 m2 of additional public outdoor space. As discussed earlier, this feature will provide benefits not only to the inhabitants of the block, but to the whole neighbourhood of Palermo.

Conclusion

This paper offers ideas and guidelines on how to enhance the densification process of the existing urban tissue, while preserving the architectural features provided by the heritage houses. Furthermore, the design of a public outdoor space is outlined, in order to address the current lack of public spaces.

The analyses performed related to the new developments lead to a design in accordance to the current urban and construction codes, and in line with the developer's capital cost limits, but with much better energy efficiency and environmental qualities.

The densification of the heritage houses will greatly diminish the incentives to demolish them, which will improve the overall urban quality as they will preserve the city's identity. The promotion of mix-uses in the block will reduce the occupants' dependency on the car, as they will be able to satisfy most of their needs within a walking distance. Buenos Aires' mild weather conditions motivate the idea of exploiting outdoor spaces for social encounter. Projects should be designed for all social backgrounds, in order to provide the possibility of integration and avoid social ghettos. The regulation should be amended in order to support these intentions, since the city's wellbeing cannot be left completely to the market forces.

The main limitation encountered in this dissertation, which limited the exploration of new spatial configurations, are the market forces which encourage developers to build the maximum amount of square meters permitted by the regulation. New combinations of maximum heights and total amount of constructed square meters allowed should be explored in order to achieve high densities in conjunction with interesting indoor spatiality: bigger patios to achieve minimum daylight values, double height roofs and deeper facades for solar control.

In Argentina, as is the case in most developing countries, no strong regulations have been implemented to guide the development of the city. The city's welfare should be analysed and planned by a multi-disciplinary taskforce of architects, economists, sociologists, politicians, and the society as a whole. Only in this way will a balance between social welfare, architectural design and market incentives be found, which will ensure a densification process in an organized and sustainable way.

Building-Integrated Carbon Capturing

Harvey Bryan, Ph.D.[1], and Fahad Ben Salamah[2]

[1] Professor, Arizona State University, Tempe, Arizona, USA, harvey.bryan@asu.edu

Abstract: Building-integrated carbon capturing (BICC) represents a new approach to existing carbon capture technology called Moisture Swing Air Capture Technology, by attempting to integrate this carbon-capturing technology onto building facades. This approach treats building facades as giant artificial leaves that absorb carbon dioxide from the air and convert it into useful carbon-based materials without negatively impacting the environment. In this paper, we will explore how this technology can be modified to be installed on a building's façade in the form of fabric shading devices that absorb carbon dioxide. A cleaning chamber moves along tracks (similar to a window-cleaning system) to moisten the fabric shades and dissolve the bicarbonate on the fibers. This process results in a carbonate and CO_2 liquid that can be compressed and stored for use in a variety of industrial applications. We will use performance data from several non-building devices that have been previously developed and tested to generate the magnitude of the CO_2 that can be captured with this type of technology.

Keywords: Building, Integration, CO_2, Carbon, Capture

Introduction

Achieving stabilization of atmospheric CO_2 concentrations at reasonable levels is looking less and less possible, especially given the present U.S. administration's withdrawal from the Paris Climate Agreement (New York Times, 2017) as well as their termination of the previous administration's Clean Power Plan CO_2 (Davenport et al, 2017). To keep global average warming by century's end to below a 2°C increase (preferable below 1.5°C increase) that is stipulated by the Paris Climate Agreement (FCCC, 2015) will take considerable effort. To reach this global target a host of aggressive and innovative strategies will need to be marshalled to meet this challenge. To date, most strategies have focused on CO_2 mitigation at national levels; while critically important, we also need to engage broader constituencies in combating global warming. Just as distributed renewable strategies have made a significant impact in achieving high levels of renewable penetration in many countries, the authors of this paper believe that a distributed approach can be applied to achieve rapid CO_2 reduction. If this is at all possible, then the question becomes how do we move from a carbon-mitigating approach to one that also includes distributed carbon capturing?

One approach that currently stands out is the process by which nature captures CO_2 from the atmosphere. In essence, we plan to propose a form of biomimicry. Plants have been capturing CO_2 for millennia, turning it into carbohydrates and oxygen in a process known as photosynthesis. What if we treated building façades like giant artificial leaves—that is to say, building facades that could absorb CO_2 from the air and convert it into useful carbon-based materials without negatively impacting the environment? To date, we have reviewed several potential technologies, but the one that looks most promising is called Moisture Swing Air Capture Technology, which has been developed by Dr. Klaus Lackner at Arizona State University's Center for Negative Carbon Emissions (Lackner, 2010). This technology uses filter-like panels made of thin fibers of sorbent material, which is capable of capturing carbon dioxide when in a dry state and then releasing it when moisture is applied. In this paper, we will showcase the Moisture Swing Air Capture Technology and explore in detail how this technology can be modified to be installed on a building façade in the form of fabric shading devices. These devices capture CO_2, which can be compressed and stored for use in a variety of industrial applications.

Capturing carbon dioxide from ambient air

Removing CO_2 from air is not a new thing; it has been around for decades in a process known as CO_2 scrubbing, which is used to generate CO_2-free air (Astarita, 1967). Yet, CO_2 scrubbing is not the same as air capture, because air capture doesn't require removing all the Co_2 from the air. Instead, air capture aims to extract CO_2 from the air efficiently (Lackner et al, 1999). Both technologies use a sorbent material to extract CO_2, with the difference being that air scrubbing requires less sorbent concentration due to the high concentration of CO_2 in the air. Dr. Lackner defines air capture technology in his 2009 article "Capture of Carbon Dioxide from Ambient Air" as follows:

> "A passive, sorbent-based air collector can be viewed as a large filter standing in an airflow with the filter surfaces covered with or made from a CO_2 selective sorbent. Air that comes in contact with sorbent surfaces will relinquish some or all of its CO_2. The larger the surface area and the longer the contact time, the more CO_2 is removed from the air." Pg. 96

In the process of selecting the right sorbent material, Dr. Lackner and his team tried a number of sorbents with the goal being to select a sorbent with lower binding energy (to allow for CO_2 extraction) while maintaining a good CO_2 uptake rate. The evaluation process of different sorbents led to the selection of a strong-base ion-exchange resin that has several appealing properties and suits the air-capture process. One of these properties is the release of CO_2 by exposing it to water. The resin particles are embedded in thin sheets of polypropylene, accounting for almost 60% of the total weight of the material. The sorbent selected was considered a successful choice because they combined two very important properties: low binding energy in the transition from carbonate to bicarbonate, and faster reaction kinetics (Lackner, 2009).

The successful selection of the sorbent leads to the possibility of creating a cycle where CO_2 can be loaded into the resin and then extracted from it through the application of moisture. Once the resin is dry, it will again capture CO_2. To put this cycle into practice, the thin polypropylene sheets with the embodied resin is folded in the planes of the air filter to maximize the amount of sorbent material. They are then exposed to airflow to start the capturing process. Once the sheets are loaded with CO_2, the resin is then exposed to water inside a sealed enclosure, from which the air has been removed. The moisture drives the CO_2 out of the resin, creating a gas that can be compressed and stored. Once the resin is dry, the cycle will continue by absorbing more CO_2 (Lackner, 2009).

The successful selection of sorbent and the laboratory experiments of the CO_2 capturing cycle lead to the design of the carbon carousel machine proposed by Dr. Lackner, which will be described in detail in the following section of the paper.

Carbon carousel: One big filter

The goal of Dr. Lackner's team is to design a device that can be built on the basis of current state-of-the-art technology and packaged in a single cargo shipping container for ease of transportation. The ability to transport such a device will not limit the device for a particular site. As CO_2 is evenly distributed in the atmosphere, the ability to transport such device will allow CO_2 capturing wherever it has been generated around the world. This device would be capable of capturing one ton of CO_2 per day, by collecting one ton per day, the device will provide an excellent scale for its first commercial application (Lackner, 2009).

Figure 1. Carbon Carousel (Source: Kevin Hand, Courtesy of Columbia University, 2010).

The envisioned apparatus will mimic the laboratory experiment of carbon capturing from airflow but on a larger scale. The apparatus will involve a set of air filters that are 1 m wide, 2.5 m tall, from 0.3 m to 0.4 m thick. Each air filter has a total surface area that is equal to 2.5 m^2. The design was intended for an air speed of 1 m/sec across the filter, which is suitable for locations with air speed of several meters per second. A number of various geometries were explored for the design of the air filter to maximize the flow of air and to allow for resin embodiment within the sheets. The selected design was a honeycomb-like structure with narrow but straight passages that function in a way similar to air filters that collect particles from airflow in a duct. Based on the filter design properties and concentration of the resin material, the continuous deployment of thirty air filters would capture one ton per day. However, due to the time required for recovery (the drying of filters takes a noticeably long time), the apparatus was designed to contain 60 filters to ensure a high rate of collection (Lackner, 2009).

Carbon dioxide air filters are placed on an automated conveyor, where the filters will be exposed to natural airflow. It is estimated that it will take one hour for the filter to become loaded with CO_2. Once the filter is saturated with CO_2, an elevator-like moving mechanism removes the air filter and place it in the evacuation chamber where the process of extracting CO_2 takes place.

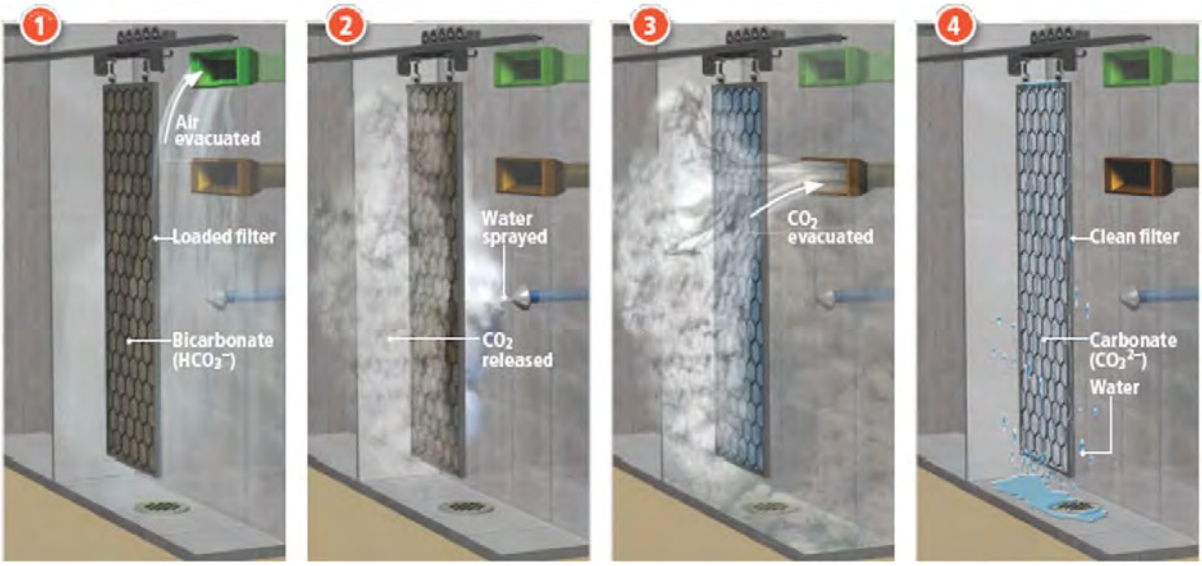

Figure 2. Cleaning Process (Source: Kevin Hand, Courtesy of Columbia University, 2010).

There are six chambers within the shipping container, and each holds 5 filter units. Once the chamber is filled with filter units, the air is evacuated. The filters are exposed to moisture, either by exposing them to briny water or by spraying clean water into the chamber to dissolve the bicarbonate on the fibers, which produces carbonate and CO_2. The CO_2 will be evacuated and compressed into a storage chamber, and the water drained and collected for further CO_2 extraction (Lackner, 2010).

The analysis of the to operate such a device showed that it can be operated using only minimal energy. In the first step, the automated conveyors and elevator mechanism move the air filters into and out of the chambers. In the second step, the air is removed from the air chamber. The third step consumes the largest amount energy in the system, as it involves the compression of CO_2 from 5 kPa to 6.7 MPa in its liquid form. The last energy-consuming step involves the compression and condensation of water vapor (Lackner, 2009).

It is estimated that the total energy required to operate such a system is equivalent to 1.1 Mj/kg of CO_2 (Lackner, 2008). Compared with the amount of CO_2 generated as a result of such an energy requirement, even in a carbon-intensive economy like China, the CO_2 captured using this system is almost 4 times the amount CO_2 released as a result of the process of energy generated for its use (Lackner, 2009).

Building-Integrated carbon capturing

The potential carbon-capturing technology described earlier in this paper will be modified to be installed on building surfaces in the form of shading devices. This method will allow buildings to lower solar heat gain through shading while simultaneously capturing CO_2 through the air filters attached to the building facade. Unlike the carbon carousel machine, *building-integrated carbon capturing* (BICC) will allow for carbon capturing in cities and urban settlements where the collected CO_2 can be stored for local use or shipped elsewhere for other applications.

BICC will mimic the properties of the air filters used in the carbon carousel machine. Thin fibers of sorbent material are arranged in a honeycomb-like arrangement that is similar to air duct filters. The alterations to the filter height, depth, and thickness are necessary to adapt the filter size to be implemented on building façades. The air filters in this system are 0.6 m in depth, 1.6 m in height, and 0.1 m in thickness and it is similar to the air filters in the carbon carousel machine with respect to the sorbent material used. The filter devices will be attached to building façades vertically, forming a column of air filters that runs from the top of the building to the bottom, arranged in a way that fits between the window bays.

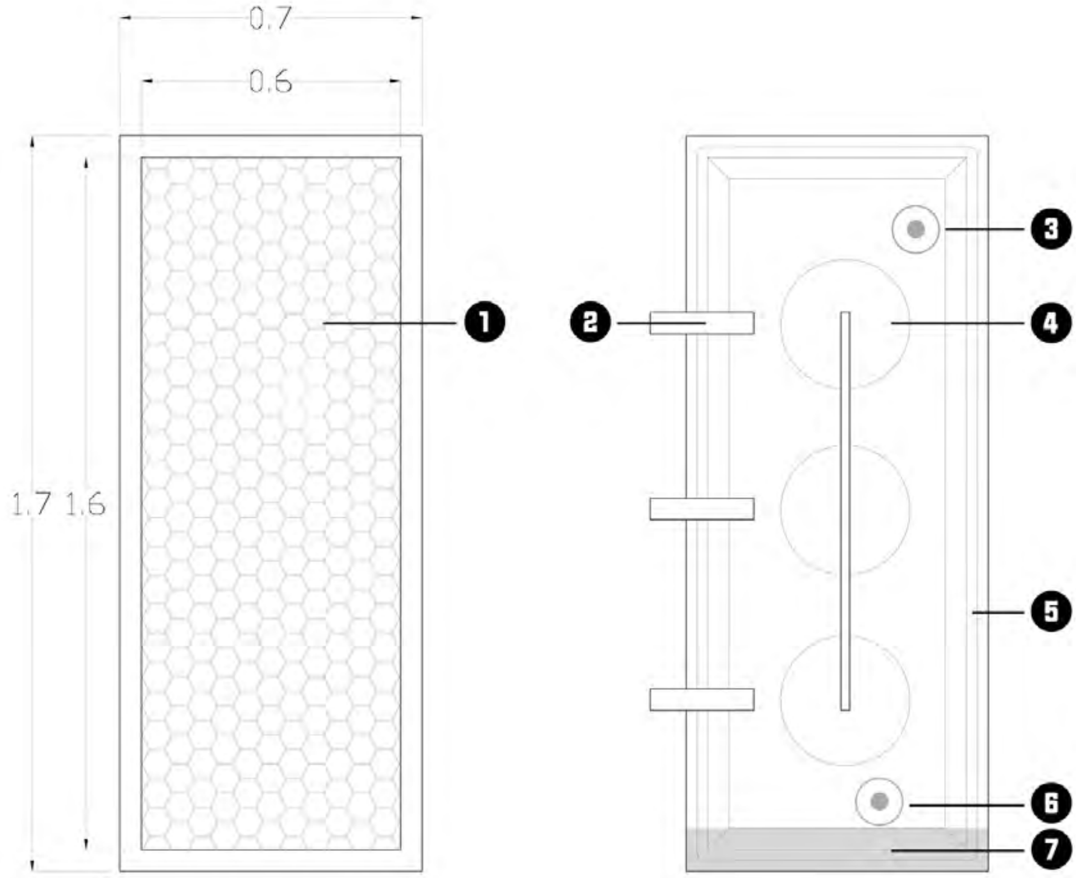

Figure 3. Front elevations of air filter (left) and cleaning chamber (right). 1) Polypropylene sheets. 2) Connection to tracks. 3) Hose to CO_2 tank. 4) Water Sprayers. 5) Sealant. 6) Hose to water tank. 7) Drain

The panels will be exposed to the air in a fixed and static condition. Unlike in the carbon carousel, the BICC panels will not move through a moving conveyor into the cleaning chamber. Once the air filters are loaded with CO_2, a moveable cleaning chamber has been designed as a replacement for the large stationary cleaning chamber in the carbon carousel machine. The moveable chamber moves along tracks (similar to a window-cleaning system) to moisten the fabric shades and dissolve the bicarbonate on the fibers. This produces carbonate and CO_2 liquid. This liquid undergoes processing to separate the water from the CO_2, with the water being recycled back into the cleaning apparatus and the CO_2 being compressed and stored for use in a variety of industrial applications. The cleaning chamber moves to the next panel while solar radiation dries the fabric shade panels, making them ready for the next cycle.

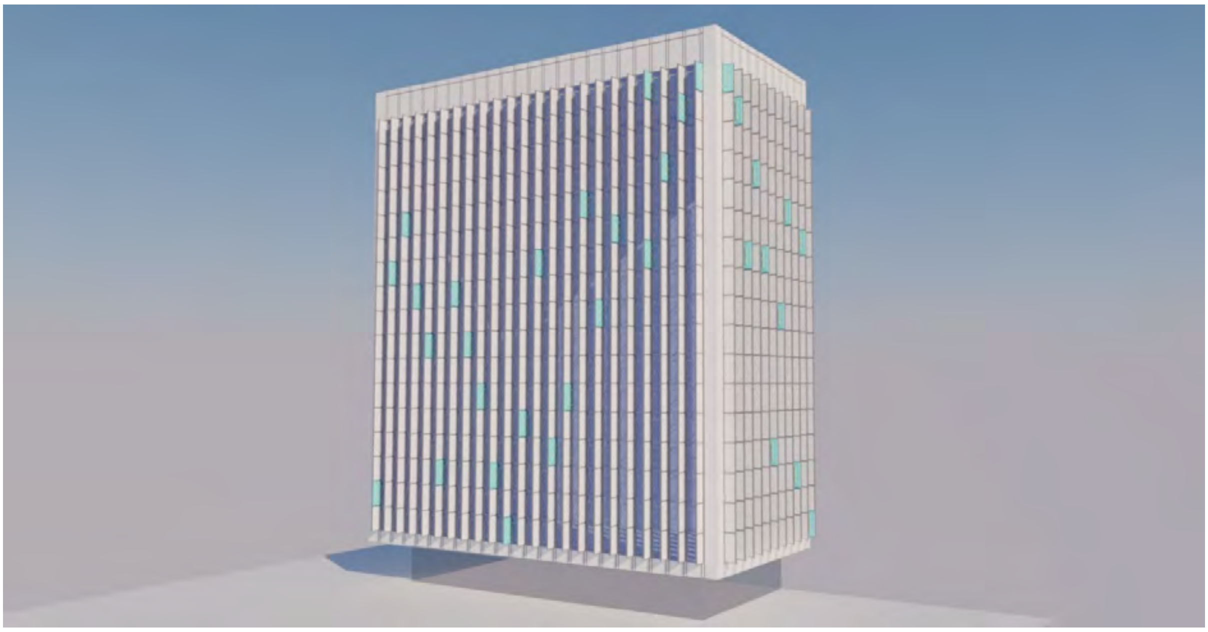

Figure 4. Representation of cleaning chambers during operation

Unlike the stationary cleaning chambers on the carbon carousel machine, the cleaning chambers for this system will move on tracks along the building's façade, similar to a window-cleaning system. The automated cleaning chamber will be connected through sealed hoses to two storage tanks—one for water used to extract the CO_2, and the other for storing the collected CO_2.

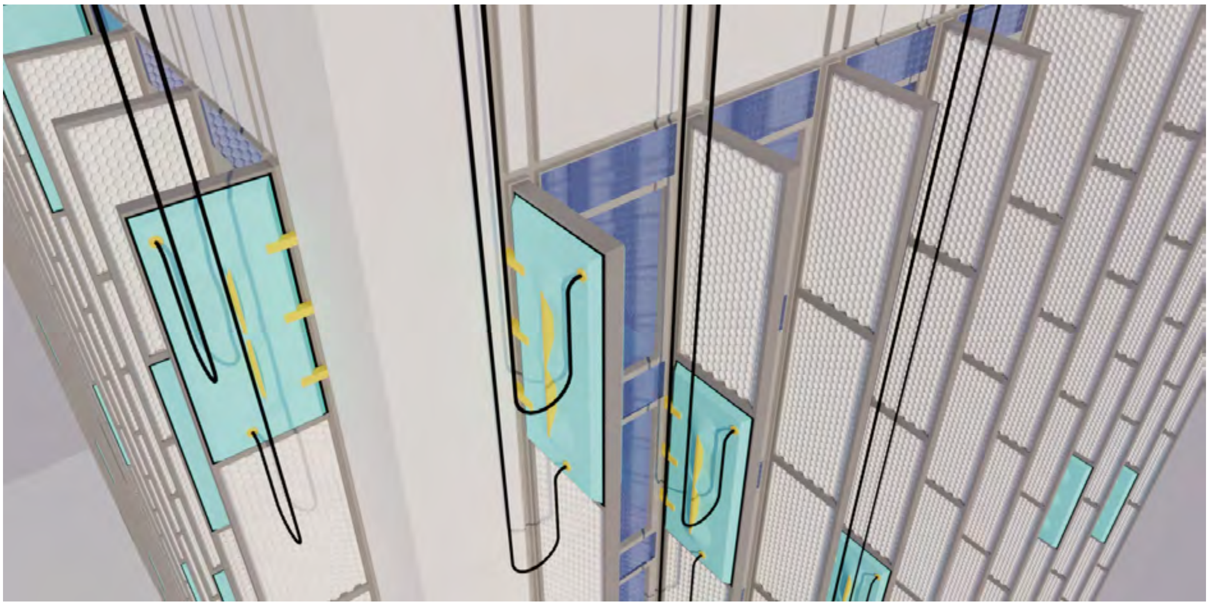

Figure 5. Representation of cleaning chambers with hoses connected to roof tanks

To determine the number of moveable automated cleaning chambers a building requires, the design team must first calculate the number of air filters that will be integrated with the façades. The team must also take into consideration that the carbon-washing process takes almost one hour for an air filter with that type to be loaded with CO_2 in addition to an equal amount of time for recovery and drying of the resin.

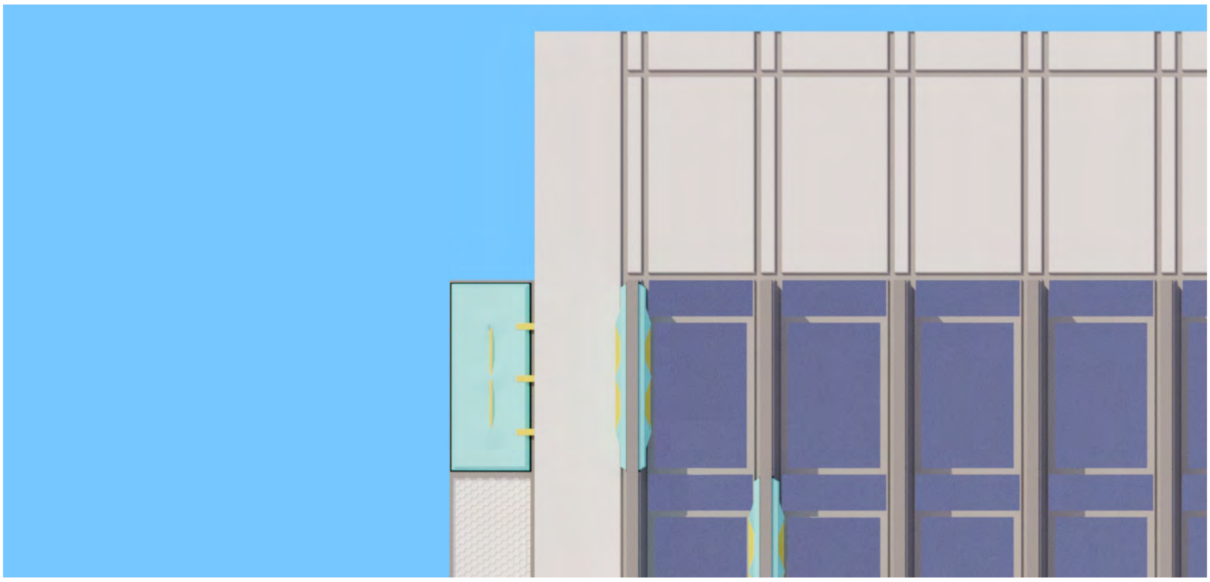

Figure 6. Cleaning chambers and tracks along building façade

The amount of CO_2 collected by such system will depend on the design, the available façade area, the height of the building, and the climate conditions at that particular site. To get a rough estimate of what one floor of a building could collect, we must set certain design parameters that could control the integration of the system on buildings. The thin side (0.1 m) of air filters must be placed perpendicular to the façade. The filters need to be spaced at least one meter away from one another to allow for at least two automated cleaning chambers to move along.

To calculate roughly how much CO_2 a building fitted with BICC would collect, one must know the design properties for the particular building. For example, a building that is 25 m in width and 36 m in depth will allow for 22 rows of air filters per floor on the smaller sides of the building and 33 rows per floor on the larger sides of the building. Since the building has 4 surfaces, and the height of the air filter is 1.6 m, the total amount of air filters per floor for this building is 136. Following the data provided by Dr. Lackner regarding how much CO_2 each filter will collect, and taking into consideration the time required for recovery and partial drying, each floor will collect roughly one ton of CO_2 per day.

Discussion and conclusion

We conclude that BICC is physically possible, and it will add a collection system within cities that surpasses the uptake rate of natural CO_2 sinks such as trees by several orders of magnitude. To have a significant impact on carbon emissions in the atmosphere, the uptake rate of a single building must be evaluated by orders of magnitude. A 20-story building similar to the example mentioned earlier would collect almost 20 tons of CO_2 per day. Ten buildings of that size within a city could collect 200 tons of CO_2 per day. That may sound like a very small number in comparison with global CO_2 emissions. The world emits nearly 29 Gt of CO_2 yearly (Lackner, 2009). Almost 750,000 commercial buildings were constructed in the United States between the years 2003 and 2012 (EIA, 2012). If 50% of these buildings implemented the BICC strategy, this would lead to a collection rate of 2.73 Gt/yr, which could have a significant impact on the world's CO_2 emissions.

The system properties and the amount of CO_2 collected by this system can be affected by the air speed in a certain location. If a building has 4 sides, the wind speed along the windward side differs from the wind speed on the leeward side. The difference in airflow may lead to changes in air filter thickness and the amount of sorbent required for collection. A location with fast-blowing air would require a collector with a small frontal area and greater filter depth, whereas another location with slow-blowing air would require a larger frontal area and a thinner filter (Lackner, 2009). This problem can be solved by designing two separate air filter units—one tailored for windward surfaces, and one tailored for leeward surfaces.

The present air-capture device is climate sensitive, meaning that tropical climates with high humidity as well as extremely cold climates may limit the operation of the device. In hot and humid climates, the humidity limits the absorption rate and load capacity of the resin, whereas in cold climates, the collection of CO_2 works, but the drying rate of the filters is much slower than in warmer climates (Lackner, 2009). The sorbent material used for the air filters was designed specifically to work for desert climates where the absorption rate of the resin and the drying time of the filters gives the devices a high collection rate. For such a system to operate successfully in other climates, the air filters must be altered accordingly.

The collected CO_2 has a variety of local uses in local markets, including food production, the carbonation of beverages, refrigeration, or as dry ice (Lackner, 2010). CO_2 can also be used as a cleaning product for dry cleaners, where it can be used as a liquid solvent for cleaning clothes. Another local use would be as a growth stimulator for indoor crops in its gas form. Collected CO_2 can be stored and shipped to remote sites and used in enhanced oil recovery, where the injected CO_2 facilitates the production of oil. Some scientists consider this method to be one of the most successful strategies for storing and disposing of carbon. Another benefit of BICC would be that it could offset past emissions and offers a great solution for offsetting emissions that are hard to avoid, such as emissions from airplanes and automobiles (Lackner, 2009). Once successfully developed and implemented, and in collaboration with other existing technologies such as the carbon carousel, BICC will provide a valuable option, whether through keeping up with the world's emissions or through reducing the CO_2 content in the atmosphere.

Considerations for extending benefits of energy retrofits at the building level to the building stock

Abstract: Enhanced energy performance at the building level is mandated through regulations and certifications such as LEED, BREEAM, EPBD, Passivehaus, etc. Their impact is limited due to the large amount of existing buildings where they are not applied. Prefabricated building envelope energy retrofit systems offer viable alternatives for large-scale implementation, reducing costs and installation times while upgrading comfort levels. The number of buildings requiring refurbishment obliges using non-conventional methods responding to a variety of climates. This paper analyses, through computer modelling, two prefabricated retrofit systems placed on the external side of the existing building envelope. The first one includes mainly passive façade technologies with some user intervention, representing a conventional approach to renovation. The second system features mainly active technologies for application on roof and façades. It represents a more ambitious method to upgrade buildings with the latest technologies, where higher energy savings are the main objective. Both systems feature options for use in different climates. Results show the passive system accounted for 50% of energy savings, but the mainly active system reached 65% using finer control responses and a variety of combinations. Choosing adequate design directions from early design stages will affect effectiveness of retrofit policies.

Keywords: Energy Retrofit, Prefabricated Systems, Design Decisions, Facade, Urban Climate

Introduction

Design consciousness towards enhanced energy performance at the building level has been expressed in different regulations and certifications such as LEED, BREEAM, EPBD, Passivehaus, Minergie, etc (Chandratilake et al, 2013). However, **the global impact of new guidelines on national energy savings is limited due to the large amount of existing buildings constructed before their implementation**. In the United States, around 72% of built space is over 25 years old, previous to the introduction of energy certifications (EIA, 2006); while in the European Union over 50% of residential buildings were made prior to the introduction of the first energy regulations (EBSO, 2017). This makes energy retrofit of buildings a suitable option to minimize energy consumption of the entire building stock in a country and reduce emissions. Additionally, energy retrofit can be a cost-effective solution that also upgrades aesthetics and enhances comfort levels for occupants of structures that do not comply with current standards and expectations.

Nevertheless, as seen from the brief statistics that have been mentioned, the sheer amount of buildings requiring intervention obliges to think of non-conventional methods to implement energy retrofits while producing the least disruption to occupants. Prefabricated façade and roof systems become a suitable option in order to reduce costs and installation times. The idea has even been considered as an energy policy by international bodies (Atanasiu et al, 2011).

Diverse options for integrated prefabricated façade and roof energy retrofit systems have been proposed as research outputs, while others are available on the market as separate components. Although it is out of the scope of this paper to provide a review of each retrofit system, they can be divided into passive and active ones, which satisfy building energy demand or supply (Ma et al, 2012). Combined systems can also be found (Passer et al, 2016).

Each building retrofit system has different characteristics that make them suitable for a variety of cases. Nevertheless, it is usual that early during the retrofit process a decision will be made on applying a particular one. Such decision will affect final retrofit performance. Although ideally the "best" system should be chosen, different criteria and constraints unrelated to energy performance affect selecting one system over the other. Examples include installation costs and local regulations. Choosing a given system option is a not trivial task in building retrofits, which require feasibility studies for different scenarios. To this end, computer simulation is a valuable tool that has helped take decisions in projects of different sizes, including large scale envelope retrofits in healthcare (Staljanssens et al, 2015) and residential buildings (Salvalai et al, 2017).

This paper analyses, through computer modelling, the performance of two prefabricated retrofit systems placed on the external side of the building envelope. It will also serve to explore how early stage retrofit design decisions affect final energy performance, by contrasting a conservative design approach with a performance-driven one. It will also indicate how energy retrofit policies can be affected from application of a given direction.

Description of the retrofit systems under study

Two modular building envelope energy retrofit systems still under development will be explored. The first system features mostly passive façade technologies, with some limited user intervention (Paiho et al, 2015). The second system features a higher degree of automation, using recent technologies that can be applied on the roof and façade (Bresaer, 2017). The former system represents a conventional approach to renovation, which can satisfy factors such as reduced cost and less maintenance. The latter system represents a more ambitious method to upgrade buildings with the latest technologies and where obtaining high energy savings is the main objective. Both systems are purposed for large-scale prefabrication. They are placed on the external side of the existing building envelope without need to demolish existing elements, accommodating a series of different technologies at once. The two systems allow flexible combinations according to each climate case. Their main characteristics are described as follows:

Mostly passive retrofit system

The main climatic strategies implemented by this system are well-known, requiring minimal or no mechanical parts, despite some user intervention needed such as opening and closing shades or regulating air intake. The system is modular, and each module in this system can offer one of the following façade strategies: improvement of insulation levels, improvement of outer surface reflectivity (albedo), glazing upgrading, a manual shading system applied according to season, and a module that regulates passive ventilation during summer. These modules can be used separately and in combination, with each alternative providing different levels of energy savings. Finding which arrangement is best for a given situation depends on studying weather characteristics in order to apply a set of pre-defined strategy choices (Capeluto et al, 2014).

Mostly active retrofit system

This system is characterized by the combination of passive and active strategies, and has more constructive flexibility in terms of modularity. It can be placed on both roof and façade. Passive strategies include improvement of insulation levels to minimum contemporary requirements, improvements in outer reflectivity, and infiltration reduction.

Options that can be chosen according to each particular case include: adding a lightweight super insulating panel, two types of solar collector cavities for air preheating, one with forced ventilation while the other with buoyant flow. There is also glazing improvement with automated solar-tracking external blinds that provide night insulation. Active ventilation is provided through an electric fan. These strategies are regulated by a building management system (BMS), which coordinates them to achieve comfort levels. Figure 1 gives a scheme that represents how the components are placed.

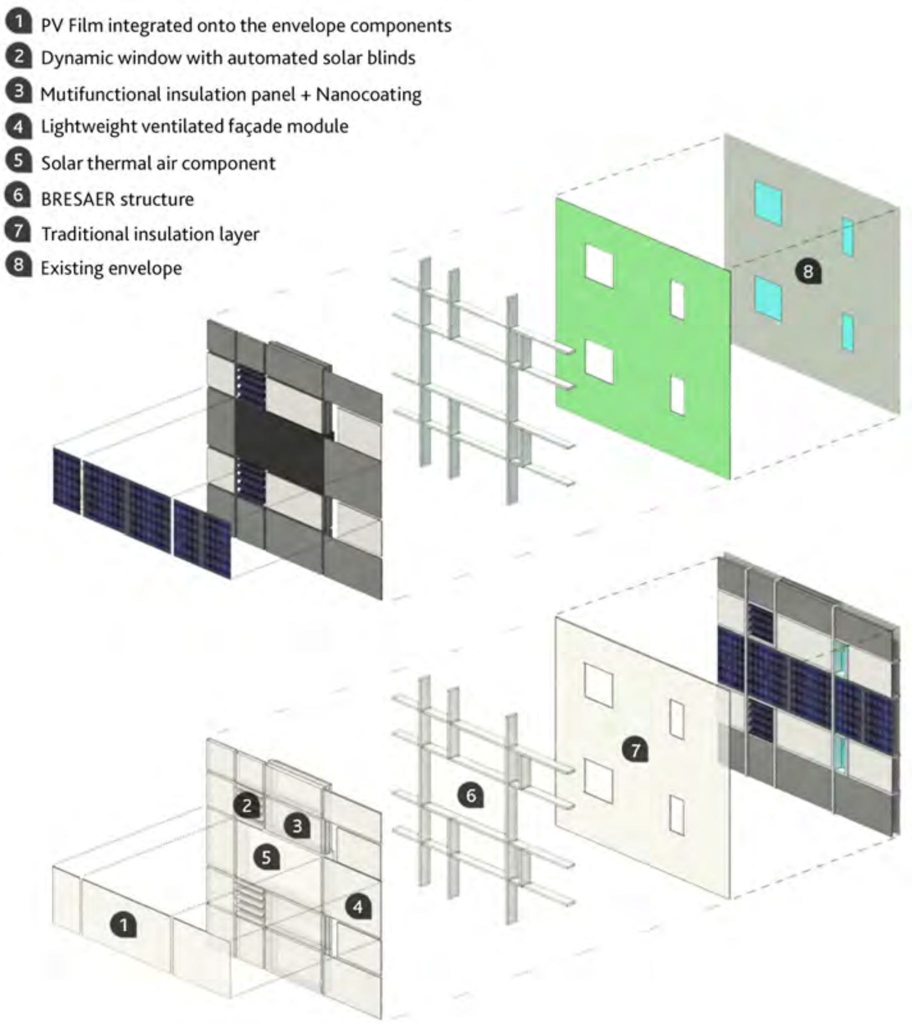

Figure 1. Schematic representation of the mostly active system. Image source: http://www.bresaer.eu

Passive strategies in this system (basic improvements in insulation, infiltration and reflectivity) must be applied together, being a pre-requisite for intervention in any retrofit project. Choices for active strategies are then applied separately or in conjunction, according to the requirements of each location under study. Optionally, a thin-layer photovoltaic panel can also be placed for energy self-generation, but it was not taken into account for this paper. Table 1 shows the strategies used by both systems.

Table 1. Climate strategies followed by each system. X* = applied as prerequisite to the system.

Strategy	Mostly passive system	Mostly active system
Insulation improvement	X	X*
Infiltration reduction	-	X*
Improvement outer reflectivity	X	X*
Glazing improvement only	X	-
Controlled summer time ventilation	X	-
Manual seasonal shading	X	-
Active cavity ventilation and air pre-heating	-	X
Insulating automated outer blinds and glazing improvement	-	X
Highly insulating panel	-	X

Conditions for comparison of the design approaches

A hypothetical case study was made to evaluate both systems focusing on their energy performance. They were modelled using the software EnergyPlus (USDOE, 2017) on a middle-floor apartment located in the urban area of Athens, Greece.

Some of the key parameters that were used for the study are based on examination of building stock databases for that area (Episcope, 2017). The example corresponds to a residential building made before the introduction of the first energy regulations, as a typical situation that would qualify for renovation. Improvement values are based on the Energy Performance for Buildings Directive (EPBD) 2010. The apartment has a floor area of 94.5 m2, with a 1:1 proportion. Window area is 25% of the total floor area, and it is assumed there are no restrictions for conservation or technology selection.

For simplicity, the apartment is assumed to have only one external wall, oriented to the South to represent a favourable location for management of solar radiation, and to test technologies designed to handle natural light penetration.

In the comparison, the external facade was retrofitted with either the active or passive system. Both systems allow a large number of combinations. All possible options were tested in the mostly passive system, but in the case of the mostly active system (which allows for many more options), verification was made on two technology combinations in the façade that could be compared with the passive system, and all strategies together. Yearly energy consumption was calculated for the two systems and detailed for heating, cooling, and where relevant, fan consumption. A summary of the main parameters used for modelling is shown in Table 2.

Table 2. Main characteristics for the residential building under study. Improvement values: EPBD 2010

Feature	Initial	Improvement
Location	Athens, Greece	-
Façade orientation	South	-
Typical apartment floor area (m2)	94.5	-
Typical apartment façade area (m2)	36.5	-
Window area as percentage floor area (%)	25.0	-
Typical existing total load consumption (W/m^2) max.	8.8	-
U-value external wall (W/m^2-K)	2.2	0.42
U-value window (W/m2-K)	6.0	2.0
Visible absorptance	0.7	0.94*
Ventilation, natural (air changes-hour)	4	4*
Recovery rate HVAC (%)	0	50%
Infiltration (air changes-hour)	1.0	0.15*
*not in EPBD		

Results

Energy consumption mostly passive system

Simulation results for this system are shown in Figure 2. Maximum energy savings of about 40-50% are achieved under the described conditions. A total of 11 combinations were checked. As anticipated in a cooling-dominated climate, strategies addressing direct solar penetration such as shading and glazing improvement helped achieve highest energy savings.

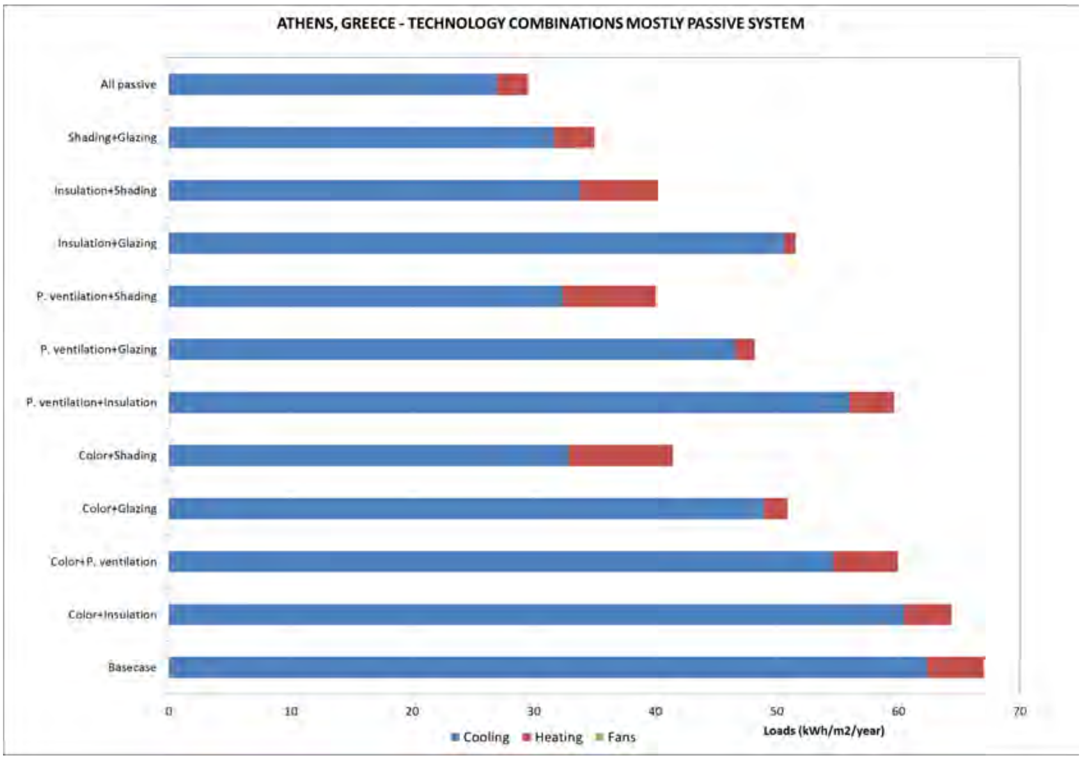

Figure 2. Energy consumption results for a mostly passive system on a residential building facade. Athens, Greece, South orientation

Energy consumption mostly active system

Cooling, heating and ventilation results for simulations using this system can be seen in Figure 3. In total, 6 combinations were studied as well as the influence of system pre-requisites (improvements in basic insulation infiltration and reflectivity). Due to mechanical requirements and resulting low infiltration, electric fan ventilation loads became more noticeable than in the passive system. Heating from external sources was practically not needed when using these active technologies and the pre-requisites.

As expected, active elements brought the highest total energy savings, around 65% when compared to the initial basecase. Heating needs were practically covered by the system. For cooling, which is important for this type of climate, using improved glazing and automated blinds helped reduce cooling consumption around 60% compared to the initial basecase. However, it was observed that despite the addition of all active elements, consumption could not be reduced further in the existing building.

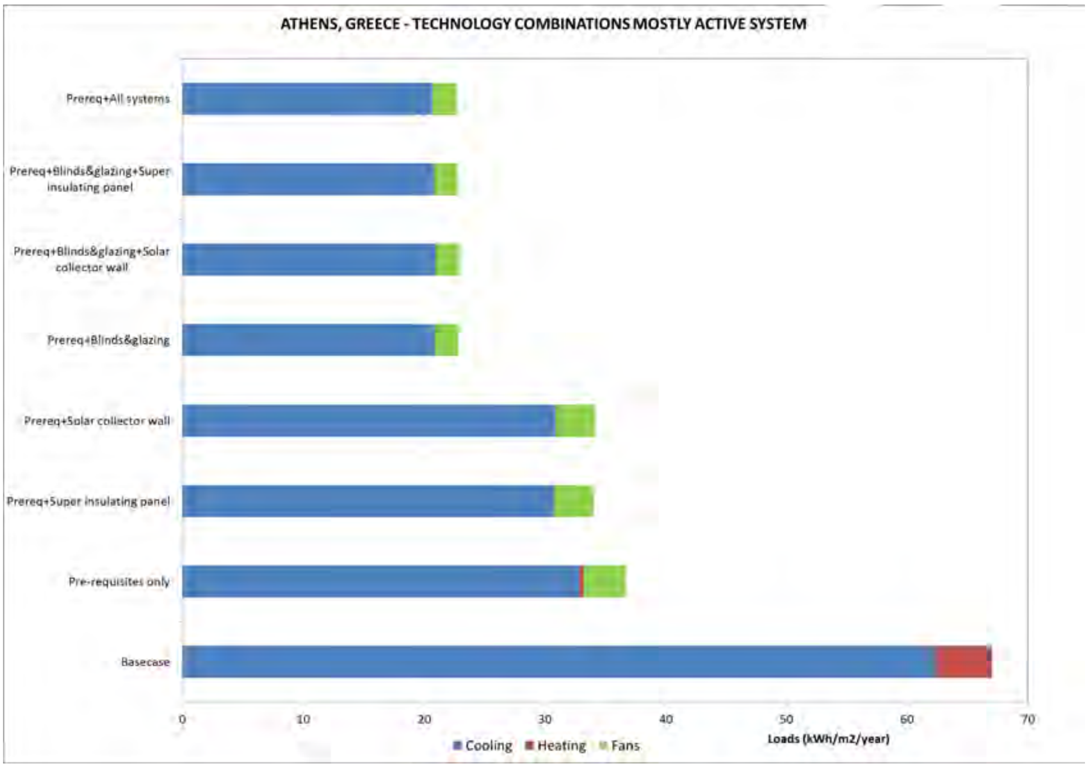

Figure 3. Energy consumption results for a mostly active system on a residential building facade. Athens, Greece, South orientation

Discussion

The mainly active system achieved the highest energy savings due to its adaptability and control systems, while these savings can be achieved using various combinations. This provides an advantage to planners and designers, who can choose a given combination according to the particular needs of their project. The active system, in order to work correctly, had as previous requirements a series of important intervention measures that help reduce energy losses. This enables the active systems to perform correctly and achieve high overall energy savings.

Energy savings achieved after adding the active systems were 40% compared to the basecase. Savings could not be reduced further despite adding all the available options. This suggests that the starting point before retrofit is important, where a “very bad” building in terms of energy consumption will benefit more from upgrading than a more recent, “better” energy-performing one using the same retrofit system.

When extended to the urban level, it can be said that energy saving estimates from renovation are not lineal or cumulative, due to dissimilar energy performances found in diverse sections of the building stock. Although it can be safely assumed that pursuing a high-performance retrofit policy path will bring the highest energy savings, not all buildings will benefit on the same percentage level, with the most recent ones not seeing significant improvements. Therefore, feasibility studies and retrofit regulations must consider differentiated time frames and specific actions for the main historic characteristics in the region’s buildings and focus first on the worst performing buildings first for significant and worthwhile effects.

The two design paths also represent the materialization of different criteria influencing design decisions. Examples include preference of policy makers towards promoting local industry, funding tax incentives for building renovation, influence of payback periods, etc.

Considering the design paths in the retrofit process, planners are faced with deciding on the best elements for obtaining suitable results in the retrofit. Choosing on one path or the other (mostly active or mostly passive) is taken early during the design process and will influence the outcome. Flexibility in taking decisions is also a desirable factor for stakeholders, and the mostly active system presented here has that feature. Such characteristic is convenient when other considerations come into play such as ease of maintenance or initial installation cost. Having different options within the same system will also help adequate and methodological assessments on performance, which need to include relevant criteria that affects the decision outcome (Ochoa et al, 2015).

Conclusions

Energy retrofits are required in the existing building stock to extend the benefit of recent energy certifications and standards. Prefabrication is a suitable alternative for large-scale implementation, but deciding on the most suitable path is an early design stage decision, which will influence final performance, therefore needing careful consideration. Paths need to be chosen according to the starting condition of the building in order to obtain maximum performance, although other factors will influence the final choice, such as cost or local regulations.

The expected impact from energy retrofit interventions has to consider performance of existing buildings according to their main historic constructive characteristics. The mostly passive system provided up to 50% savings while the active system provided higher performance (65% energy savings when compared to the basecase). Additionally, the mostly active system provides high performance through a variety of options that adapt to different project conditions.

The Carbon Balance Index: a simple metric for progress toward zero-net carbon

Mark DeKay[1]

[1] Professor, University of Tennessee, Knoxville, USA, mdekay@utk.edu

Abstract: In North America, “Architecture 2030” has established targets for reducing building fossil fuel use to zero by 2030, now called “zero net carbon” (ZNC). This paper introduces the Carbon Balance Index (CBI) as a simple metric that allows performance comparison along a spectrum from typical buildings that depend entirely on fossil fuels to those that export energy, comparing a range of carbon performance. CBI assesses greenhouse gas production (as CO_2 equivalent) relative to a typical building’s carbon use intensity (CUI), using EUI data categorized by climate and building type. CUI is equal to the building’s EUI times a CO_2e conversion factor/s based on fuel type/s used. CBI is defined as the designed building’s net CUI divided by the CUI of a typical building, expressed as a percentage. The methods for calculating CUI benchmarks, the designed building’s CUI and CBI are explained in simple terms. Building on earlier work on the Energy Balance Index (EBI), the CBI and EBI targets, curves and zero points are compared. Carbon-neutral buildings have CBI = 0. Positive CBI means some fossil fuels are used and carbon is produced, while negative CBI projects “consume” carbon by exporting excess energy and offsetting fossil grid energy.

Keywords: zero net carbon, carbon-neutral, carbon use intensity, energy balance index, carbon metric

Introduction

There are many definitions for net-zero carbon buildings (Riedy, et al, 2011), zero emissions buildings (RCOZEB, 2017), net-zero energy (Sartori, et al, 2012), among many others. What seems like a simple concept, “zero carbon,” can get complicated with issues of lifecycle boundary, operation and construction carbon, building type, climate, grid source energy types and interconnections, spatial boundaries, etc. The question might then be, “Why do we need the subject of this paper, a new carbon metric for buildings?” The reason is not so much about building science precision as it is about the urgency of climate change and expediency of simplicity. As Simon Sinek (2015) puts it, “Simple ideas are easier to understand. Ideas that are easier to understand are repeated. Ideas that are repeated change the world.” In this realm, we need simple.

In the North America, the Architecture 2030 organization has done a good job at making the challenge for the building community clear and simple with their 2030 Targets. The “2030 Challenge” sets targets, shown in Fig. 1, for designers to reduce fossil fuel use incrementally, culminating in *carbon-neutral* building performance by the year 2030 for all new construction and major renovations (Arch 2030, 2011).

At PLEA 2016, DeKay and Giddings (2016) presented the *Energy Balance Index* (EBI) to assesses energy performance relative to a typical building’s *Energy Use Intensity* (EUI) based on climate and building type. The EBI shows that, depending on the level of imported renewables, the 2030 target of “carbon-neutral” can achieve a performance level of *site net-zero energy*, or in some cases something 20% short of that target. The paper finished with outlining the need for and giving a preliminary definition of the *Carbon Balance Index* (CBI), now developed further in this paper.

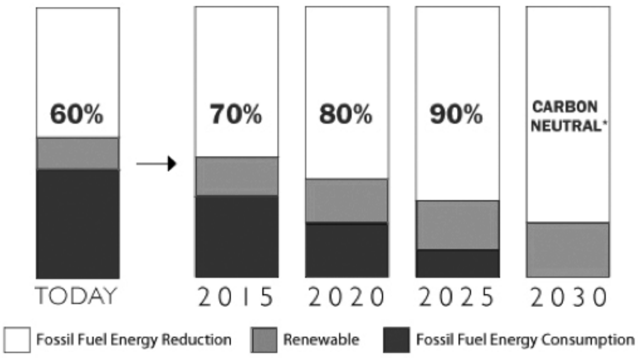

Figure 1: Targets for fossil fuel reduction

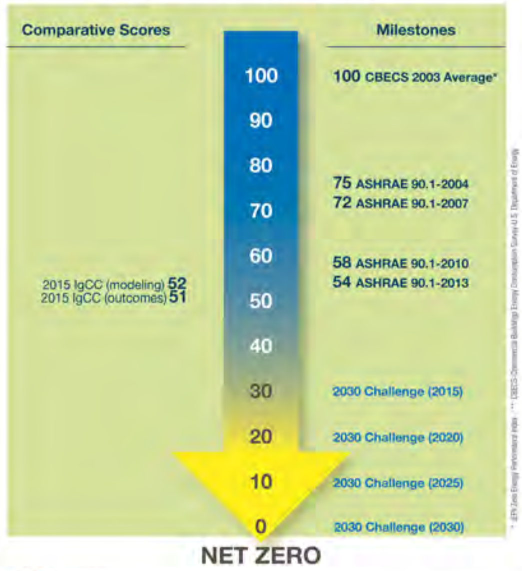

Figure 2. zEPI Scale from NBI

The Issues and Need for a Carbon Index

The need to define an index for carbon performance in buildings came about in part because of numerous related definitions, and the desirability of understanding the relative carbon performance or one building to another, rather than simply the absolute production or consumption value of greenhouse gases. For example, the US EPA's Target Finder allows a relative score for energy, but reports carbon use in "total GHG Emissions," (metric tons CO_2e). This is in contrast to Energy Use Intensity (EUI), which is expressed in energy per unit of floor area per year, and can thus be compared with benchmarks and with other buildings similar in case. Like for energy use, there is a need for measuring carbon on a "more stable, absolute scale that would be used to benchmark buildings, as opposed to the typical percent-better-than-code metric" (NBI, 2017).

Recently, Architecture 2030, along with the New Buildings Institute (NBI, et al, 2016) defined *Zero Net Carbon* (ZNC) as "a highly energy efficient building that produces on-site, or procures, enough carbon-free renewable energy to meet building operations energy consumption annually." In defining "net zero" as linked to carbon and delinked from the building's site boundary, the NBI's coalition has 1) Put the focus on operational energy and carbon, 2) Established a simple legible approach for the complex issues of energy and carbon balance, and 3) Focused the building community on making progress toward solving climate change that is widely inclusive of many building types and site contexts. It aligns with Architecture 2030's emphasis on cities and urban buildings, which in many cases lack good access to solar energy. This is all good, *and* there are problems, the main one being that there is no way to align carbon and energy at any other place on the implied ZNC scale.

Figure 2 shows the *Zero Energy Performance Index* (zEPI) scale as promoted by the New Buildings Institute (2016). Note that this is an *energy* scale with 100 set at the EUI of a benchmark building and zero for "net-zero" energy, with the year 2030 target, which is "carbon-neutral," meaning no fossil fuels used in building operation, aligned to zero. This "net-zero" definition allows imported renewables and so is *not* "site" net-zero energy or carbon. The new Architecture 2030/NBI definition of ZNC also aligns with zero on the zEPI scale, essentially conflating energy and carbon—simple, but rather, too simple.

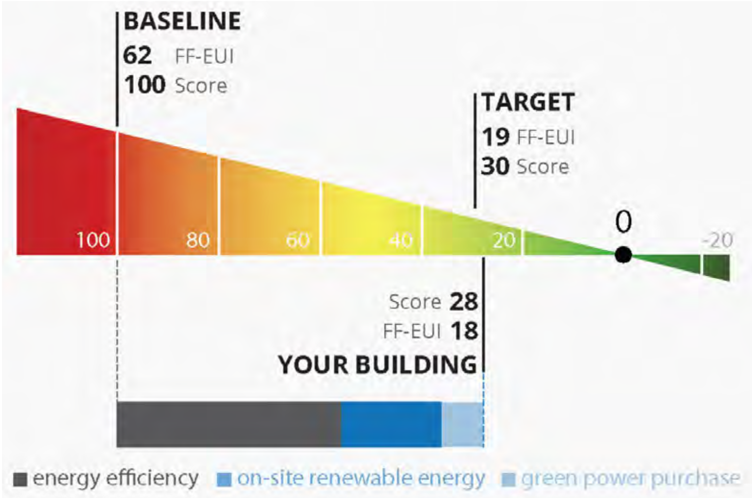

Figure 3: The "Zero Scale" by Arch 2030

During the writing of this paper, Architecture 2030 (2017) released the "Zero Scale," shown in Fig. 3, along with an on-line tool to replace the EPAs Target Finder, a zEPI-like linear scale based on fossil fuel EUI (FF-EUI). It upgrades the previous approach to the 2030 Targets by making clear the role of on-site renewables and sets ZNC at zero. It is, however, not a carbon scale but, rather, a fossil energy scale—for the main reason that it makes no distinctions among the GHG impacts of various fuels. For example, the CO2*e* of grid-supplied electricity and natural gas are treated equally by the surrogate measure of total fossil fuel use.

Dekay and Giddings (2016) showed that because Architecture 2030's guidelines for its influential 2030 Targets allows 0-20% of the fossil fuel reduction target to be met by imported off-site renewables, a confusion can arise about the meaning of the year 2030 "carbon-neutral" target and terms like net-zero energy, site net-zero carbon, etc. The ZNC solves the confusion about the meaning of zero carbon in the 2030 Targets, by allowing on-site or procured renewables to balance the scale. It does not however, allow users an easy way to calculate something comparable to the 2030 targets for fossil fuel use, which is tied to benchmark EUI for a building type and climate, or offer how to extend these into the future. The ZNC/zEPI approach also collapses the distinction between the emissions offset value of on-site renewables, which have no grid losses or transportation fuel consumption, and off-site renewables, which do (See Table 1). This paper and its CBI solve all three of the above problems. The *Carbon Balance Index* allows performance comparison along a spectrum from typical buildings that depend entirely on fossil fuels to those that export energy, comparing a range of carbon performance.

Table 1 Emissions factors for grid-supplied and renewable electricity in the US and Canada
Sources: Environment Canada, Natural Resources Canada, and ASHRAE

CANADA CO_2e EMISSIONS, NATIONAL AVERAGES	
Fuel Type	**Emissions Rate CO_2e lbs / kWh (kg / kWh)**
Electricity, grid displaced	N/A
Electricity, off-site renewable	–0.441 (–0.200)
Electricity, Canada, average	0.441 (0.200)

USA CO_2e EMISSIONS, NATIONAL AVERAGES	
Fuel Type	**Emissions Rate CO_2e lbs / kWh (kg / kWh)**
Electricity, grid displaced	–1.835 (–0.083)
Electricity, off-site renewable	–1.670 (–0.758)
Electricity, USA, average	1.670 (0.758)

Method

Carbon Use Intensity Benchmark

The CBI is a way to compare a building's greenhouse gas production, as CO_2 equivalent (CO_2e) relative to a typical building's *Carbon Use Intensity* (CUI), using EUI data categorized by climate and building type. In the same way that EUI is widely used to describe and compare a building's energy performance, the Carbon Use Intensity (CUI) method was expanded by DeKay and Brown (2014, p 280–291), based on work developed by Bryan (2009). The CUI, with units of CO_2e lbs/ft^2/yr (or CO_2e kg/m^2/yr) is used as the basis to develop the CBI, accounting for the relative impacts of different fuels and renewables on CO_2e. CUI is equal to the building's EUI times a CO_2e conversion factor/s based on the emissions rate of the fuel type/s used. To convert site EUI to Carbon Use Intensity (CUI) multiply by the CO_2e conversion factor:

$$\text{CUI} = \text{EUI} \times CO_2e \text{ conversion factor}$$

EPA's Target Finder tool (2012) gives the typical percentage mix of gas and electricity use for the building's region. These percentages can be used along with the average building EUI to establish a benchmark CUI (Bryan, 2009). "The total CUI is the sum of CUIs for each fuel used. For example, if the building uses some natural gas and some electricity, as many buildings do, then the EUI attributable to each fuel is used to find a CUI for gas and a CUI for electricity and then these are added to get the total building CUI" (DeKay & Brown, 2014, p281). Table 2 shows an excerpt from CUI targets published in *Sun, Wind & Light* by US climate zone and building type. They provide similar calculations for residential and non-residential buildings in the US and Canada, using a variety of emissions factors from EPA, NRC Canada, and ASHRAE.

Carbon Balance Index Defined

CBI is defined as the designed building's net CUI (after accounting for renewables) divided by the CUI of a typical building, expressed as a percentage:

$$\text{CBI} = (\text{CUI}_{\text{Design}}) \div \text{CUI}_{\text{Typ.}} \times 100\%$$

The task then is to find both the building design's CUI and that of a benchmark building. The CUI_{Typ} can be calculated as described above or found in *Sun, Wind & Light's* "Emissions Targets" chapter. A similar method can be done for any country with median data for building EUI by class and climate.

Calculating CUI for a Building

To estimate the CUI_{Design}, the following steps are recommended (modified from Dekay and Brown, 2014, p289-91):

1) After *selecting CO_2e rates* for each fuel used from emissions factors data for your country or region, *calculate the source CUI for each fuel* by multiplying the site *Energy Demand Intensity* (EDI), which is the energy demand component of site EUI, for each fuel, by the CO_2e emissions rate for that fuel (from step 1), for example natural gas: site $EDI_{gas} \times CO_2e_{gas} = CUI_{gas}$, where, site EDI is in kWh/ft^2/yr (kWh/m^2/ yr), CO_2e is in lb CO_2e/kWh (kg CO_2e/kWh) for the fuel, and CUI is in lb CO_2e/ft^2/yr (kg CO_2e/m^2/yr).
2) *Find the total demand CUI for the building design* by adding together the CUI for each fuel. For example: $CUI_{gas} + CUI_{electric} = CUI_{demand}$
3) *Estimate the emissions savings from on-site renewables,* in CUI units, by multiplying the on-site renewable *Energy Production Intensity* (EPI) by the emissions rate for on-site renewables: $EPI_{on\text{-}site\ RE} \times CO_2e_{on\text{-}site\ RE} = CUI_{on\text{-}site\ RE}$. The emissions for renewables are negative and on-site renewables typically count for more emissions offset than do grid-supplied renewables. To do this step, one must know the amount of energy produces on-site.
5) *Estimate the emissions savings from off-site renewables,* in CUI units, by multiplying the off-site renewable EPI (such as from utility-generated wind power) by the emissions rate for off-site renewables: $EPI_{off\text{-}site\ RE} \times CO_2e_{off\text{-}site\ RE} = CUI_{off\text{-}site\ RE}$
6) *Find the net CUI* by subtracting credits for on-site (step 4) and off-site (step 5) renewable energy from the gross total CUI for the building demand (step 3): $CUI_{demand} - CUI_{on\text{-}site\ RE} - CUI_{off\text{-}site\ RE} = CUI_{design}$

The following additional interpretations apply: A net design CUI = 0 means a carbon neutral building by the *SWL* emissions targets criteria, while a net design CUI < 0 means a "carbon consuming building," which helps offset greenhouse gases generated by other buildings.

The *SWL Tools* spreadsheet (DeKay, 2016) facilitates the calculation of CUI and allows comparison against a benchmark building and reduction targets for carbon, similar to the 2030 Targets for fossil fuel reduction (See Fig. 4).

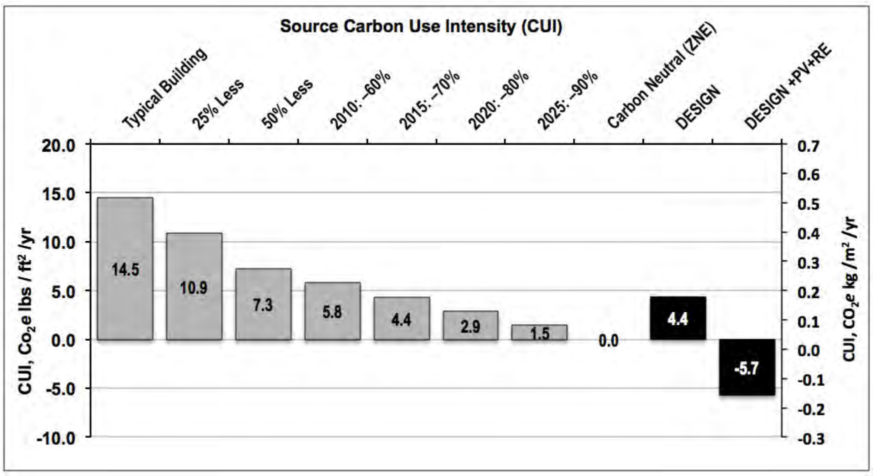

Figure 4. Comparative Carbon Use Intensity (CUI), from *SWL Tools* (DeKay, 2016)

Expanding on the 2030 Targets for Carbon

The CUI_{design} value as described above can then be used to find the Carbon Balance Index (CBI):

$$CBI = (CUI_{Design}) \div CUI_{Typ.} \times 100\%$$

If we take the CUI of a typical benchmark (base) building as a CBI value set at 100 and a zero net-carbon performance (ZNC) as zero, then we can establish a range of targets more or less calibrated to the 2030 Targets for fossil fuel use reduction, as shown in Fig. 5. To do this we have to make an assumption that the zero (ZNC) value includes the 20% allowable off-site renewable energy. While EUI values are commonly published for various base buildings, the CUI is rarely available and must be calculated as described above using the fuel mix and country or regional emissions rates. So, CBI = 100 is *not universal*; rather it is calibrated to local energy supply infrastructure performance, climate, and end use energy mix. With this as a given assumption, we can establish relative reductions in CBI aligned to the targets of Architecture 2030 (80% less fossil fuels in 2020, carbon-neutral in 2030, etc.). The *SWL Tools* spreadsheet workbook (DeKay, 2016) helps to calculate a building's CUI, CBI, and to compare these against various targets. An excerpt is shown in Fig. 6.

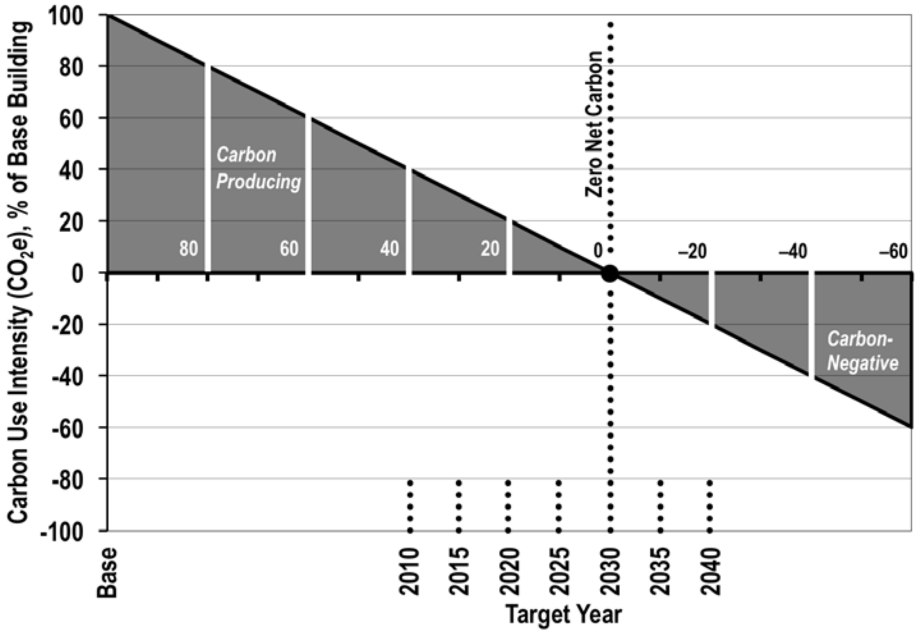

Figure 5. Carbon Balance Index (CBI) Targets

From the 2010 target onward, the targets become a linear progression, with negative CBI targets (carbon-consuming or carbon-offsetting) after 2030. In this manner, CBI = 0 is both "carbon-neutral" in the 2030 Targets schema and "zero net-carbon" in the NBI, et al, definition of ZNC. However, the reader and user of CBI should be clear that, in buildings with a positive CBI (left of zero), depending on the mix of fossil fuel types, the level of energy design for conservation and passive design, and the degree and mix of on-site and off-site renewables, a building meeting the 2030 Targets for a given year, say 2020, may or may not meet the CBI targets shown in Fig. 5. Said another way, a building with a given energy use can produce more or less carbon than a building with the same energy use and a different mix of fossil fuel types and renewable energy types.

CARBON USE INTENSITY TARGETS

Target % Emissions Reduced from Typical Bldg.	Target CUI CO_2e lbs/ ft^2, yr	Targets Achieved?	
Typical Building	14.5	NA	
25%	10.9	NA	
50%	7.3	YES	
60%	5.8	YES	
70%	4.4	YES!	GOOD WORK!
80%	2.9	YES!!	CLIMATE STEWARD!
90%	1.5	YES!!	NEAR CARBON NEUTRAL BUILDING
Carbon Neutral	0.0	YES!!!	CARBON CONSUMING BUILDING!

CARBON BALANCE INDEX: YOUR DESIGN $CBI = (EUI_{des} \div EUI_{typ}) \times 100\%$

[Net] Your Design CUI CO_2e lbs/ ft^2/ yr	Base Bldg. Typ. CUI CO_2e lbs/ ft^2/ yr	Carbon Balance Index (CBI)
(5.7)	14.5	-39.5%

Figure 6. Carbon Use Intensity (CUI) and Carbon Balance Index calculated in *SWL Tools* (DeKay, 2016)

EBI and CBI Compared

Building on earlier work of Dekay & Giddings (2016) on the *Energy Balance Index* (EBI), the CBI and EBI targets, curves and zero points are compared in Fig. 7. The EBI is indexed to the same base building performance in EUI units and a zero value is a site net-zero energy building, meaning that it produces as much energy on-site annually as it consumes. EBI values are negative when the building is a net energy consumer and positive when it is a *plus-energy* building that exports net annual energy. Carbon, on the other hand, is produced by the building's use of fossil fuels and, therefore, has a logically positive value (CBI > 0) to the left of zero when it burns source fossil fuels, while a building is "carbon-negative" (CBI < 0) when it no longer uses fossil fuels for operation and produces renewable energy for export.

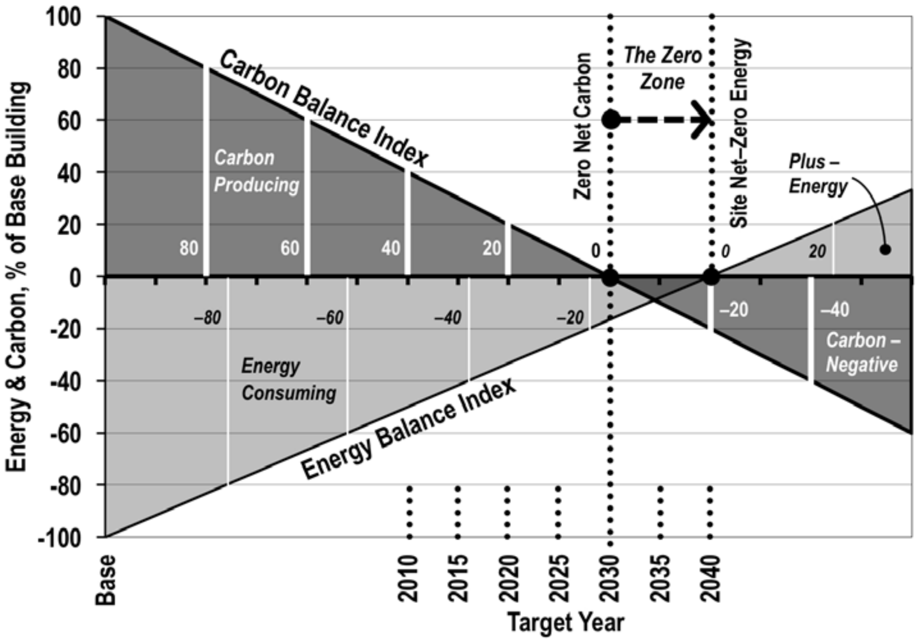

Figure 7. Carbon Balance Index (CBI) and Energy Balance Index (EBI) Targets compared

Therefore, one can see that Figure 7 shows two building performance indices with different definitions of zero. When EBI and CBI are overlaid, an ambiguous "Zero Zone" appears. The difference is in the system boundary. We could set the EBI zero at the CBI zero point, but critics argue that one could simply purchase one's way to zero energy, rather than design and engineer the performance. The distinction of *site net-zero* seems to remain useful, if not necessarily for all buildings. We could similarly move the CBI zero point to align with EBI, with critics arguing for the efficacy of a focus on fossil fuels, rather than where the renewables are sourced. The good news is that if every building operated in the Zero Zone, the climate crisis would be solved by design. Buildings in the Zero Zone would all be high-performance buildings. It is useful to note that if a ZNC building uses no on-site renewables and imported renewables are maxed out at the 20% set by the 2030 Challenge, the only way to further improve CBI and become carbon-negative is to add on-site production.

Findings

With the Carbon Balance Index, carbon-neutral buildings (as defined by the 2030 Challenge) have CBI = 0. Positive CBI means some fossil fuels are used and carbon is produced, while negative CBI projects "consume" carbon by exporting excess energy and offsetting fossil grid energy. Depending on the rate of imported renewable energy, 'carbon neutral' can have a range on the Energy Balance Index (EBI) from 0 to –20.

The paper provides a method to quantify and index CO_2e performance relative to the ZNC definition (and beyond) and relative to the 2030 Target of "carbon-neutral," by using carbon reduction targets in the five-year increment promoted by Architecture 2030 for fossil fuel reduction. The value of the CBI is that it honors and builds on the work of NBI and Architecture 2030 as important driving forces in solving the climate crisis by design, while also giving credit and value to the more impactful emissions offset power of on-site renewables. The CBI, being based in the carbon use intensity (CUI) methodology outlined, also helps with the critical distinction between fossil fuel types on the way to ZNC, and provides a way to fairly assess progress toward and beyond ZNC.

Abstract: To reduce greenhouse gas emissions from the built environment, a holistic approach for energy efficient design over the life cycle of buildings is necessary. Little research exists that simultaneously investigates structural efficiency and energy efficient operation. Therefore, in this paper, we present a framework for considering both the embodied and operational energy in the context of a tall building. For this, we integrate code-based structural design of tall buildings with energy demand simulations and perform a multi-objective optimization in various climate zones. The presented framework is effective at generating the Pareto fronts for structural efficiency, and operational energy (heating and cooling) demand. For a given structural topology, it allows one to determine the most efficient designs with respect to each domain for a given climate. The designer can then a) evaluate how close his or her design is to these efficient designs, and b) make an informed decision as to which design to pursue. By relating operational energy to structural performance, we have introduced a tool that allows one to compare the initial investment of a building (material and construction) to the costs incurred over the lifetime.

Keywords: structural design, energy performance, tall buildings, urban densification, shading, multi-objective optimization

Introduction

The building industry is responsible for roughly one-third of the global energy demand as well as anthropogenic greenhouse gas emissions (Lucon & Ürge-Vorsatz 2014). Considering this relatively large impact, it is necessary to ensure that buildings are designed, constructed and operated in a sustainable manner. At the same time, over 50% of the global population lives in cities (United Nations 2014), poising cities to be the *key to sustainability* (Rees & Wackernagel 1996). As densification of the building stock is inevitable, tall buildings are, and will become, an increasingly important building typology in the future.

For tall buildings, a *premium for height* exists resulting from the exponential increase of the required material to withstand lateral, i.e., wind loadings (Ali & Moon 2007). In recent years, several studies have investigated whether a similar premium exists for energy demand or CO2 emissions, without definite conclusion, mainly due to the prototypical nature of buildings, case study type investigations, as well as the scarce availability of consistent data for comparison (Optis & Wild 2010). One systematic study of a generic tall building found that a) lowest weight does not imply lowest embodied energy (EE), b) reinforced-concrete (RC) frames are more favorable than steel frames from an EE point of view, and c) the flooring system has the largest impact on EE, with RC floors having the least impact of all considered systems (Foraboschi et al. 2014). In fact, it is concluded that considering EE does not impose an additional premium for height, i.e., “sustainable tall building structures can be obtained without modifying the architecture”.

Similarly, the impact that the structure of the tall building has on the overall energy performance has not received significant attention in the scientific literature. In his seminal work, Yeang was the first one to investigate the interaction between the placement of the structural core and energetic performance in tall buildings (Yeang 1999). More recently, Krem et al. have analyzed Yeang’s combinations with preliminary structural calculations, and combined it with energy performance results (Krem et al. 2013). They found that while asymmetric distribution of structural walls may reduce energy consumption by up to 32% depending on the climate zone, it also results in higher torsional stresses and deformations. They concluded that there is a substantial opportunity to optimize structural performance and improve sustainability. However, great care must be taken to ensure that energetic performance does not compromise the structural integrity.

Structural optimization aims at achieving efficient structural performance while at the same time minimizing structural weight under a set of constraints, such as maximum allowed displacements and stresses (Christensen & Klarbring 2008). Since the design space can be quite large, and the optimization problem may be non-convex, e.g., in topology optimization, heuristic optimization methods, especially genetic algorithms have been used successfully, outperforming gradient-based methods (Rajan 1995; Chatzi & Koumousis 2009). Further, interactive approaches have been integrated with heuristic methods to include the designer into the optimization process (Felkner et al. 2013; Felkner et al. 2013; Felkner et al. 2015; von Buelow 2008; Mueller & Ochsendorf 2013).

Despite these efforts, to date, the simultaneous investigation of structural efficiency and energy efficient operation has been largely neglected. Therefore, in this paper we present a multi-objective optimization framework for considering both structural efficiency and operational energy in a tall building. We focus on the operational energy of tall buildings of 20 to 70 stories, with an RC core and RC frame on the perimeter. To avoid torsional effects, we limit the study to a symmetric, square floor plan with a center core. This scheme is capable of balancing conflicting objectives in supporting the decision-making process of the designer.

Optimization Framework

In a multi-objective optimization, there is typically no single best solution that optimizes all the objective simultaneously. Rather, the concept of Pareto-optimality is used. A solution/design is said to be Pareto-optimal if it cannot be improved in one objective without worsening the other, and constitutes with all other Pareto-optimal solutions the Pareto-set. The optimization framework is shown in Figure 1. Matlab is used to investigate numerically the trade-offs between energy efficiency and structural optimization (www.mathworks.com) by generating the Pareto-set using a genetic algorithm.

Sofistik (www.sofistik.de), a commercial finite element (FE) package, is used for structural analysis. The model is generated using the CADIMP programming language, which allowed it to be saved as a text file, which can be manipulated automatically by the optimizer to update parameters, execute the simulation and gather the results. The main advantage of using a commercial analysis tool is the fact that code-based RC structural design is possible. Sofistik calculates the necessary amount of reinforcement for a given structure, and if the resulting design fails to comply with the given design code, a warning or error is issued.

For the energy model, first a base geometry model is created in the 3D modeling environment Rhinoceros (www.rhino3d.com). Then, the parameters to be investigated are designed using the generative plug-in Grasshopper (www.grasshoppe3d.com). Care must be taken to ensure that the structural model in Sofistik and the geometry model in Rhino/Grasshopper are equivalent. Finally, energy demand, is determined using the DIVA modeling plug-in for Grasshopper (www.diva4rhino.com), which provides a visual interface between the Rhino/Grasshopper design environment and energyPlus.

In practice, for our analysis, we define a custom Matlab procedure that takes as arguments the varied parameters, then generates the input file, executes, and retrieves the results for both Sofistik and Rhino/Grasshopper. Finally, it returns the structural and thermal objective values to the optimizer.

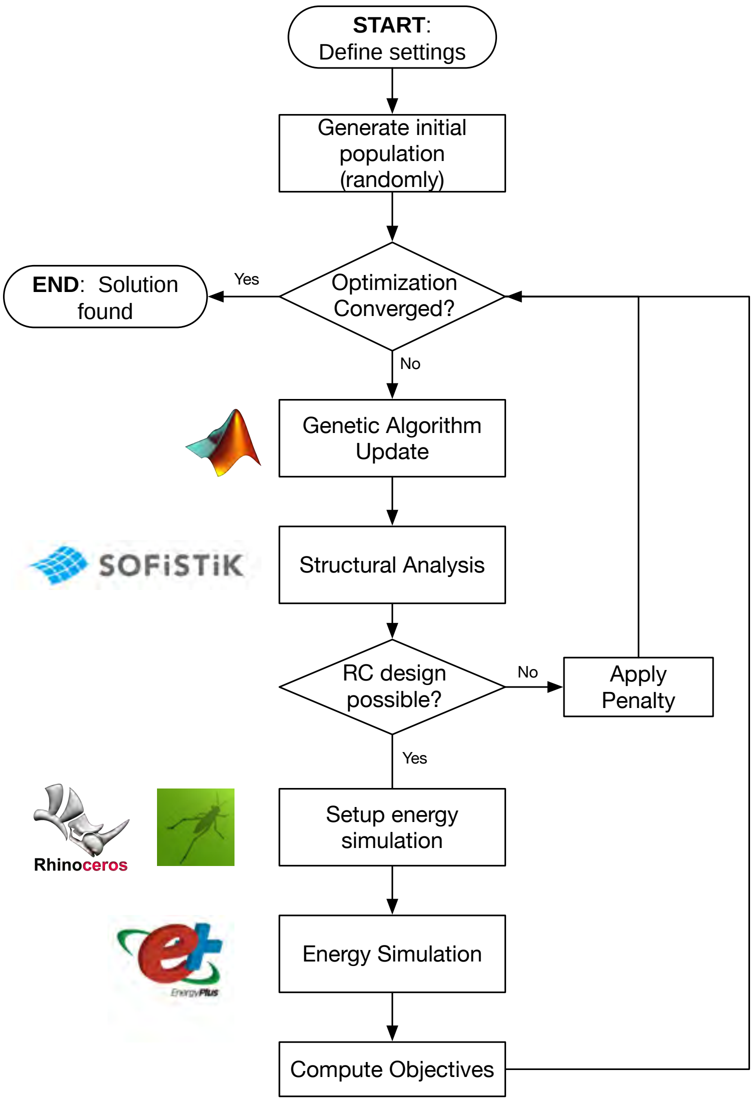

Figure 1: Developed optimization framework

Case Study

We apply the previously introduced framework to analyze the structural design of a tall building. Specifically, we are interested in an exterior wind resisting structure (Ali & Moon 2007), and we investigate how the design of the exterior columns influence the structural performance and the operational energy.

We study reinforced concrete (RC) columns, floors, and walls, suitable for tall buildings with N = 30 stories. Figure 2a) shows a typical floor plan. For simplification, the floor plan is quadratic, and the number of columns on each side is fixed to nine. The core side length is L_c=10m. The side length of the building is $L_b = 2 \cdot 8 + 10 = 26$m, assuming a floor depth of 8m. The wall thickness Tc of the core is defined as follows: For the top ten stories, we set T_c = 20cm, then for every ten stories, T_c is increased by 10cm. Figure 2b) shows the section view of the building. The columns on the periphery are connected via spandrel beams with a constant quadratic cross section of 25 cm side length, creating the exterior tube, and transfer loads to the center core via the floor plates, which have a constant thickness of 25 cm. The story height is set to 3.5m as the average value be- tween typical residential (3m) and commercial (4m) buildings. The resulting Sofistik model is shown in Figure 2c).

To study the influence of column sizes on the structural and energy performance, the Sofistik model is setup as follows:

- We use the Swiss SIA code for reinforced concrete design.
- As load case we define wind loading, acting on one side of the building. The wind zone is set to 2 (reference wind velocity 90 km/h), and the category/class of terrain roughness is set to II (large plain).
- For the materials, we use concrete with a nominal strength of $35N/mm^2$, and reinforcement steel class 500B, with yield strength of $500N/mm^2$, and Young's modulus of $200 \cdot 10^3 N/mm^2$

With this setup, Sofistik performs RC design of the columns, the spandrel beams, the floor plates, as well as the core walls for the ultimate loading. If violations of the building code are found during the design, an error or warning is returned depending on the severity. If the design is feasible, the amount of required reinforcement is returned. For a feasible design, the total mass m of the structure, as well as maximum displacement u_{max} due to wind is extracted. The maximum permissible displacement constraint C is set to $C = u_{max} - H/500$, where H=3.5 x 30 = 105m is the height of the building (Mendis et al. 2007). The structural objective is then $f_s = m \cdot (1 + \max(C,0))$. Structurally infeasible designs are penalized with a large value, and no thermal analysis is performed for them to save computational time.

Figure 2d) shows an example of a floor generated by the Rhino/Grasshopper model. It is created such that the same parameters, i.e., column sizes, can be varied as in the structural model described above. It suffices to consider a single floor without the core structure, which will be considered as a single thermal zone, i.e., office partitioning with individual set-points are excluded. Each of the four sides of the columns are defined as fixed shading components.

The top and the bottom areas of this thermal zone are considered adiabatic, i.e., no heat transfer occurs through them. The remaining four sides are considered fully glazed.

In the thermal/energy simulation, we utilize hourly resolution, and consider the four climate zones humid continental (Boston), humid subtropical (Houston), desert (Phoenix), and temperate (San Francisco). Settings are kept at their default values. The output of the simulation are the annual heating, h_A, and cooling demand, c_A, for one floor, which are then used as heating and cooling objectives.

Denoting by x the width and depth of the columns, the optimization problem is then stated as

$$\text{minimize } [f_s(x), h_A(x), c_A(x)]$$

and solved using Matlab's built in function *gamultiobj*.

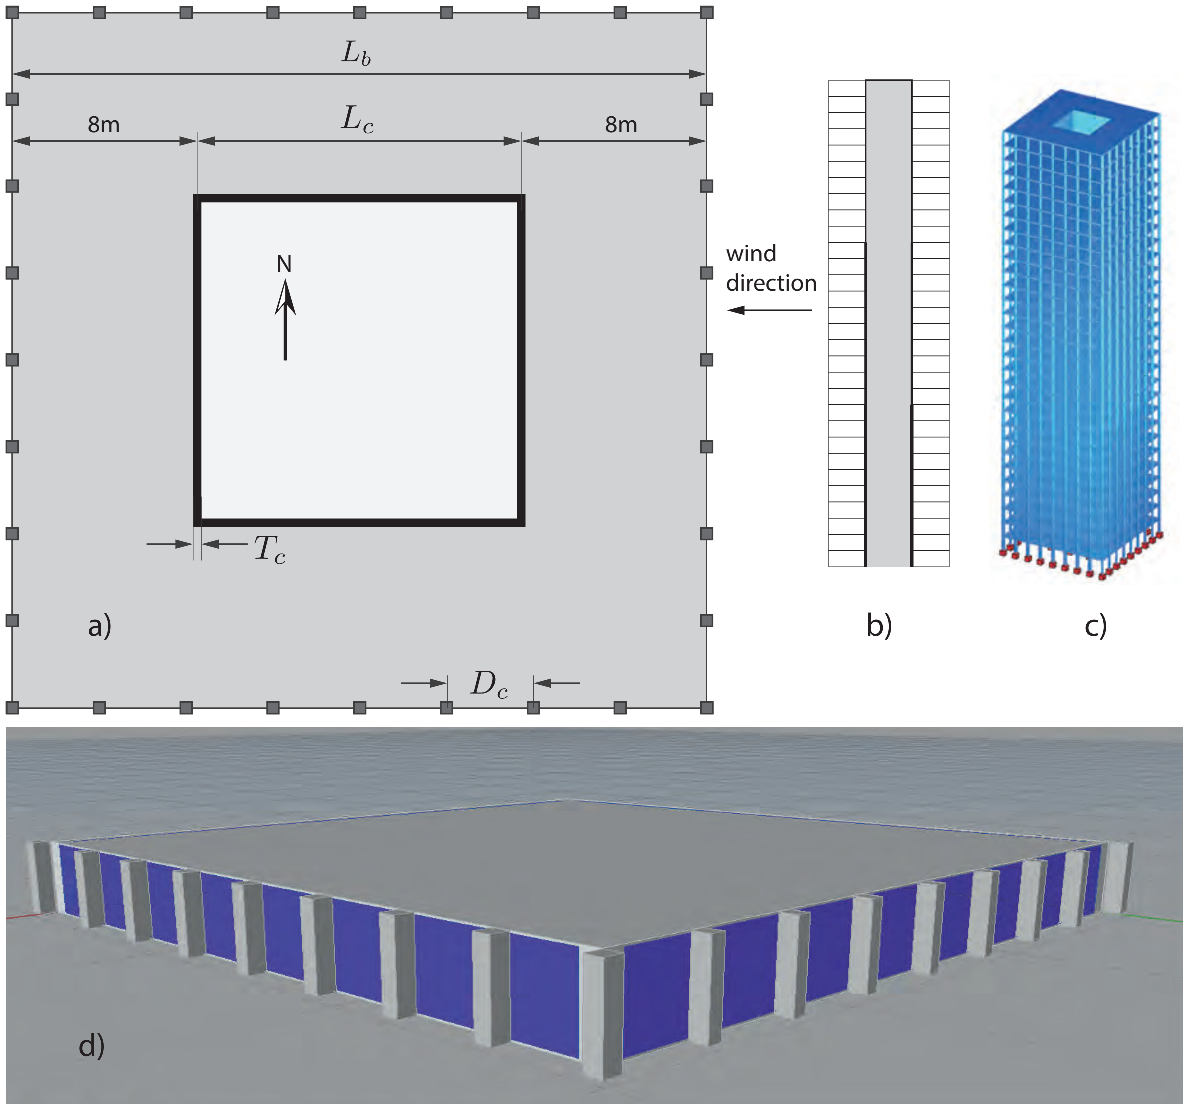

Figure 2 a) Typical floor plan,b) Section view, c) Sofistik model, and d) Rhino/Grashopper model

Results

We normalize both energy demand values with respect to their respective equivalent for the fully glazed case, i.e., when the structure does not act as shading, and show the resulting Pareto-sets as savings in percentage in Figure 3.

In general, we can observe that structure acts as shading, reducing the solar gains in the building. As a consequence, the cooling demand is reduced by up to 50%. The reduction is largest in the San Francisco climate. As for the heating demand, for N=30, the exterior structure acts to reduce some of the heating losses through the window. This demonstrates the trade-offs between structural efficiency and operational energy in different climates, providing the designers with structural variations but also energetic constraints to consider.

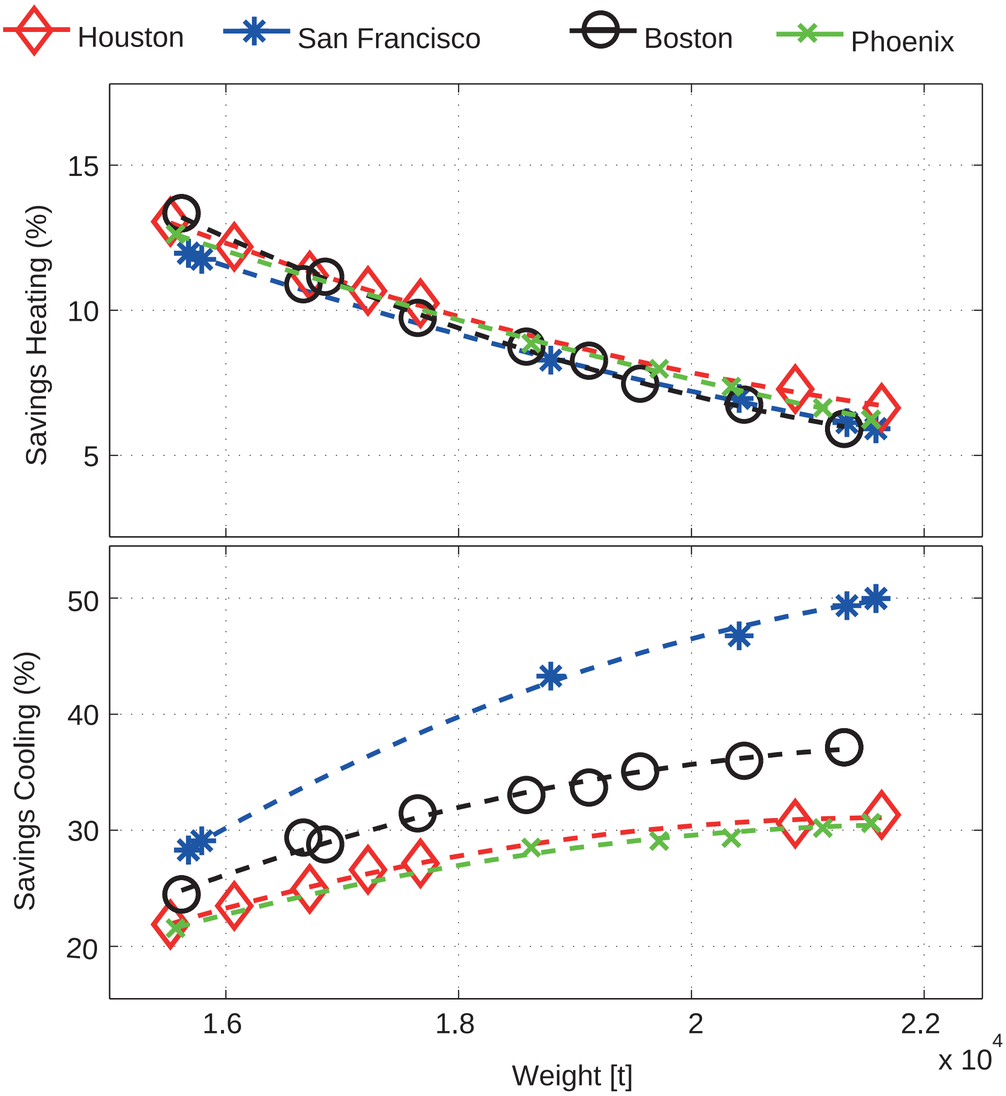

Figure 3 Pareto-sets for the studied climates, showing the trade-offs between structural weight, heating and cooling savings.

As for the column designs, consider Figure 4, which shows again the cooling savings from Figure 3, now with the corresponding columns. We can observe that the optimization framework determined solutions for the whole allowed range from 30cm to 90cm for both the depth and width of the columns in each climate. As mentioned above, every configuration, from the lightest to the heaviest will produce cooling energy savings with respect to the fully glazed facade, and hence should be favored.

The trade-off between operational (cooling) energy and embodied energy (mass/weight) of the building is apparent, as lighter buildings offer less shading, and therefore less cooling savings compared to heavier buildings. This trade-off is more pronounced in the temperate climate, where the cooling savings vary from 28% to 50%. In cooling dominated climates, the trade-offs are less intense, and the savings vary between 22% and 31%. Nonetheless, there is no favor for a specific solution, leaving the architect the freedom of design, while informing him on the trade-offs.

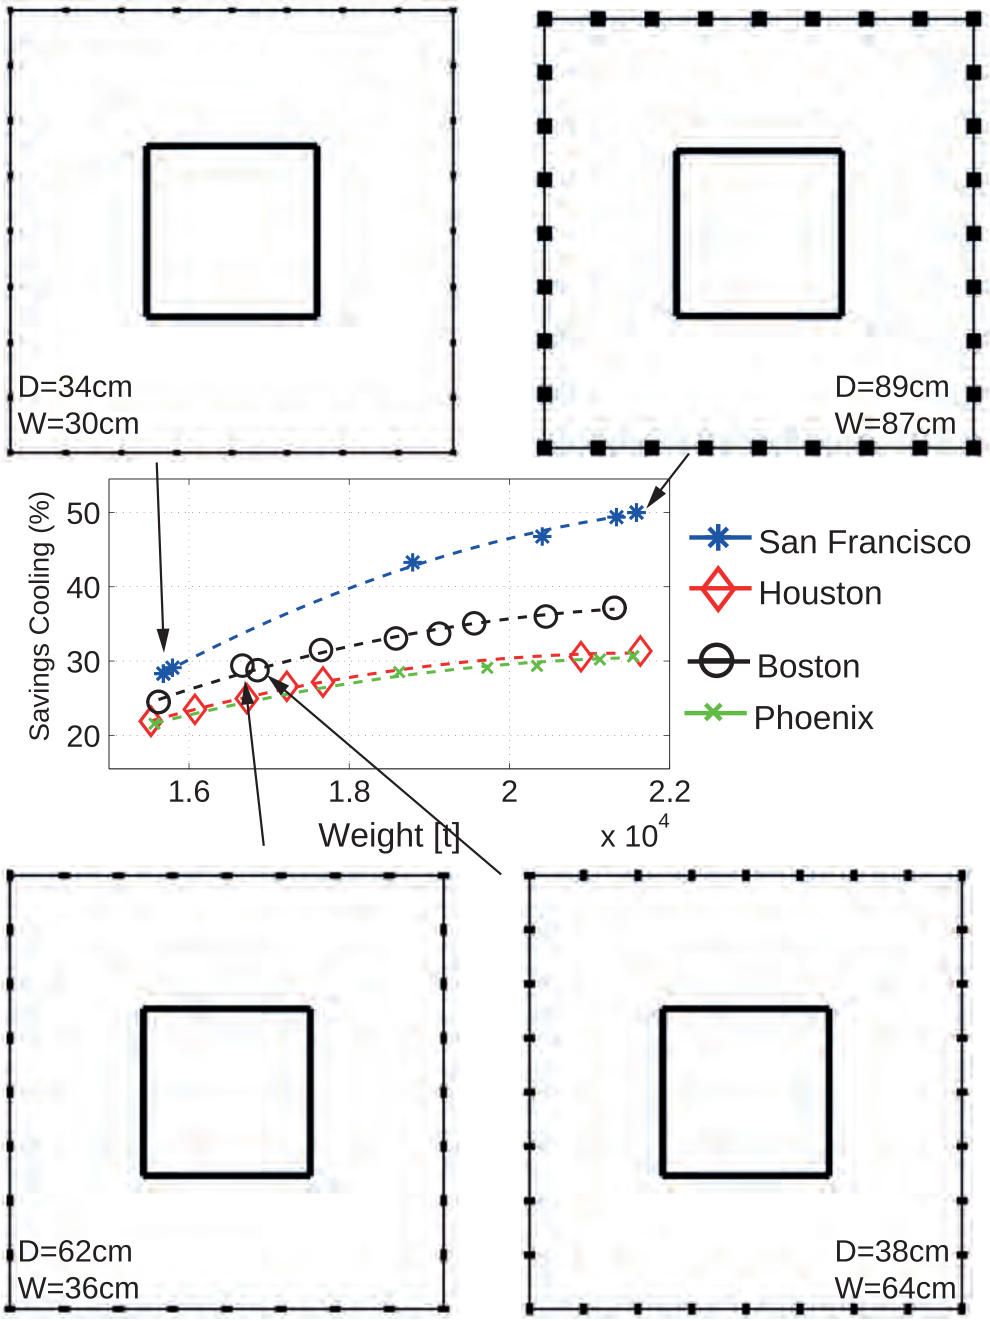

Figure 4: Pareto-set and resulting column structures. The (D)epth and (W)idth of the column are indicated in the individual floor plans.

Conclusion

We have presented an extensible framework for the simultaneous analysis of structural and operational energy performance. Code-based structural analysis is performed using the commercial software Sofistik. Thermal analysis is done using energyPlus through the DIVA plugin for Rhino/Grasshopper. This framework is the first of its kind to successfully combine state of the art structural analysis with operational energy demand. We have applied our framework for the column design of a tall building with 30 stories in various climates, and conclude that in temperate climates (San Francisco), the impact of structure on the perimeter can provide significant savings for both cooling and heating.

Establishing building environmental targets to implement a low carbon objective at the district level: methodology and case study

Marine Fouquet[1], Thomas Jusselme[1] and Jérémie Vareilles[2]

[1] COMBO Solutions, Lyon, France;
[2] Milieu Studio, Lyon, France

Abstract: To face climate change, greenhouse gas (GHG) emission targets are specified into national policies. In France, the objective is to divide by 4 (Factor 4) the *GHG* emissions by 2050 comparing to 1990. The built environment, as a main contributor, is targeted by these policies: the future 2020 French regulation will set up *GHG* emissions targets for the building life cycle. However, the implementation of this regulation and its labels into real-estate development is challenging because it is uncorrelated to factor 4, architectural and technical constraints due to these labels are yet unknown and targets are defined at building scale and not at the district scale. This paper offers some answers to this challenges based on a case study from a real estate developer who wanted to implement a 2025 objective to a new district in Lyon, France. It was done thanks to a review on Factor 4 and labels' history, on calculation of *GHG* emissions from 1990s building and objectives for 2050 and illustration of labels' constraints. Finally, objectives were allocated at building scale to meet the overall district ambition.

Keywords: Factor 4, labels, low carbon targets, district

Introduction

In the European Union, the construction sector is responsible for 40 % of the energy consumption and for 36 % of the greenhouse gas (GHG) emissions (European Commission, 2017). In 2012 in France, 44.5% of the final energy consumption was due to this sector (SOeS, 2013). Thus, several regulations has been enforced at the European level and at country scales to lower building energy consumption and environmental impacts (Charlier and Risch, 2012). In France, the objective is to divide by 4 (Factor 4) the *GHG* emissions by 2050 comparing to 1990 (MEDDE, 2013). To that end, a new regulation will be implemented in 2020 to specifically reduce *GHG* emissions during life cycle of new buildings (Boyer and Cleret, 2014). Meanwhile, two labels are already available and prefigure the future 2020 French regulation: BBCA (Low Carbon Building label) (BBCA Association, 2016) and E+/C- (Plus energy and low carbon building label) (MEEM, 2016). However, the implementation of these labels into real estate development project faces many challenges:

1. New labels are uncorrelated with the Factor 4 objective, which decreases their communication impact
2. Architectural and technical constraints from labels' targets are not known yet
3. Label's targets are defined at building scale and not at the district scale

This paper suggests answers based on a case study from a real estate developer who wanted to implement a 2025 objective (regarding Factor 4 for 2050) to a district in Lyon, France (11 buildings, around 32 000 m²).

First, this paper reviews how Factor 4 was integrated in regulation and labels, how the latest were built and the existing tools to evaluate performance at district level. Then, the amount of *GHG* emissions of buildings in 1990 and the objective for 2050 are determined using a linear regression. This helps to understand to which year, according to Factor 4 objective in 2050, the labels are corresponding. Similar projects are used to illustrate the architectural and technical constraints of the labels. Finally, objectives are iteratively allocated at the building scale to respect the district overall ambition.

State of the art

The concept of Factor 4 represents the goal of reducing by 75 % *GHG* emissions by 2050 compared to 1990. It represents the reduction that France should target to keep the mean emission per habitant and per year below 0.6 t_{eq} C. This is to meet the objective of a maximal concentration of CO_2 of 450 ppm and limit the average temperature rise to 2°C (Houghton et al., 2001).

Politics around Factor 4 in buildings mainly focus on reducing energy consumption during the use phase (Villot, 2012). However, as energy carriers do not emit the same amount of *GHG* emissions, this strategy does not permit to reduce efficiently the *GHG* emissions. Moreover, a shift of impacts between use stage and construction stage is observed as the decrease of impacts due to heat requirement (thanks to better insulation) is higher than the increase of impacts due to change in materials or construction technique (Blengini and Di Carlo, 2010) Thus, a new regulation and labels (BBCA and E+/C-) are implemented, which directly evaluate the amount of *GHG* emissions during the building life cycle.

In both labels, two different thresholds are imposed. A first one for *GHG* emitted by the building components and equipment (embodied emissions) and a second one for the overall *GHG* emitted along the overall building life cycle. Moreover, different performance levels are available for each labels which are summed up in Table 1 for offices and in Table 2 for apartment buildings (BBCA Association, 2016; MEEM, 2016).

The objective of the BBCA label is to reduce significantly the *GHG* emissions due to the construction products and equipment while the E+/C- label has more a pedagogic objective in order to encourage the Architecture, Engineering and Construction (AEC) industry to evaluate the *GHG* emissions emitted by new buildings.

Table 1: Levels and corresponding threshold for office buildings for BBCA and E+/C- labels

BBCA label		
Levels	Construction threshold [kg eq CO_2/(m².yr)]	Global threshold [kg eq CO_2/(m².yr)]
BBCA (Standard)	11.66	17.66
BBCA Performant	10.06	15.06
BBCA Excellent	9.06	13.06
E+/C- label		
Levels	Construction threshold [kg eq CO_2/(m².yr)]	Global threshold [kg eq CO_2/(m².yr)]
Carbone 1	21	30
Carbone 2	18	19.6

Table 2: Levels and corresponding threshold for apartment buildings for BBCA and E+/C- labels

BBCA label		
Levels	Construction threshold [kg eq CO_2/(m².yr)]	Global threshold [kg eq CO_2/(m².yr)]
BBCA (Standard)	9.08	25.08
BBCA Performant	7.48	22.48
BBCA Excellent	6.78	18.48
E+/C- label		
Levels	Construction threshold [kg eq CO_2/(m².yr)]	Global threshold [kg eq CO_2/(m².yr)]
Carbone 1	16	31
Carbone 2	15	20

Regarding district performances, tools already exist, for instance Sméo (Lausanne and Canton de Vaud, 2014) or the calculation site sheets from (2000 W Society, 2015). However, they require detailed building information which are not necessarily available at urban early design stages. Furthermore, they cannot set up specific *GHG* emissions targets to be included in the building design briefs.

Methodology

Calculation of GHG emissions from buildings in France in 1990 and objectives in 2050

To our knowledge, the objective Factor 4 was not translate into objective for new building expressed in equivalent kilogram of CO_2 emissions per square meter and no study were found about the *GHG* emissions of buildings built in 1990. Nevertheless, the HQE Performance project study the environmental impacts of 24 offices, 17 residential buildings and 22 individual houses were presented (Lebert et al., 2013). This project aimed to identify the biggest impacts' contributor in buildings and the studied buildings are representative for performant buildings in France in 2012. The average impacts from office buildings from HQE Performance are 20.6 kg eq CO_2/(m².yr) and 22.7 kg eq CO_2/(m².yr) for apartment buildings.

Based on the results from HQE Performance, *GHG* emissions from buildings from 1990 are determined for office buildings and apartment buildings considering the fact that energy regulations before 2020 only applied to the use phase and more specifically on energy consumption of heating, cooling, hot water production, ventilation and lighting, also commonly called "regulated uses". In 2012, the objective of energy consumption for this regulated uses were 50 kWh $_{\text{Primary Energy}}$[1]/(m².yr) for office buildings and 57.5 kWh $_{PE}$/(m².yr) for apartment buildings (JORF, 2013) whereas they were around 380 kWh/(m2.yr) for office buildings in 1990 (Manexi, 2012) and around 173 kWh/(m2.yr) for apartment buildings (Shanthirabalan and Rochard, 2014). Moreover, we also assumed that the impacts of construction or other energy uses did not change. Then, these impacts are summed and add to the one of the "regulated uses" from 2012 multiplied by the ratio for energy consumption for this regulated uses between 1990 and 2012. Overall, impacts from 1990s building might be underestimated. Finally, the impacts calculated from 1990s office buildings are 40.7 kg eq CO_2/(m².yr) and 40.6 kg eq CO_2/(m².yr) for apartment buildings.

Then, we divided by four these results to meet the objectives for 2050: 10.18 kg eq CO_2/(m².yr) for office buildings and 10.15 kg eq CO_2/(m².yr) for apartment buildings. Previous work from Switzerland found a target of 12.3 kg eq CO_2/(m².yr) for an office building in 2050

[1] Primary Energy (PE)

(Hoxha et al., 2016). The results cannot really be compared as the context is different (e.g. LCA database) but the order of magnitude is validated.

Labels and corresponding year according to Factor 4 objective

We used linear regression to position the labels' global thresholds according to Factor 4 objective. Figure 1and Figure 2 show the evolution of *GHG* emissions, respectively for office buildings and apartment buildings, which should be followed to reach Factor 4 for new construction in 2050 and the corresponding year for the labels.

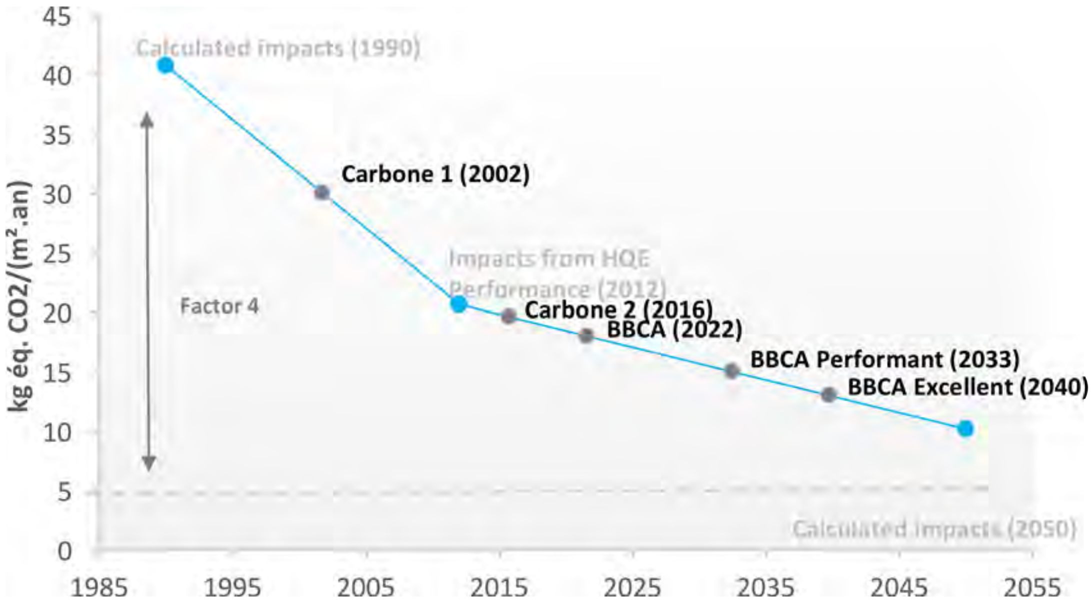

Figure 1: Objectives and labels for office buildings in France

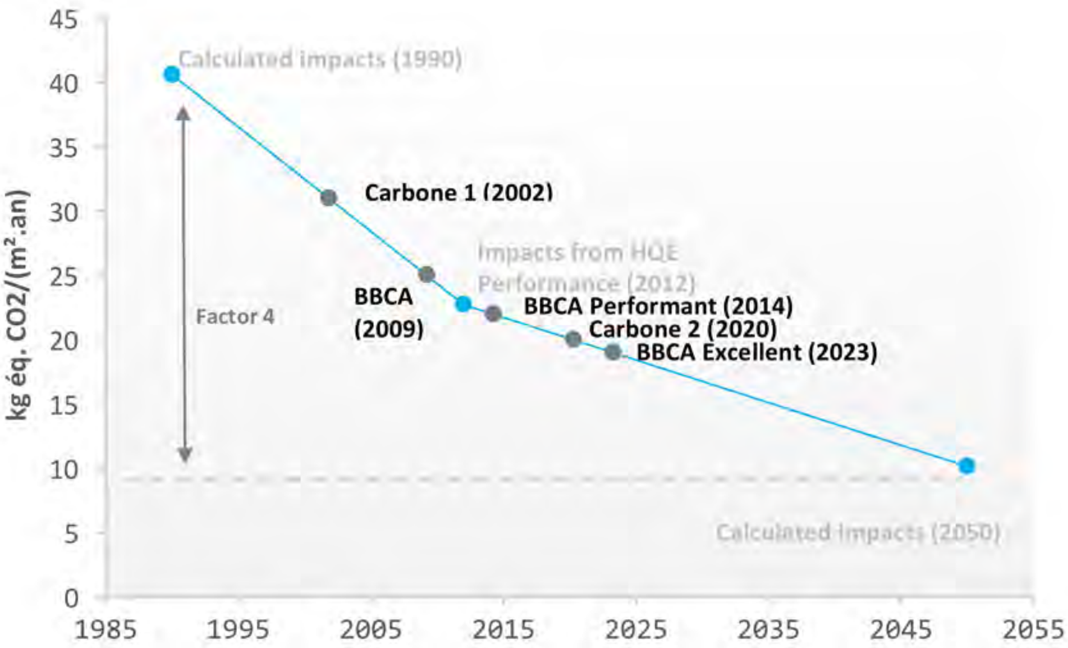

Figure 2: Objectives and labels for apartment buildings in France

For both building functions, improvements through regulations on energy consumption have decreased significantly *GHG* emissions from buildings. Now, the slope is gentlest but the targets for Factor 4 are still ambitious. The different thresholds from the labels are spread and allows the *AEC* industry to choose which performance they want to aim though the labels. Some levels do not even reach today's objective (Carbone 1 & 2 for offices or Carbone 1, BBCA and BBCA Performant for housing). Moreover, labels are more ambitious for offices, 2040 is reached while for apartment building the best year reached is 2023.

Illustration of architectural and technical constraints of the labels

In order to illustrate the technical and architectural constraints induced by the labels, we chose two performant projects, an office building and an apartment building from the same region as the district and built in the past two years. For both projects, detailed information of the construction products, equipment and quantity used were available, even for different construction types for the apartment building. We did not consider underground parking as the district do not have one. As shown by (Lebert et al., 2013), the biggest impacts' contributor in office buildings are the construction products followed by the energy use during the building's life whereas for apartment building, the biggest impacts' contributors are the same but in the opposite order. Therefore, we choose to study different frame structure and energy systems for each project depending on the questions from the real estate developer and choices made by designers. Elodie software (CSTB, 2015) is used to perform the LCAs and the data describing the LCA impacts of construction products are taken for all the scenarios from the INIES database ("INIES, The French EPD Database for building products," 2004).

Our first study is an office building of 8 storages and a total surface of 8 799 m² built in Lyon and compliant with the current French energy regulation : maximum consumption for "regulated uses" of 66 $kWh_{PE}/(m^2.year)$ (JORF, 2013). We evaluated three frame structures and four energy strategies as summed up in Table 3. For each energy strategy tested, the operational energy for the use phase is evaluated annually thanks to French thermal regulation (JORF, 2013). Numerical results for all construction and energy types for the building can be found in Table 3.

Table 3: Embodied and total *GHG* emissions [kg eq. $CO_2/(m^2.yr)$] for an office building for different frame structures and energy systems

	A. Reinforced concrete	**B. Wood facade and reinforced concrete structure**	**C. Wood façade, horizontal reinforced concrete structure and wood-concrete flooring**
1. Water/air heat pump	Embodied : 13.1 Total : 15.6	Embodied : 12.9 Total : 15.4	Embodied : 11.3 Total : 13.8
2. Water/air heat pump without cooling	Embodied : 13.1 Total : 15.3	Embodied : 12.9 Total : 15.1	Embodied : 11.3 Total : 13.5
3. Water/air heat pump and PV panels	Embodied : 13.1 Total : 15.1	Embodied : 12.9 Total : 14.9	Embodied : 11.3 Total : 13.3
4. Gas boiler without cooling	Embodied : 13.1 Total : 19.8	Embodied : 12.9 Total : 19.6	Embodied : 11.3 Total : 18

Results suggest that the choice of materials has an influence on the impact of climate change but not as significant as the energy carrier. However, the impacts for the construction products and equipment are the main contributor of the total *GHG* emissions. Furthermore, compared to the threshold presented in Table 1, Carbone 1 and Carbone 2 are reached easily except the case A+4 (reinforced concrete with a gas boiler without cooling). For the BBCA standard level, lowest GHG emissions than the global threshold are reached in all cases except for cases A+4, B+4 and C+4. However, the thresholds for construction is exceeded for all cases except C+1, C+2 and C+4. Moreover, for cases C+1, C+2 and C+4, the global threshold for "BBCA Performant" is reached but not the one for construction. Regarding our work on Factor 4, objective years reached vary between 2015 (Case A-4) and 2039 (Case C-3).

The second building studied is an apartment building of 7 storages (21 apartments) and a total surface of 1 993 m² built in Ferney-Voltaire and compliant with the current French energy regulation : maximum consumption for "regulated uses" of 63 $kWh_{PE}/(m^2.year)$ (JORF, 2013). Three different frame structures and three different choices for energy were also assessed as illustrated by Table 4. Numerical results for all construction and energy types for the building are summed up in Table 4.

Table 4: Embodied and total *GHG* emissions [kg eq. $CO_2/(m^2.yr)$] for an apartments building for different frame structures and energy systems

	A. Reinforced concrete	**B. Wood**	**C. CLT**
1. 30 % wood boiler/70 % gas boiler	Embodied : 11.4 Total : 21.9	Embodied : 10.9 Total : 21.4	Embodied : 11.2 Total : 21.7
2. 70 % wood boiler/ 30 %gas boiler	Embodied : 11.4 Total : 16.6	Embodied : 10.9 Total : 16.1	Embodied : 11.2 Total : 16.4
3. Heat network	Embodied : 11.4 Total : 19.8	Embodied : 10.9 Total : 19.3	Embodied : 11.2 Total : 19.6

As for the office building, the choice of the energy system seems to be more sensitive than the frame structure but the impacts for the construction products and equipment are the main contributor of the total GHG emissions. Regarding the thresholds from Table 2, Carbone 1 is reached in every scenario while Carbone 2 cannot be reached with the first energy system. For BBCA and "BCCA Performant", for all cases, lowest GHG emissions than the global threshold are reached whereas the maximum construction threshold is overtook. The same conclusion is valid for cases A+2, B+2 and C+2 and level "BBCA Excellent": the overall GHG emissions are lower but emissions for construction are higher than the threshold from the label. Regarding Factor 4 objective, the years reached vary between 2015 (Case A+1) and 2032 (Cases B-2 and C-2).

District case study: iterative allocation of objectives at building scale

For each building of the district (housing or offices) based on their function and their size and on average *GHG* emissions from the HQE Performance project, we calculate the weight of each building in the impact of the district. Some buildings are a mix of different functions so each part of the building is considered separately. The 2012 average performance of the district, based on HQE Performance, should be 692 t eq. CO_2/year. The target of 2025 represents a reduction of 19 % of *GHG* emissions compared to 2012. To reach this objective, iterative targets are set for each building depending on their weight in the impact of the district, the specificity of the program and the architectural ambition. Results are summed up in Table 5 as well as final targeted year for each building and the labels finally reached

Table 5: District building functions, sizes and GHG emissions weights in the district performance based on average from HQE Performance and final targeted year and corresponding label

	Surface [m²]	Storages	Average from HQE Perf. [kg eq. $CO_2/(m^2.yr)$]	Total impact [t eq. $CO_2/(m^2.yr)$]	Weight in impact of the district (%)	Final targeted year	Label
A – Social housing	1529	4	22.7	35	5 %	2019	BBCA Performant
B- Housing	5113	16	22.7	116	17 %	2032	BBCA Excellent
B- Offices	850	16	20.6	18	3 %	2039	BBCA Performant
C - Housing	1061	3	22.7	24	3 %	2019	BBCA Performant
D – Social housing	2019	6	22.7	48	7 %	2019	BBCA Performant
E - Housing	3184	15	22.7	72	10 %	2032	BBCA Excellent
E - Offices	2374	15	20.6	49	7 %	2039	BBCA Performant
F - Offices	756	3	20.6	16	2 %	2019	Carbone 2
G - Offices	3464	6	20.6	71	10 %	2022	BBCA (Standard)
H – Social housing	2120	6	22.7	48	7 %	2019	BBCA Performant
I - Offices	1200	2	20.6	25	3 %	2019	Carbone 2
J - Offices	5048	8	20.6	104	15 %	2022	BBCA (Standard)
K - Housing	1759	5	22.7	40	6 %	2019	BBCA Performant
K - Offices	1284	5	20.6	26	4 %	2019	Carbone 2

Conclusions

This paper shows how to implement low carbon objective at district level based on Factor 4 objective with targets for buildings depending on their characteristics (types, area and number of storeys). First, the amount of *GHG* emissions of 1990s buildings were calculated: 40.7 kg eq $CO_2/(m^2.yr)$ for offices and 40.6 kg eq $CO_2/(m^2.yr)$ for apartment buildings as well as the objective for 2050: 10.18 kg eq $CO_2/(m^2.yr)$ for office buildings and 10.15 kg eq $CO_2/(m^2.yr)$ for apartment buildings. Then, existing labels were positioned according to the Factor 4 objective. Carbone 1 & 2 for offices and Carbone 1, BBCA and BBCA Performant for apartment are late as they do not even reached the current objective. Regarding architectural and technical constraints of the labels, it seems that the energy choice is most sensitive than the frame structure. Finally allocation of objectives at the building scale to respect the objective at the district scale was done with an iterative method depending on the weight of each building in the impact of the district, program's specificity and the architectural ambition.

Further researches will be needed to refine the method and include more characteristics as roof solar potential, compactness and mobility connections for allocation of objective at building scale. Moreover, the development of low carbon buildings will lead to new references which could be used to transform year objectives into example of architectural and energy strategy.

Abstract: Aligned to IEA Annex57 investigation of energy and GHG emissions embodied in buildings, UNICAMP's minLCee Living Lab design shifted focus from operational stage ('net zero') to complete lifecycle. Here we highlight how lifecycle energy and GWP, calculated through CED and CML 2001 v.2.05 methods, enlightened its conception process. Secondary data was collected from literature and manufacturers' brochures, or adapted from existing databases for production cycle modelling in SimaPro 7.3. Energy Plus and Homer Energy software supported operational energy simulation and photovoltaic array sizing. Simulated electricity consumption was 31 kWh/m^2 GFA/year of reference service life. Neutralizing operational electricity plus non-renewable CED of building products was settled as feasibility threshold. PVs would generate 3.6 times the operational electricity and offset 14% of GWP_{LC}. Steel frame, partitions, PVs/BOS and façade panels summed 98% of CED_{PROD} and GWP_{PROD}. Pre-use stages rivaled the operational stage contribution for CED_{LC} (44.5 GJ/m^2 GFA). Contrastingly, GWP_{LC} (7 tCO_{2eq}/m^2 GFA) was dominated by the use stage, from which 91% GWP_{OP} referred to material replacement. For our operational-energy optimized building, the most effective design strategies comprise reducing concrete usage and clinker content, specifying for extended service life and limited material replacement, and prioritizing less transportation-intensive supply chain and EOL treatment.

Keywords: net zero buildings, LCA, low carbon design, CED, GWP

Introduction

The Net Zero concept emerged some years ago as an exciting - and challenging - reference to establish goals and describe success towards aggressive energy use reduction. As only the building operation is considered, the energy input to deliver the building and its components or involved in any other building lifecycle stage is not accounted for. NZ concept also depend on distributed renewable energy generation. From all renewable energy sources, photovoltaic (PV) energy currently shows the fastest growth rate. Considered as one of the cleanest sources of energy available, PV's environmental impacts are basically restricted to manufacturing and disposal (FTHENAKIS; KIM, 2011). Based on the literature reviewed, this embodied impact fraction is seldom acknowledged in neutralization calculations.

The past decades have focused on increasing operational energy efficiency levels. As top operational performance became mainstream, focus has shifted to the proportional share of (grey) energy embodied in the products stage and in end of life processes. Existing databases and much of the literature provide data for the embodied impacts in product stage. In fact, there seems to be a consistent shortage of data across the construction sector on the energy used during all lifecycle stages (MONCASTER; SONG, 2012). Description of transport to site is a big grey area and demands continuous and close interaction with logistics and transport sectors. Prediction of energy use during standard site operations becomes a fundamental part of the whole life embodied energy equation, which has been hampered by a lack of general data on energy intensity of construction equipment and activities, as well as on energy savings related to optimized site management operations. Finally, a clear understanding of the service life of individual components is necessary to support calculations of maintenance, repair, replacement and refurbishment as part of the use stage. There is also limited data on the energy used by demolition, reuse and recycling processes at the end of life of a building.

This paper has the International Energy Agency (IEA) Annex57 as backdrop, which investigated embodied energy and CO_{2eq} in building construction. Motivated by the limited number of publications to support detailed lifecycle energy and green house gas emissions modelling, we describe the procedures and major outcomes from low energy and carbon-oriented design process implemented for (minLCee) Living Lab, designed for the University of Campinas – Brazil. Compensation scenarios beyond operation stage are explored to identify feasibility thresholds and optimize architectural design and specifications.

Purpose and methodological approach

Overview

Building design development and optimization comprised five main parts: (i) developing an integrated design concept for the minLCee; (ii) simulating operational energy (100% electricity) using Energy Plus; (iii) modeling production cycles and the building's lifecycle; (iv) calculation of cumulative energy demand (CED) and global warming potential due to emission of greenhouse gases (GWP) respectively through CED and impact assessment CML 2001 v.2.05 methods, using SimaPro 7.3 LCA support platform; (v) simulating performance of four different PV technologies, using Homer Energy software. This paper focuses on the latter three steps.

Our case study is a 1,005.21 m^2 gross floor area (GFA) building incorporating integrated design process, low-energy and resource use optimization strategies, low-energy aircon system, onsite renewable energy technologies, living roofs and façade, earth construction, storm water management, online resource use and indoor monitoring, among other best practices (Figure 1).

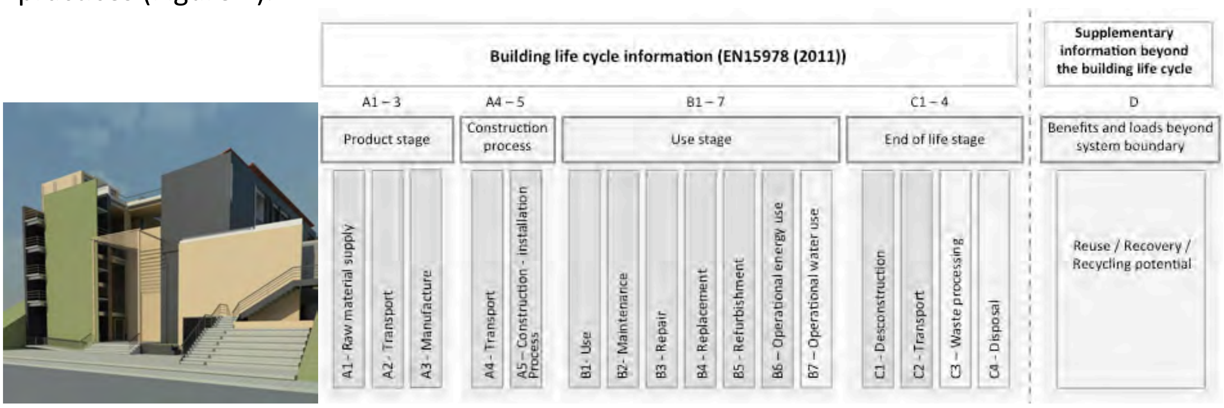

Figure 1 – minLCee Living Lab BIM model. Lifecycle modelling system boundary is shaded over BS EN 15978 (2011) framework for building life cycle information stages and respective modules

The system boundary established for lifecycle modeling in this study spans from 'product' to 'end of life' (Figure 1). Ten neutralization statuses using four different PV technologies were preset, ranging from operational stage (Scenarios 1 to 4) to whole lifecycle

(Scenarios 5 and 5a). Compensation of total operational electricity (net zero) *plus* non-renewable primary energy embodied in raw material supply and manufacturing of building products (NZ(CED) Plus status) was set as design target (Table 1).

Table 1 - Compensation scenarios analysed. Beyond operation (Plus statuses) include building products non-renewable CED accounted for in the Product stage ($CED_{NRen}PROD$). NZ(CED) Plus status [Scenario 4a] was set as design target.

	Compensation Scenarios	PV generation targets
Operation neutral statuses	1. NZ(Emission)	Annual *non-renewable* operational energy consumption (TORCELLINI et al, 2006)
	2. NZ(E) = Net zero energy	Annual operational energy consumption (TORCELLINI et al, 2006)
	3. NZ(CED_{NRen})	Annual *non-renewable* operational CED (Brazilian mix, grid-supplied electricity)
	4. NZ(CED)	Annual operational CED
Beyond Operation (Plus)	1a. NZ(Emission) Plus	NZ(Emission) *plus* $CED_{NRen}PROD$
	2a. NZ(E) Building Plus	NZ(E) *plus* $CED_{NRen}PROD$
	3a.NZ(CED_{NRen}) Plus	NZ(CED_{NRen}) *plus* $CED_{NRen}PROD$
	4a. NZ(CED) Plus	**NZ (CED) *plus* $CED_{NRen}PROD$**
LC	5. LC(CED_{NRen}) neutral	Non-renewable CED *over the building's lifecycle*
	5.a LC(CED) neutral	Total CED *over the building's lifecycle*

Building lifecycle modelling

The CED calculation is based on the method published by Ecoinvent version 1.01 (FRISCHKNECHT; JUNGBLUTH, 2000). CED, expressed in MJ, of each stage of the building's lifecycle was calculated and aggregated for whole lifecycle figures (Equation 1). As implemented in SimaPro (PRÉ, 2008), characterization factors are given for the energy resources in five impact categories, expressed by the renewable (biomass, wind/solar/geothermal and water) and non-renewable (fossil and nuclear) CED components. Lifecycle GWP (GWP_{LC}, equation 2) aggregates GWP calculated for each stage of the building's lifecycle.

$$CED_{LC} = CED_{PROD} + CED_{TR} + CED_{CON} + CED_{OP} + CED_{EOL} \quad \textit{(eq. 1)}$$
$$GWP_{LC} = GWP_{PROD} + GWP_{TR} + GWP_{CON} + GWP_{OP} + GWP_{EOL} \quad \textit{(eq. 2)}$$

Where CED_{LC} stands for lifecycle CED, in MJ, and GWP_{LC} is lifecycle GWP, in tCO_{2e}. PROD is the CED/GWP of extraction/manufacturing of the building products; TR is the CED/GWP of transport activities; CON is the CED/GWP of construction activities; OP is the CED/GWP of operation activities; EOL is the CED/GWP of end of life (EOL) treatment activities.

- **Product stage (Modules A1 and A3)**

CED_{PROD} (in MJ) and GWP_{PROD} (in tCO_{2e}) were calculated by adding all building products consumption (Modules A1 and A3) times their specific CED and GWP per functional unit (kg, m^3 or m^2). Materials and components included in the design were quantified from the construction drawings and bases of design (BODs) documented for the Living Lab, and inventory data sourced for the best possible match. With the exception of concrete (authors' data) and the green roofing system (manufacturer's brochure), materials and components production processes were adapted from Ecoinvent v.2.2 (ECOINVENT, 2010), ELCD v.2.0, Industry Data v.2.0 and US LCI v.1.6 databases (PRÉ, 2008). Ecoinvent database v.2.2 offered information for most items and was preferred for consistency sake, but merging different inventory databases and secondary sources was unavoidable.

- **Construction process stage (Modules A2, A4 and A5)**

CED_{TR} (in MJ) and GWP_{TR} (in tCO_{2e}) of freight transport registered within the supply chain (Module A2) and freight and CDW transport later on in the construction process stage (Module A4) were calculated by multiplying transported mass (in tones) times travel distance (in km) times specific CED and GWP (i.e. per tkm of the fuel and freight modals used) for all building products considered. For estimating CED_{CON} (in MJ) and GWP_{CON} (in tCO_{2e}) of construction activities (Module A5), we multiplied the items/activities considered times their specific CED and GWP per functional unit.

Transported mass and transportation distances were included either accurately, based on actual travel distances, or on best of knowledge estimations, in case of missing information. Data from Ecoinvent v.2.2 and ELCD v.2.0 databases were used for modals and fuel types. The original material mass and corresponding transportation and material usage impacts were corrected using wastage factors derived by Agopyan et al (2003) or observed in actual construction practice. Since the case study is not built yet, construction equipment fuel use was estimated using data for consumption per m^2 of gross floor area (Yan et al, 2010) for a high-rise building in Hong Kong. Even though construction practices may differ significantly from the original context, as well as the fuel intensity for high and low-rise building construction, Brazilian data for construction activities separated from materials usage are not readily available, and a potentially more suitable figure was not found in the literature reviewed.

- **Use stage (Modules B1-B6)**

CED_{OP} (in MJ) and GWP_{OP} (in tCO_{2e}) of the use stage were calculated by adding contributions from maintenance/repair/replacement (Modules B1-B5, i.e. material intake and transportation to the building, as well as corresponding CDW transport to EOL treatment) and operational energy use (Module B6, 100% electricity). Operational energy consumption was simulated using Energy Plus. Data from Ecoinvent v.2.2 (ECOINVENT, 2010) for low voltage electricity in the Brazilian mix were used for operational electricity CED and GWP calculation. Substitution of building products during the building's service life (Use stage, in Figure 1), was planed in accordance with the Brazilian performance standard NBR 15575 (ABNT, 2013), which establishes minimum design service lives (DSL) for major building subsystems. Loads from building parts replacement ('gate to site' freight and corresponding CDW 'site to EOL' transport) were calculated accordingly.

- **End of life stage (Modules C1-C2)**

CED_{EOL} (in MJ) and GWP_{EOL} (in tCO_{2e}) of the end of life stage were calculated by adding contributions from demolition/dismantling equipment energy use (Module C1) and from CDW transport to end of life treatment facilities (Module C2). Two EOL scenarios were considered): (1) demolition as usual (BAU, 0% reuse | 76% recycling | 23%landfill), with 90% of material recovery rate, followed by crushing of concrete, recycling of metals as scrap and incineration of wooden material without energy recovery and landfilling of the remaining CDW; and (2) 90%-recovery efficient selective dismantling (19% reuse | 60% recycling | 20%landfill), followed by partial (40%) reuse of steel frame, crushing of concrete, recycling of steel rebar and 60% of the structural frame and incineration of wooden material without energy recovery and crushing of uncoated glass, and landfilling of the remaining CDW.

Energy demand scenarios and photovoltaic (PV) system modelling

Four crystalline silicon (single-Si, multi-Si) and thin film (amorphous-Si and CIGS) PV technology generations were simulated. Amorphous-Si (a-Si) is the most efficient PV technology from the demanded system power perspective, and could be a good alternative for projects with more surface available; whereas single-Si is the most efficient alternative in terms of area needed to deliver each kWp. PV system sizing procedure using Homer Energy software discounted generation losses to account for *(1)* orientation and exposure angle of the envelope surfaces variation for facade- and rooftop-mounted applications; *(2)* exposure to outdoor temperatures above standard test conditions of 25 ± 2°C (RÜTHER, 2004); and (3) panel ageing. To account for the latter, a degradation factor of 0.5% per year was applied, assuming a 25-year panel service life (LIMA et al, 2012), to ensure that the desired performance is maintained over the whole period of study.

Results presentation and discussion

The minLCee building would consume less than 31 kWh/m^2 GFA per year of reference service life (50 years). Figure 2 shows that offsetting Scenarios 1, 2, 3 and 4 (*i.e.* ranging from the non-renewable portion to total operational electricity CED) is potentially achievable by using all technologies but a-Si, in the latter case. This brings important flexibility to decision-making, particularly in terms of costs and smooth integration to architecture. Considering non-renewable CED embodied in building products in the neutralization targets ('Plus' statuses) basically dismisses surface-intensive PV technologies and single-Si PV stands out.

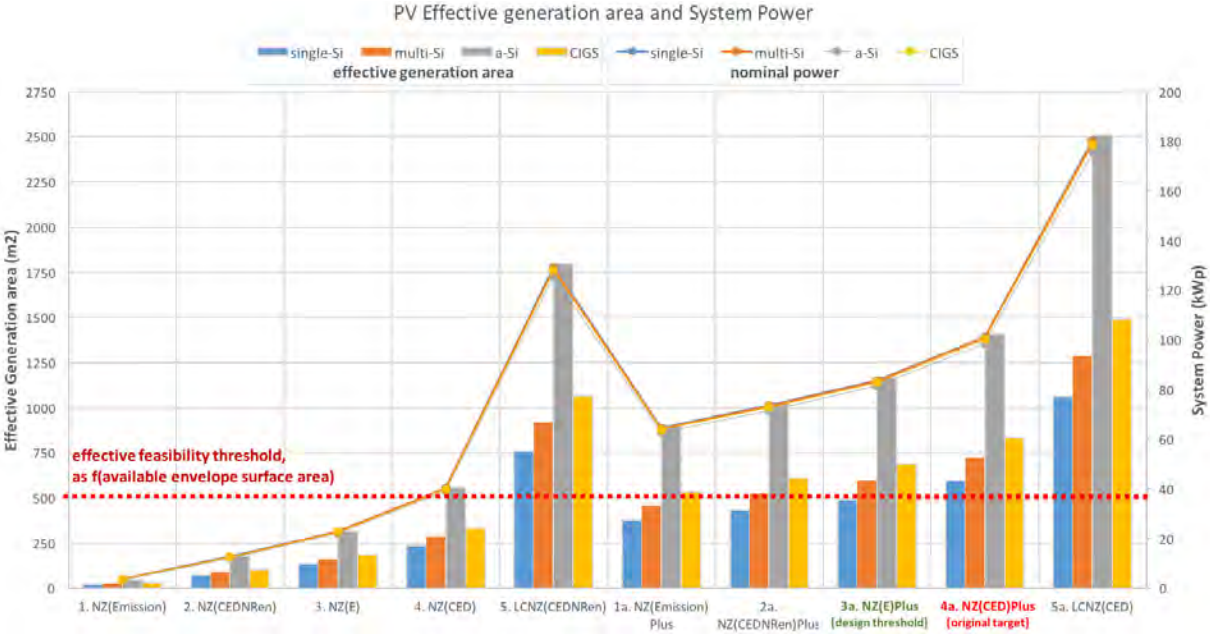

Figure 2 - Energy balance scenarios simulated and respective nominal system power and effective area requirements for the four PV technologies tested. Despite sharing a similar system power profile, effective generation area varied significantly with PV technology. Available envelope area for PV installation ultimately determined the feasibility threshold, to ensure architectural design coherence.

Sizing of the PV array to neutralize operational emissions [NZEmission status, Scenario 1] makes it very evident that such concept does not stimulate progress in contexts with high renewable content electricity mixes, like Brazil. Accounting for non-renewable CED [Scenario 2] instead; achieving 'net zero energy' [Scenario 3] or jumping from that to 'net zero CED' [Scenario 4] would all be goals easily reached through PV onsite generation.

Optimized envelope surface usage for PV mounting while keeping overall architectural coherence ultimately set the practical compensation limit: offsetting the total operational electricity (30,877 kWh/yr) plus the non-renewable CED embodied in Product stage [NZ(E) Plus status, Scenario 3a]. The corresponding installed area of single-Si PV panels was inserted in the building's lifecycle calculations (Figure 3 and Figure 4). The minLCee building would totalize a CED_{LC} of 44.5 GJ/m^2 GFA and a GWP_{LC} under 7 tCO_{2eq}/m^2 GFA. The designed single-Si PV array would generate 3.6 times the simulated operational electricity and offset 14% of GWP_{LC}.

Effective generation area needed by scenarios beyond this threshold exceeded the building's envelope area and would require extra land use, which could be substantial: coping with lifecycle CED demands an effective generation area 98% larger than the building footprint. Nevertheless, CED takes into account the whole energy involved in delivering and using buildings and provides comprehensive and valuable performance description to building professionals, construction and transportation/logistic services and policy makers.

Product modelling (Figure 3) showed that the structural system (steel frame and concrete slabs), partitions (particularly from galvanized steel), the PV system plus BOS, and façade panels contributed to over 98% of CED and GWP embodied in building products accounted for in the Product stage (Figure 4).

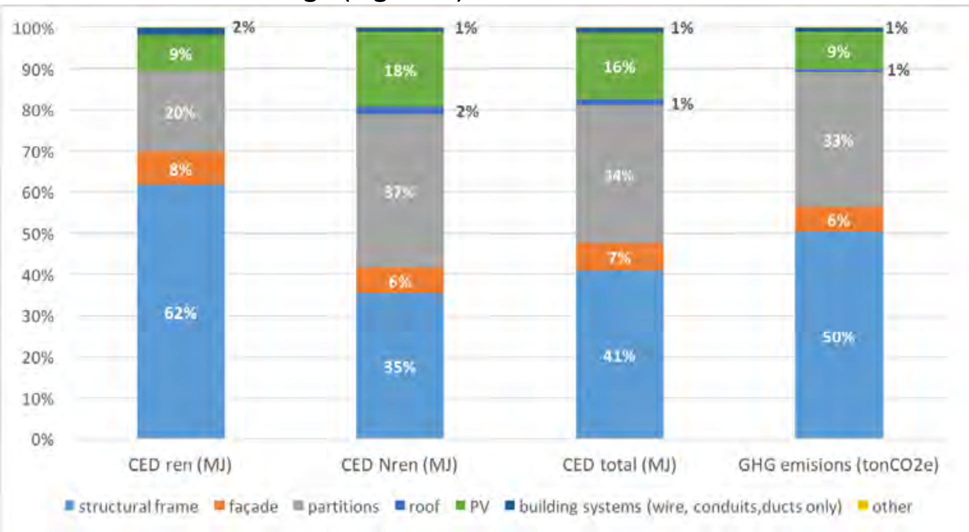

Figure 3 – Major building subsystems contributing to lifecycle CED (renewable and non-renewable) and GWP

Pre-use stages (47%) nearly equaled the use stage (52%) contribution to lifecycle CED (Figure 4), proving their importance in energy assessment of highly efficient energy buildings. Contrastingly, almost 70% of GWP_{LC} refers to the use stage, despite operational energy being mainly renewable. While electricity provision and usage indeed responds for little GWP (8% GWP_{OP}, 44% CED_{OP}), material replacement over the reference service life contributed significantly to operational impacts (91% GWP_{OP} and 56% CED_{OP}). Transportation proportion during the use stage was negligible. EOL treatment also had insignificant effect on lifecycle CED (<1% CED_{LC}) and GWP (<0,1% GWP_{LC}), regardless of the the approach (business as usual demolition or selective dismantling) and material recovery rates combination simulated.

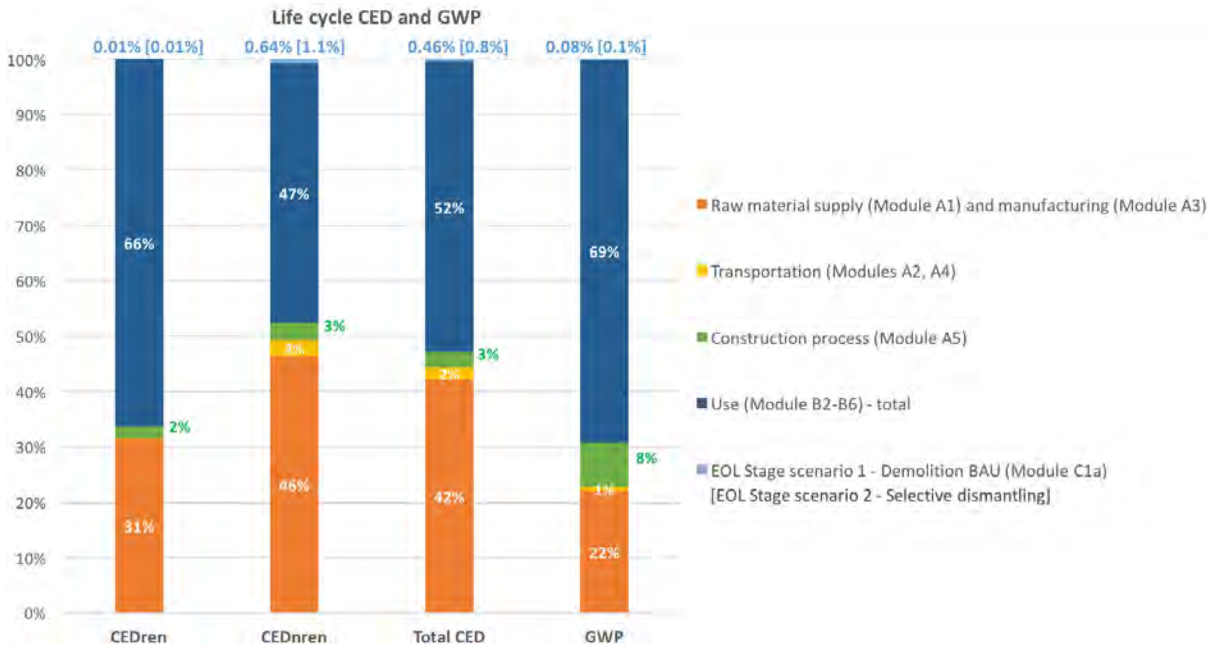

Figure 4 – Contribution to total CED and GWP broken down into building lifecycle stages. EOL treatment had negligible effect, regardless of the scenario simulated.

Conclusions and final remarks

This experience elucidates major gaps and challenges to turn ambitious energy and emissions budgeting goals into mainstream practice in our context. Major takeaways are:

- Once operational energy performance was optimized, the most effective low carbon design strategies for our case study comprised reducing concrete usage and clinker content; specifying for extended service life and limited material replacement/CDW generation; and prioritizing less transportation-intensive supply chain and EOL treatment;
- Replacement rates to comply with a given (or to extend) service life must be carefully analysed. The lack of reliable service life performance data on most building components introduces high uncertainty to a major operational impacts contributor;
- Similarly, material wastage during construction must be also controlled. Though its contribution to GWP is not too high (10%), its CED_{CON} share is important (55%) and so are the respective modelling uncertainties;
- Accounting for benefits of materials EOL attributes (e.g. biodegradability, recyclability) faces modelling limitations. EOL potential can be entered as supplementary information in Module D of the examined cycle, whilst it would be 'harvested' in future lifecycles actually benefiting from reuse/recovery/recycling. Opportunities for CDW to re-enter material cycles within Brazilian construction activities are still limited, and Module D was not included in this study boundaries, which stopped at basic material recovery at the construction site followed by transportation to an EOL treatment facility.
- 'Beginning-of-life' attributes (e.g. renewable, recycled content, local sourcing) are more easily captured within the examined building lifecycle. Renewability net benefit would depend on processing, treatment and transportation profiles, which might not be adequately detected by the two selected impact indicators. Recycled content does play a significant role though, particularly if avoided burden (consequential) LCA

approaches are used, for best capturing such benefit. Finally, prioritizing low transportation-intensive *supply chains* (not only 'local suppliers') can help reducing GWP, in particular, given the predominance of road freight transportation in the country; and

- The product stage allows for attributional LCA application. Consequential (scenario-based) LCA seems to be more appropriate afterwards, given the long service life buildings have, during which a number of technological and contextual changes can occur, and the number of unavoidable assumptions made over the subsequent life cycle stages.

For being a demo building, the maximum generation capacity was basically limited by the available surface for applying traditional rooftop - and façade-mounted PV. The use of BIPV was not explored and could bring further material intake benefits. Ubiquitous use of visible PV panels sends a powerful message for passersby and is tuned with this particular building's mission, but would not necessarily suit other construction types. Furthermore, in real-life implementation studies, cost would still probably be the strongest restriction for aggressive energy and GWP reducing goals.

How an increase in house size affects the LCA of a bedroom

Iman Khajehzadeh[1] and Brenda Vale[2]

Abstract: Many developed countries including New Zealand have experienced an increase in average house size. Those who living in large houses generally argue that it is just a matter of the initial investment in terms of the financial and energy impact and ignore the long-term resource implications of large housing. The master bedroom has a constant use over the life of a house. The results of a floor plan study of 287 New Zealand houses indicate that with increasing house size the average size of most rooms including master bedrooms also increases. An online survey of 260 owner occupied houses also shows that larger houses with their larger rooms are filled with more furniture. While having spare rooms might be a choice, having a larger master bedroom with more furniture seems to be an inevitable consequence of choosing a larger house. The energy embodied in the construction of a bedroom and its furniture and operation in an LCA study reveals that, for the same function, occupants of larger houses use significantly more energy. This increase in energy for a room with a normal fixed use in different sized houses is generally ignored and needs public awareness.

Keywords: Large housing, Life Cycle Energy, Bedroom, Furniture, New Zealand

Introduction

A QV report (2011) shows the average floor area of new New Zealand houses increased from 112.7 in the 1940s to 128.2 in the 1960s, 142.4 in the 1980s, 194.2 in the 2000s, reaching 205.3 in the 2010s. Statistics New Zealand building consent figures (2014a) confirm this trend. At the same time, Statistics New Zealand (2008) show the occupancy rate of 3.7 in 1951 decreased to 2.8 by 1991 and 2.6 by 2006, and is projected to reach 2.4 by 2031. So on average, fewer people live in larger houses. The same house size pattern is seen in many developed countries, including those in Europe (Dol and Haffner, 2010), the US (United States Census Bureau, n.d), Australia (Fuller and Crawford, 2011), and Canada (Anderson, 2013).

An investigation (Khajehzadeh, 2017) of these new, large houses in New Zealand revealed they have several spare bedrooms (with no usual occupant), double/triple living rooms, double/triple garaging, several bathrooms (including en-suites) and specialised rooms (such as a study, playroom, games room, and studio). People choose large houses for many different reasons, although the extra flexibility of these is the main one (Khajehzadeh, 2017). While some aspects of new, large houses can bring flexibility, others do not seem to help with this. For instance, having an additional room for occasional guests seems useful, since the extra room could also be used as a study or as a sick room when someone is ill. However, having four or five extra bedrooms does not seem particularly flexible. Having a reasonably sized bedroom could give flexible space (somewhere to have a desk, or a quiet place to read) while having a huge bedroom helps less with flexibility and is more a matter of fashion.

Most people think living in a large house is only a matter of initial investment while Khajehzadeh (2017) shows there are future consequences of this initial decision over the life of the house. Larger houses usually have larger rooms of the same type, including bedrooms. As suggested above, an increase in the bedroom floor area seems to offer space for additional functions. However, the same study shows most large houses have a separate study and the bedroom is only used for sleeping. This means that, for the same function (sleeping), larger houses use up to 66% more floor area. This additional floor area is just the outcome of having a larger house and not necessarily something intended by the occupants.

Obviously, a larger bedroom needs more building materials for its initial construction and refurbishment, as well as more energy for lighting and heating over the life of the house. Clause G7 of the New Zealand Building Code (MBIE, 2014) states the window area of a habitable space is at least 10% of its floor area. This means larger bedrooms also need more (or larger) windows to meet the code. Analysed floor plans (Khajehzadeh, 2017) revealed larger bedrooms also have more area for built-in wardrobes, adding to the materials that go into these items, which may be replaced more than once in the life of the house.

Over the life cycle of the house, energy is also required to heat each bedroom. Assuming a similar construction technology for all bedrooms, size of bedroom and its windows have key roles in heating energy. Mithraratne et al. (2007) calculated the annual energy for heating a $94m^2$ light construction house in Auckland using ALF 3.0 simulation software, resulting in an energy use of 2,123kWh/annum for “all day” and 1,768 kWh/annum for “intermittent” heating. A monitoring study by BRANZ (Isaacs et al., 2010) of energy use in New Zealand households shows total national average energy is 11,410 kWh/annum of which 34% (3479 kWh/annum) is for space heating. Isaacs et al. (2010) also compared their results sample ALF 3.0 house simulations and found significant differences. ALF 3.0 predicts whole house heating while their monitoring study shows most households only heat part of the house. They also found differences in length of heating season (months) and daily heating (hours) between their monitoring study and ALF 3.0 simulations (Isaacs et al., 2010). The same BRANZ study also found that in New Zealand homes 45% of space heating energy comes from solid fuel, 32% is electric, 15% gas and 8% LPG (Isaacs et al., 2010). The main solid fuel is wood used in wood burners normally installed in living rooms. This means New Zealanders need another way of heating other rooms, including bedrooms. Personal experience and observation shows that portable gas or electric heaters are used for bedroom heating.

Khajehzadeh (2017) and Khajehzadeh and Vale (2016) found large New Zealand houses, including master bedrooms are filled with more furniture and appliances, and these items normally have a very short life (Treloar et al. (1999) and Vale and Vale (2009)), not only because of wearing out, but also from changes in fashion or technology (Mithraratne et al., 2007). Based on these issues, this paper investigates how the initial decision to buy a large house, with a large master bedroom, might affect the life cycle energy of the house.

Methodology

Floor plan study

As a part of a PhD study on the impacts of house size on occupant behaviour and resource-use, floor plans of 287 New Zealand houses were analysed using AutoCAD 2015-2016. Floor plans were selected from a range of old and new New Zealand houses. All plans were redrawn in AutoCAD 2015-2016 and the overall floor areas of the house and each room were calculated and entered in an excel spreadsheet. Houses were categorised according to the number of rooms following the Statistics New Zealand (2014b) room standard. Full details of this study are available elsewhere (Khajehzadeh and Vale, 2017). An ANOVA one-way test was also conducted in SPSS. This showed the average floor area of master bedrooms is significantly different at 0.01 level ($F_{(5, 272)}$=36.20, p=0.000). The average floor area of the master bedroom in a 4 room house is 14.9m^2 increasing to 16.8, 17.4, 21.2, 23.4 and 27.9m^2 in 5, 6, 7, 8 and 9-9+ room houses. Accepting this, a floor plan of each size of master bedroom was selected from the case study houses and a furnishing plan drawn (bedrooms A to F, Figure 1). The furniture and appliances found in each size of master bedroom are based on a study of New Zealand houses in TradeMe and the survey of owner-occupied houses mentioned above. Full details of both studies are available elsewhere (Khajehzadeh, 2017).

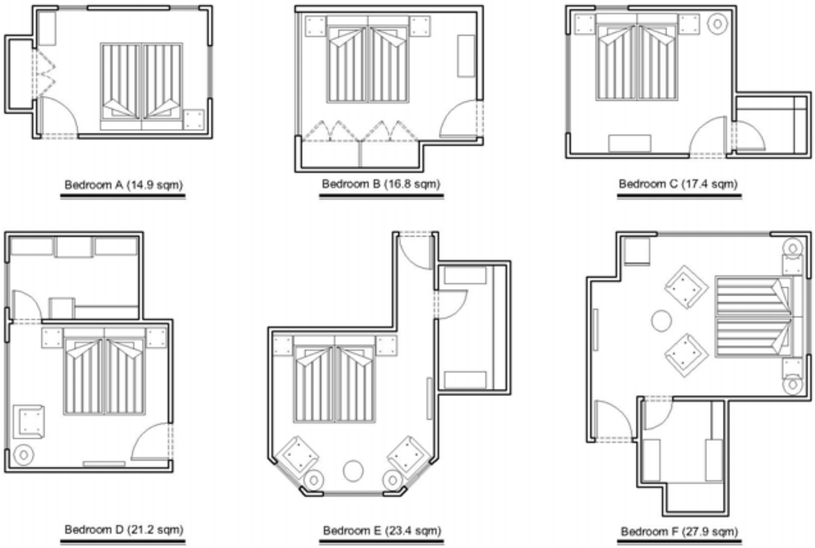

Figure 1 Furnished floor plans of different sized bedrooms from the floor plan study by Khajehzadeh and Vale (2017) (Sources for Bedrooms A-F are respectively Chrystall (1982), McCoy (1956), Navigation homes (2014a), Wood (1993:58-59), Navigation homes (2014b) and Certifiedplans (2016d))

Life cycle assessment of each bedroom size

To simplify calculations, all bedrooms are assumed to be in timber frame houses with timber cladding, which is the most popular construction type in New Zealand (Isaacs, 2015). Mithraratne et al. (2007) conducted a detailed LCA for a typical NZ house, including this construction type. Their study produced the embodied energy per square metre for the different elements of a New Zealand house (Table 1). Based on this and according to the floor area of each bedroom, the embodied energy of each element was calculated for the different bedroom sizes and added to give an overall initial embodied energy (Table 1).

Building elements need maintenance and some need replacement over the life of a house. Mithraratne et al. (2007:130) found very different useful lives for building elements from various sources concluding "there is no commonly accepted useful life for various materials and elements used". This study follows the maintenance schedule of Mithraratne et al. (2007) where the useful lives are an assumed 100+ years for foundation, floor, wall and roof, 60 years for joinery, 50 for electrics and 10 for finishes.

Each bedroom needs lights and over the life of the house, these need electricity to run them and will be replaced at intervals. Accepting a useful life of 1000 hours for each lamp and an average use of 2 hours/day, the overall lamp life is 1 year 4 months. Assuming each lamp costs NZ$1 and has an embodied energy intensity of 1.0MJ/NZ$ (Mithraratne et al., 2007), the embodied and life cycle energy of lamps was calculated and added to the EE and LCE of each bedroom size. Accepting larger bedrooms need more lamps to light them, Table 2 gives the number and Wattage of lamps for each room size and the hours per day each lamp is used. Table 2 also gives the annual electric energy required for lighting each size of bedroom.

Table 1 Embodied energy of elements of a typical NZ house (based on Mithraratne et al., 2007) and relevant embodied energy for similar elements in different sized bedrooms

Bedroom elements	**EE (MJ/m^2) based on Mithraratne et al. (2007)**	**Bedroom size (m^2)**					
		14.9	**16.8**	**17.4**	**21.2**	**23.4**	**27.9**
Foundation	30	447	504	522	636	702	837
Floor	220	3278	3696	3828	4664	5148	6138
Walls	450	6705	7560	7830	9540	10530	12555
Roof	400	5960	6720	6960	8480	9360	11160
Joinery	230	3427	3864	4002	4876	5382	6417
Electric work	100	1490	1680	1740	2120	2340	2790
Finishes	210	3129	3528	3654	4452	4914	5859
Subtotal EE (MJ) bedroom construction elements		24436	27552	28536	34768	38376	45756

Table 2 Number and Wattage of lamps and annual energy for electric lighting of each bedroom size

Bedroom size (m^2)	**Number × Wattage required**	**Hours/day used**	**kWh per annum**
14.9	1 × 100	2	73.0
16.8	2 × 60	2	87.6
17.4	1 × 100 + 1 × 40	2	102.2
21.2	1 × 100 + 1 × 60	2	116.8
23.4	1 × 100 + 2 × 40	2	131.4
27.9	1 × 100 + 1 × 60 + 1 × 40	2	146.0

As noted, bedrooms are normally heated by portable electric heaters for a few hours a day and usually near sleeping time. A time-use study of rooms in New Zealand houses by Khajehzadeh et al. (2016) shows on average New Zealanders spend 8.7 hours per day in each sleeping bedroom. Isaacs et al. (2010) found the average New Zealand heating season lasts for 6 months. Here it is assumed people will heat their bedrooms for 2 hours per day in the evening for 6 months using a portable electric heater. The New Zealand company Aber Holdings Ltd (Kent, n.d.) sell wood fires and portable heaters. They have a guide to selecting a suitable portable heater for the size of room, based on a typical timber frame house with a "tin roof, wooden windows and modest insulation", and an assumed heat loss of 80 Watts per m^2 to keep the temperature at 21 degrees Celsius. Based on this the Wattage required for each bedroom size is calculated using the nearest appropriate size of heater (Table 3).

Table 3 Wattage of portable heater required and energy-use per annum for heating each bedroom size

Bedroom size (m^2)	**Wattage required based on Kent (2017)**	**The nearest available Wattage in market**	**Energy-use per annum (kWh)**
14.9	1190	1200	438
16.8	1340	1300	475
17.4	1390	1400	511
21.2	1700	1700	621
23.4	1870	1900	694
27.9	2230	2200	803

Life cycle assessment of bedroom furniture

Each bedroom needs furniture and appliances and larger bedrooms need more of these (Figure 1). The embodied energy of furniture and appliances was calculated using the cost method developed by Treloar (1998) and previously used by Fay (1999), Mithraratne et al. (2007), Vale and Vale (2009) and Khajehzadeh (2017). It uses an estimated 8MJ/$ for furniture and 10MJ/$ for appliances (Treloar, 1998). Treloar's (1998) values use the Australian dollar although the very small difference between that and New Zealand dollar is ignored here.

Table 4 Furniture and appliances used in each bedroom size, their NZ median price and estimated useful life

Furniture type	Median NZ market price ($NZ)	Useful life (Years)	Number available in each bedroom
Double bed frame	739	25	A-F (1X)
Double mattress	479	10	A-F (1X)
Chest of drawers	500	25	A-C (1X) and D-F (2X)
Free standing mirror	150	25	D-F (1X)
Bedside table/cabinet	170	25	A (1X) and B-F (2X)
Armchair	749	25	D (1X) and E-F (2X)
Coffee table	364	25	E-F (1X)
Vases	89	30	E-F (1X)
Rug	699	15	E-F (1X)
Ottoman/Footstool	364	25	E-F (1X)
Floor lamp	249	20	C-D (1X) and E-F (2X)
Wall clock	32	10	A-F (1X)
LCD/LED TV	1689	10	D-F (1X)
Bar fridge	450	13	F (1X)
Hair dryer	69	8	A-F (1X)
Hair straighter/Hair curler	79	8	A-F (1X)
Electric oil filled radiator	180	10	A-F (1X)

The furniture analysed, replacement schedule, and cost follow Khajehzadeh (2017) (Table 4). The judgement of what to include was based on the survey of owner-occupier households and observations of houses advertised in TradeMe (Khajehzadeh, 2017). For example, the survey shows the average number of bar fridges in 9-9+ room houses is significantly higher than all other house sizes and is almost zero for houses with less than 9 rooms (Khajehzadeh and Vale, 2016). At the same time, images of 9-9+ room houses advertised for sale in TradeMe show some master bedrooms include a bar fridge (Khajehzadeh, 2017).

Results

Following the cost method and useful lives of furniture and appliances, the life cycle energy of building elements and their maintenance, operating energy (heating and lighting) and furniture/appliances were calculated for 0, 25, 50, 75 and 100 years (Table 5). Adding these for each bedroom size gives the overall life cycle energy at each life stage (Table 6). From Table 5, by living in an 8 rather than 4 room house, over 100 years 57% more energy will be used for construction and maintenance of the master bedroom, with a 60% increase in operating energy and 269% increase for furniture and appliances. In a 100 years, by living in an 8 rather than 4 room house, occupants will use 114% more energy for the master bedroom.

Table 5 Life cycle energy (GJ) of building elements and their maintenance, operating energy (GJ) and energy (GJ) required for furnishing each bedroom size at certain life stages

Figure 2 shows the share of building elements, operating energy and furnishing over the life cycle of a small (14.7m^2) and large bedroom (23.4m^2), revealing more than half (57%) of the total energy of the former (in year 0) goes into building elements while the share of furniture (43%) is also considerable. As the house ages, for a small bedroom, the share of its building elements and their maintenance decreases and operating energy gradually increases, while after year 25 the share of furniture/appliances remains relatively constant (Figure 2). After 25 years, for a small bedroom operating energy is 37.4% of total life cycle energy increasing to 43.1%, 46.5% and 47.5% after 50, 75 and 100 years.

To see how this pattern differs for a large master bedroom, the life cycle energy breakdown of the master bedroom of a small house (Bedroom A) was compared to that of a large house (Bedroom E) (Figure 2). As seen, the energy for furnishing the latter in year 0 is a significant 281% more than the former. In addition, furniture and appliances form a larger proportion of the overall energy of the large bedroom in year 0 compared to the small one (65.0% against 43.4%). This means the impact of furnishing a large bedroom is more than its building, as the energy for the former can be almost double that required to build it. Over the life cycle of the house, the share of operating energy becomes important in both bedrooms. The key difference is that furniture/appliances are more important in larger bedrooms while operating energy is more important in small bedrooms.

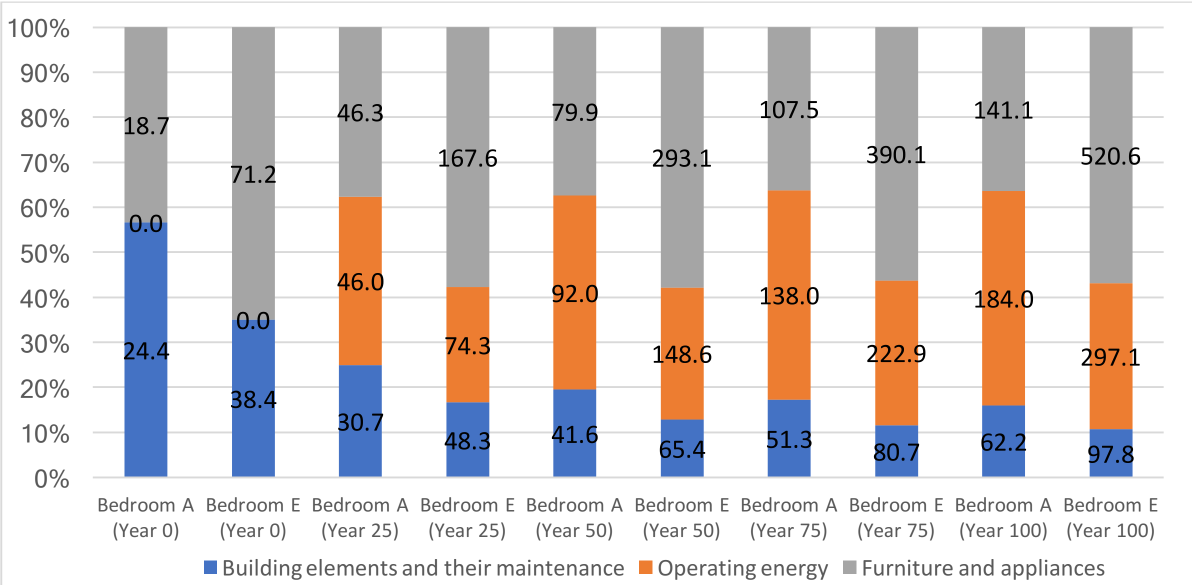

Figure 2 Breakdown of life cycle energy of a small (A) and large (E) master bedroom at various life stages

Conclusion

This investigation indicates that by choosing to live in a large house rather than a small house, the energy required for construction, maintenance, operating and furnishing master bedrooms is increased by 182% in year 0 and 162% in year 100. This becomes more important given that both large and small master bedrooms are designed to fulfil the same function. Results of the New Zealand time-use survey 2009-2010 by Statistics New Zealand (2011) shows New Zealanders aged 12+ daily sleep 8.8 hours, which is very similar to the average bedroom use of 8.7 hours/day found in the survey noted above. This means that almost all the time spent in a master bedrooms is for sleeping and so size does not matter a lot. Most increase in the life cycle energy of larger bedrooms comes from furnishing and heating and lighting these spaces, something most people do not consider when they buy a large house. Perhaps more public awareness is required to familiarise people with the future consequences of living in large houses. In addition, this study show that furniture and operating energy are the important components of the life cycle energy of a master bedroom so it is important to reduce these uses of energy. This means having better insulated houses, including retrofitting the uninsulated housing stock, and making more use of durable and second hand furniture items.

The share of furniture and appliances in the life cycle energy of New Zealand houses

Abstract: New Zealand houses comprise various outdoor and indoor spaces. Apart from the resources used for the construction of these, the occupants need furniture, appliances and tools (FATs) to make these spaces liveable. Because FATs have a short replacement time, the life cycle energy of these over the life of the house becomes significant. Different levels of each are needed to support the intended function and so the energy embodied in these for each space is also very different. Additionally, the time occupants spend at home both indoors and out differs significantly. The results of an online survey of 538 New Zealanders living in owner-occupied houses in summer show that while private outdoor spaces are used for an average of 0.55hour/day, bedroom, living room, kitchen and laundry are used for 8.7, 2.9, 1.1 and 0.1hour/day. Less used spaces, such as kitchen, laundry and garden, need a lot of energy for furnishing them and hence, their energy-use may not be as efficient as it might be. In terms of house resource-use efficiency, sharing facilities could lead to a more sustainable use of resources. This paper shows how sharing gardens, kitchens and laundries in a form of co-housing could be a key parameter in reducing the life cycle energy of a house.

Keywords: Life cycle assessment, Sharing, Furniture, Appliances, New Zealand

Introduction

A life cycle assessment study of New Zealand houses by Khajehzadeh (2017) indicates furniture, appliances and tools (FATs) form a significant proportion of the initial life cycle energy of New Zealand houses. For many reasons, including technological improvement and fashion changes (Mithraratne et al., 2007), furniture and appliances have short lives (Treloar et al. (1999) and Vale and Vale (2009)). This means the share of FATs in house life cycle energy becomes more important over the life of the house (Khajehzadeh, 2017).

A survey of 260 owner-occupied New Zealand houses by Khajehzadeh (2017) shows that with the exception of single person households (who have significantly fewer FATs than other household types), the number of people living in a house does not affect the number of FATs. The same study clearly shows that house size has a significant impact on number of FATs in a house (Khajehzadeh, 2017). Regardless of how many people live in a house, some core FATs are required for any household size. For example, a couple with 2 children and a single person household would be expected to have a fridge, stove and washing machine, although the energy required to make and run these is divided by 4 for the former and 1 for the latter. This suggests the number of people sharing certain resources may be key in their sustainable use.

The type of FATs in a space or room reflects the activity expected there (Canter and Lee, 1974). In other words, it is possible to group furniture and appliances according to room types. For example, appliances such as stove, fridge, freezer or dishwasher, which are associated with eating, are usually kept in a kitchen. This makes it is possible to measure the share of various rooms in the overall energy used for furnishing a house.

Results of a summer-based time-use study of 538 New Zealanders living in owner-occupied houses show they spend an average of 15.94 and 0.55hour/day at home indoors and at home outdoors (Khajehzadeh and Vale, 2016a) with 8.7, 2.9, 1.1 and 0.1hour/day spent in bedroom, living room, kitchen, and laundry (Khajehzadeh et al., 2016). Assuming the occupancy rate of 2.65 people per house based on census 2013 (Statistics New Zealand, 2014), the resources that goes to furnishing each of these rooms are not being used effectively.

Obviously sharing private rooms like bedrooms and even bathrooms is not acceptable but sharing spaces that might be considered less private could be. For example, neighbouring houses could share certain spaces, which is similar to but not the same as cohousing (McCamant and Durrett (2011) and Sanguinetti (2012)). Agreement over which spaces can be shared is both a personal and cultural matter that is outside the scope of this study.

Census 2013 indicates that there are more 6 room owner-occupier houses than other sizes in the New Zealand housing stock. At the same time, Statistics New Zealand (2014) shows that 56.2% of 3 bedroom houses (the usual 6 room house) are occupied by 1-2 usual residents. This means that the resources bound up in less-used spaces are shared between 1-2 people. Based on this, this paper aims to investigate how sharing the less private spaces (i.e. laundry, kitchen and garden) of 6 room house with more than 2 people can decrease the overall life cycle energy of a house.

Methodology

As a part of a PhD study, an online survey was undertaken from February to April 2015 using the web-based service Qualtrics (Qualtrics, 2015) to investigate the features of New Zealand owner-occupied houses including their FATs. The survey was limited to small households (single person households, childless couples and couples with 1-2 children) and owner-occupied houses to make sure the FATs belong to the normal occupants.

The questionnaire asked about occupants, type/number of rooms and type/number of FATs in the house. Overall 445 households took part in the survey of which 260 (58.4%) finished the FATs section. In total, 131 FAT items that were most likely to be found in New Zealand houses were covered in this survey. Full details of this survey, associated investigations, and results are available elsewhere (Khajehzadeh, 2017).

The embodied energy of each of the 131 FAT items was calculated using the cost based method developed by Treloar (1998). This method is based on an estimated 8MJ/$ for furniture and 10MJ/$ for appliances (Treloar, 1998) with the minor difference between the Australian and New Zealand dollar being ignored. Using the median price of each item based on main New Zealand suppliers and the useful life of various items (Mithraratne et al. (2007), Fay (1999), Blanchard and Reppe (1998), FannieMae (2014), Fiol (2013), Mr. Appliance (2016), Statista (2011), InterNACHI (2016), Brown (2011), Welch and Rogers (2010), Demesne (2010), Seiders et al. (2007), Cooper (2004), New Zealand Inland Revenue (2015)) the life cycle energy of each item was calculated. Based on the number of each FAT in each sample household (from the survey) and the embodied energy from the cost based method, the embodied and life cycle energy of FATs for each household at various life stages (0, 25, 50, 75 and 100 years) of the house were calculated.

Table 1 Furniture, appliance and tool items found in kitchen, laundry and garden of 6 room New Zealand houses, with median NZ price, useful life, and average number of each

Furniture/appliance/tool type		Average no. in 6 room houses	Median price ($NZ)	Useful life (years)
Kitchen appliances	Fridge/Freezer	1.09	1749	15

	Chain saw	0.41	279	10

The survey houses were grouped according to their size, the latter being based on the number of rooms. The number of rooms follows Statistics New Zealand (2014) definitions. It includes all habitable spaces (with floor area more than $4m^2$) enclosed by walls, floor and ceiling/roof excluding all service areas (bathroom, laundry etc.). The kitchen, living room and dining room are counted separately even where these are combined. Based on this, the average energy used for furnishing different sizes of New Zealand owner-occupied houses can be found. On average, a 6 room owner-occupied New Zealand house needs 154.5GJ energy in Year 0 and 325.2 at Year 25, 538.3 at Year 50, 738.8 at Year 75 and 951.5 at Year 100 for furnishing the whole house, including replacing FATs as necessary.

Because of the popularity of 6 room houses, this house size is used here for further analysis. The average number of FATs found in the garden, kitchen and laundry of 6 room houses was extracted from the survey (Table 1). Table 1 also gives the Median price of each item in New Zealand and the estimated useful life for each item from the previously noted references.

Using the cost based method (Treloar, 1998) and the useful life of each item, the embodied and life cycle energy of items kept in kitchen, laundry and garden were calculated separately for the life stages of the house. It is then assumed that with appropriate design adjacent houses can share a kitchen, laundry and garden and the FATs in these spaces. The idea of sharing these spaces is not new. The idea of the 'kitchenless' house was put forward at the turn of the 20th century as a step in the emancipation of women (Hayden, 1981). The shared garden for food growing is often common in less developed countries (Hill, 2011) and is also promoted for social cohesion in developed ones (Veen et al, 2016). The laundrette (coin operated public laundry) first appeared in the UK in the middle of the 20th century (BBC, 2010). Rather than building purpose designed co-housing it would be possible for adjacent houses, or even houses in the same street, to share more, whereby one house has the communal kitchen, one the common laundry and gardens are redesigned to have communal areas for food growing, play, and entertainment.

The energy embodied in building a shared larger kitchen and eating area should be less than building the same spaces for each house, but this has been ignored in this study which is only focussed on the life cycle energy related to FATs and their replacement. The additional assumption is that the operating energy of the shared spaces is not more than the equivalent operating energy of the non-shared spaces. It might be possible to convert existing houses to provide these common facilities but this is also outside the scope of this paper. The aim here is to see whether the savings in life cycle energy from sharing make such design attempts worthwhile.

To see how sharing these spaces might affect energy-use in individual houses, different scenarios of sharing were considered. With proper design it would be possible for all or one or two of kitchen, laundry and garden to be shared with 2-3 neighbouring houses. Table 2 presents 14 possible sharing scenarios. For example, in Scenario 1 a kitchen is shared between two houses while in Scenario 14, a kitchen, laundry and gardens are shared by three houses. Energy savings from each scenario, were calculated and compared to the same house with no sharing to see the impact of various levels of sharing on the life cycle energy of a house.

Table 2 Scenarios for sharing kitchen (K), laundry (L) and garden (G) by 2 or 3 houses

Scenario	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Spaces shared	K	K	L	L	G	G	KL	KL	KG	KG	LG	LG	KLG	KLG
No. of houses sharing	2	3	2	3	2	3	2	3	2	3	2	3	2	3

Results

Following the methodology described earlier and the items listed in Table 1, the embodied and life cycle energy of the average FATs kept in the kitchen, laundry and garden of a 6 room NZ house was calculated for various life stages (Table 3). As seen, the embodied and life cycle energy for furnishing a kitchen is several times that of a laundry and garden.

Table 3 Embodied and life cycle energy of furniture and appliances kept in kitchen, laundry and garden

Spaces	Embodied and Life Cycle Energy (GJ) at various life stages				
	Year 0	Year 25	Year 50	Year 75	Year 100
Kitchen	80.4	199.6	365.8	540.0	666.7
Laundry	22.0	60.5	92.6	151.8	197.7
Garden	25.8	81.0	157.6	206.1	289.9

Using the levels of sharing set out in Table 2 the energy saved by each scenario at various life stages is presented in Table 4.

Table 4 Energy saving (GJ) in each scenario at 5 life stages

Life stages	Energy saving (GJ) in each scenario (S)													
	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11	S12	S13	S14
Year 0	40.2	53.6	11.0	14.7	12.9	17.2	51.2	68.3	53.1	70.8	23.9	31.8	64.1	85.5
Year 25	99.8	133.1	30.2	40.3	40.5	54.0	130.0	173.4	140.3	187.1	70.7	94.3	170.5	227.4
Year 50	182.9	243.9	46.3	61.7	78.8	105.1	229.2	305.6	261.7	348.9	125.1	166.8	308.0	410.6
Year 75	270.0	360.0	75.9	101.2	103.0	137.4	345.9	461.2	373.1	497.4	178.9	238.6	449.0	598.6
Year 100	333.4	444.5	98.9	131.8	144.9	193.2	432.2	576.3	478.3	637.7	243.8	325.1	577.2	769.5

These energy savings were compared to the overall energy required for furnishing the whole of an average 6 room house of 154.5GJ in Year 0 and 325.2 in Year 25, 538.3 in Year 50, 738.8 in Year 75 and 951.5 in Year 100 (Khajehzadeh, 2017). The percentage energy savings from each sharing scenario were then calculated (Table 5). Figure 1 presents the percentage energy savings for each scenario for Year 0 in descending order from greatest to least savings.

Table 5 Energy saving as a percentage of the overall energy required for furnishing an average 6 room house for each scenario (S) for certain life stages

Discussion and conclusion

A significant part of the energy used for housing goes into furnishing the house. Because FATs have short lives, the energy impact of these increases significantly and becomes more important over the life cycle of the house. On the other hand, people spend little time in some parts of their houses and so the energy embodied in these parts is not used efficiently. In particular, a time-use study of rooms and spaces of New Zealand owner-occupied houses shows that New Zealanders spend little time in the kitchen, laundry and gardens of their houses. Accepting that sharing these might not be acceptable to all people, this study tried to consider different scenarios for sharing these spaces and the effect of this on house life cycle energy.

This study shows the embodied energy of FATs usually found in a kitchen is several times that of laundry and garden FATs in Year 0, although the life cycle energy of FATs becomes significant in all three spaces over the whole life cycle of the house. This study also found the two key parameters for saving energy through sharing were the type of shared space and number of houses sharing. An earlier study by Khajehzadeh and Vale (2016b) shows that number of people sharing a facility is the key parameter in the success of shared spaces and usually spaces shared between smaller groups are more successful. Following this, this study assumed up to three houses could share a kitchen, laundry and garden or any combination of these. This assumption gave 14 sharing scenarios.

As could be predicted, more households sharing a space means more energy savings. While sharing all of the selected spaces produces energy savings the kitchen is the key space when it comes to sharing, as all seven top scenarios for energy saving include a kitchen. In reality sharing a kitchen could be more problematic than sharing a laundry or garden, as many people at the flat sharing stage discover. However, for extended families or very good friends a shared kitchen may be less of an issue. The open plan family kitchen/dining/entertaining space as found in many new houses is also a model for what such a shared space might be like. As could be predicted, the best scenario for energy saving is three houses sharing a kitchen, laundry and garden and in this scenario, each house/household will save 85.5GJ in year 0 compared to a house with no shared spaces. This energy saving increases to 227.4GJ in Year 25 with 410.6GJ in Year 50, 598.6GJ in Year 75 and 769.5GJ in Year 100.

While there is as yet no study on what domestic spaces New Zealanders might be prepared to share it is probable that sharing the garden and laundry would be much more acceptable for most people. With 3 houses only sharing the garden and laundry, each house/household will save 31.8GJ in Year 0, increasing to 94.3GJ in Year 25, 166.8GJ in Year 50, 238.6 in year 75 and 325.1GJ in Year 100. This equates to 20.6% of the overall energy required for furnishing the whole house in Year 0 or respectively 29.0%, 31.0%, 32.3% and 34.2% of the other house life stages.

Sharing only a laundry with 2 other houses, only gives an energy saving of 14.7GJ in Year 0, increasing to 40.3, 61.7, 101.2 and 131.8GJ after 25, 50, 75 and 100 years. These savings are respectively 9.5%, 12.4%, 11.5%, 13.7% and 13.9% of the overall energy required for furnishing the whole houses at the same life stages. Sharing only a garden between 2 houses saves more energy than sharing a laundry (17.2, 54.0, 105.1, 137.4 and 193.2GJ after 0, 25, 50, 75 and 100 years, or 11.1%, 16.6%, 19.5%, 18.6% and 20.3% of the overall energy required for furnishing the whole house). As seen, though these savings are not as big as from sharing a kitchen, they are still worth consideration.

This study also shows the energy saved from sharing the kitchen, laundry and garden of an average 6 room house between 3 houses is 55.3% of the overall energy required for furnishing the whole 6 room house in Year 0, 69.9% in Year 25, 76.3% in Year 50, 81.0% in Year 75 and 80.9% in Year 100. Even following scenario 1 where 2 households share a kitchen, the saving is 26.0% of the overall energy for furnishing the average 6 room house in Year 0, and 30.7% in Year 25, 34.0% in Year 50, 36.5% in Year 75 and 35.0% in Year 100. This is important as while designers fill the kitchens of modern houses with more and more luxurious fittings and appliances, studies show that many people are not cooking at home anymore (Smith et al., 2013). This questions the need for a private kitchen for all houses given the significant energy saving that comes from sharing this particular space of New Zealand houses.

What will affect all these results is the acceptability of the concept of sharing in New Zealand. A further study is required to understand what is and what is not acceptable for New Zealanders when it comes to sharing domestic spaces, and who people would be prepared to share these space with, given they are appropriately designed for easy sharing.

Towards Near Zero Energy in High Density Residential Areas

Olga Kolodiy and Guedi Capeluto

Faculty of Architecture and Town Planning, Technion – Israel Institute of Technology, Haifa, Israel

Abstract: The aim of this work is to check the feasibility and limitations of near ZERO Energy design in highly dense conditions. The study is carried out by examination and comparison of various density design alternatives of an existing urban plot in the coastal climate zone of Israel. In this paper, we introduce design alternatives that increase on plot residential units' number by about 200%, compared to existing plot conditions (Kolodiy and Capeluto 2016). Increased dwelling units' number leads to higher energy use on the one side and mutual shading of new high rise residential buildings on the other, and then present to us new challenges. Preserving solar rights within the plot borders and outside for PV systems installation become more complex. The relations between urban density and passive solar urban design, energy consumption and energy production within plot borders are presented and discussed.

Keywords: Zero energy. Urban density. Photovoltaics. Solar energy. Energy consumption.

Introduction

Carbon dioxide is considered one of the major components of all greenhouse gases responsible for climate change. The buildings sector is responsible for about 30% of total world carbon emissions and other greenhouse gases (UNEP, 2009). In Israel, the electricity consumption by all buildings sectors accounts for about 60% of the total consumption (Ministry of National Infrastructures, 2010), and almost 50% of total greenhouse gasses are emitted by buildings (Teshner et al., 2012). Nowadays, with more than 8 million inhabitants, about 90% of Israel's population lives in urban areas (Word Bank, 2015). The increasing urban population and current lifestyle will lead to the growth in households' number and urban areas densification. As a result, the energy consumption and greenhouse gases emissions will grow, as well as mutual environmental influences between buildings. To reduce the construction industry's negative effects on the environment, buildings should minimize their energy consumption and become energy producers. This industry has the highest potential for immediate action with economic benefit and long-term effects of significant reduction in greenhouse gasses emissions.

Previous studies of urban zero energy districts (Marique et al., 2013) (Hatchem et al., 2012) are concentrated on single family houses or relatively small apartment buildings which does not match new Israeli minimum density requirements. Generally, studies of zero energy feasibility for high-rise buildings (Cho and Kim, 2015) relates to a single building and does not refer to challenges as mutual shading or variable buildings' orientations.

Previous study results

In a previous study (Kolodiy and Capeluto, 2016) the existing condition of the case study plot was examined in terms of zero energy design feasibility. The plot is located in Tel Aviv – Jaffa (32.5N, 35E), one of the densest cities in Israel. It includes twenty-one, four-storey height residential buildings. These buildings were built in early 50`s, when the construction speed was more important than quality. Each building is composed from 22 housing units.

The first stage of the study was to determine on plot buildings' energy consumption. Two conditions were checked: existing condition with no envelope insulation, and improved, which included envelope insulation improvements according to Israeli Energy Rating of Buildings Standard (ST 5282-1, 2011). In addition, a densification alternative of two floors addition above the existing buildings was checked.

The second stage was to examine potential buildings envelope surfaces for photo voltaic (PV) array installation. It was found that roof is the preferable surface for PV system implementation, while horizontal turning of the PV array is most suitable for the examined urban situation. Although, the energy production of a horizontally placement method is slightly lower than ideally south oriented PV panels with 30° tilt, it can be suited to any building orientation and aesthetically integrated, creates minimum shading on neighbouring buildings if rises above rooftop.

According to the study, there is a direct relationship between urban density, energy consumption and area needed and available for electricity production. As the density grows, total energy consumption rises and less well exposed areas are available for PV systems implementation due to the bigger shading areas caused by the higher buildings. Thus, passive solar design principles are important as much as energy efficient envelope design to approach the goal of near zero energy buildings. To make the PV systems worthwhile in dense areas, passive solar design must to be implemented on urban level as much, as in building design. The study showed that even near zero energy goal is difficult to achieve using less effective, 12% efficient PV panels array implemented on the roofs. Existing buildings' protrusions and balconies, limits PV array installation on main facades.

For this case study using low efficiency PV panels, 50% energy generation within building borders should be a realistic target. However, currently more effective solar panels, from 16% to more than 20% efficiency, are available. Moreover, in 2014, a 4-junction solar cell with 46% efficiency was announced (Tibbits et al, 2014). It takes less high-efficiency panels to generate the same amount of energy as more low-efficient panels. In addition, less area is required for more efficient PV array installation, which brings us closer to the goal of zero energy.

Under this scenario of more efficient solar panels, it is theoretically possible to achieve Zero Energy goal for the existing plot situation with improved envelope using solar panels roof installation with about 30% efficiency. When plot density increased (addition of 2 floors), more efficient panels are needed. Zero Energy for this condition will be possible to achieve with 40% efficient PV panels (Figure 1).

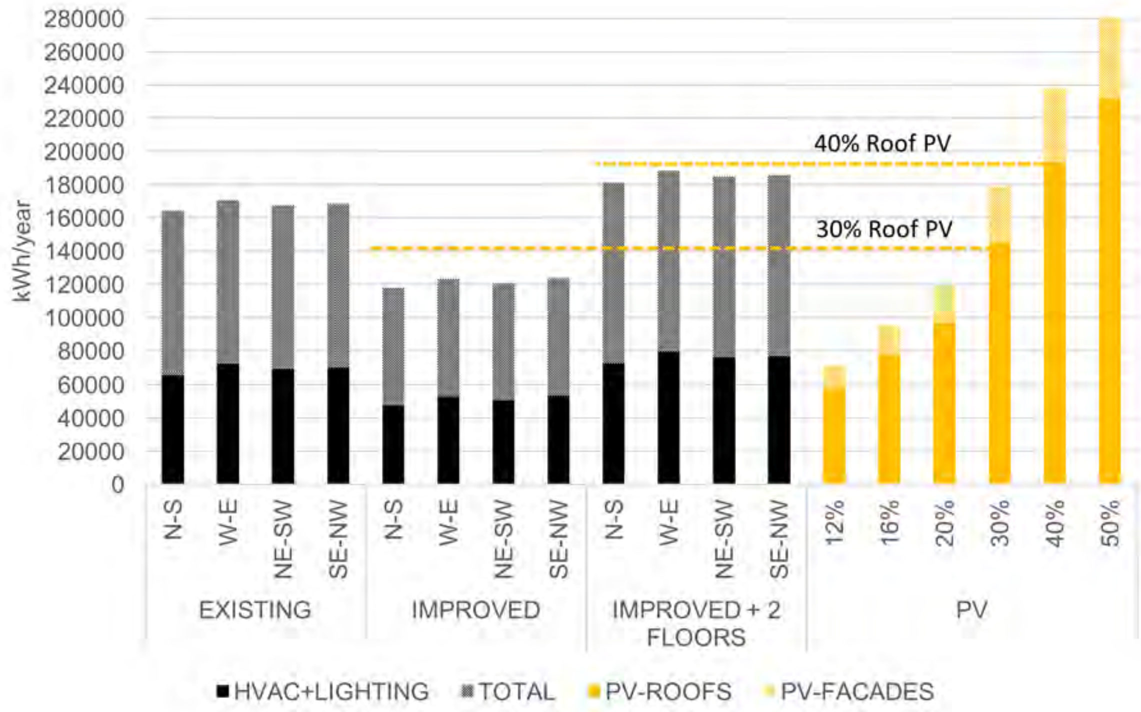

Figure 1. Electricity consumption by building in various orientations compared to roof and facade PV installation for electricity generation.

Densification Programs in Israel

The land is the most precious natural resource in Israel. Despite the importance of protecting the open spaces and natural areas, the situation shows a constant reduction of these areas. According to "Sustainability Plan for Israel 2030" (Ministry of Environmental Protection and Jerusalem Institute for Israel Studies, 2012) a recommended strategy is concentrated dispersion and revitalization of existing city centres.

To minimize damage to open spaces, in the early 2000s an urban renewal plan was developed. Within the framework of the plan, the government of Israel proposed two main tracks for the promotion of municipal urbanization processes (Ministry of Construction and Housing, 1999):

1. Urban Renewal (increased building rights)
2. Urban Redesign (clearance and construction)

The aim of both tracks is better land utilization within built-up areas, the creation of a new housing inventory in cities and their improvement by upgrading existing buildings and infrastructure. In the context of the “Urban Renewal” track, the committee promotes the intensification of built-up areas without demolition activities and maximal use of existing infrastructures. The “Urban Redesign” route requires fully re-planning of an existing area with significant plot densification and related infrastructure renewal. The case study complex in our work is facing an approved “Urban Redesign” densification program. Plot density will increase by more than 200% compared to the existing condition. The densification plan and general design layout was already approved by District Committee in 2015.

Urban Densification Alternatives

In this paper, we introduce two additional alternatives with increased urban density to the previously discussed plot case study (Figure 2):

0. Existing – Current plot condition (Kolodiy and Capeluto 2016).
1. Approved – plot design as approved by District Committee.
2. Proposed – redesign of approved building's volumes to maximize electricity production potential by minimizing mutual shading, and maximizing usable roof area.

0. Existing 1. Approved 2. Proposed

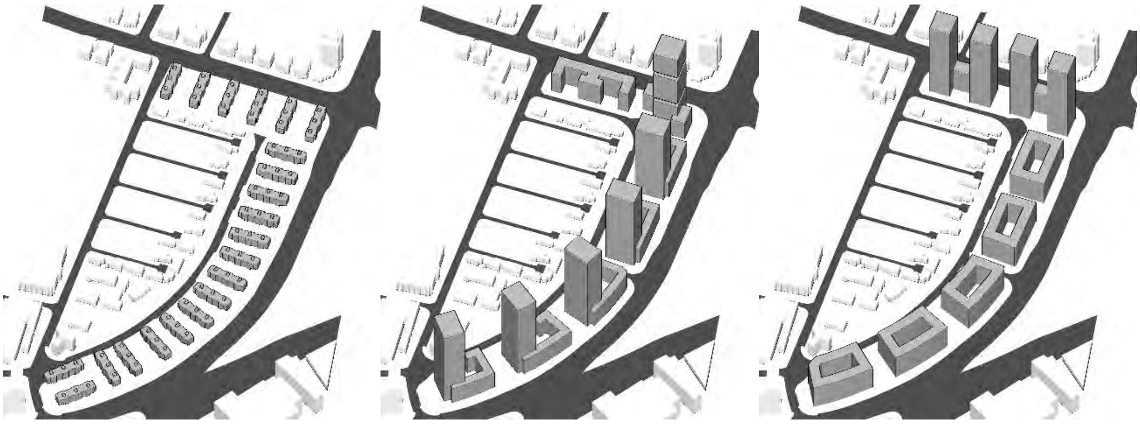

Figure 2. Plot Design Alternatives schemes compared one to another.

The existing plot condition density is 10.7 units to 1 dunam. It does not match to the minimal density requirements by in force National Building Plan 35 (Ministry of Interior, 2010), which is 12 units to 1 dunam. The newly approved plot design will increase plot density by about 3 times. With both densification design alternatives, (1) approved and (2) proposed, both with improved insulation, we achieve equal plot density, namely 32.4 housing units to 1 dunam (Table 1).

Table 1. Comparison of housing units amount by plot and design alternatives.

Case Study Plot with New Site Division	Plot Number	Units Amount by Design Alternatives		
		Existing	Approved	Proposed
	Density (unit/dunam)	10.7	32.4	32.4
	1	132	391	680
	2	66	201	143
	3	66	201	143
	4	66	201	143
	5	66	201	143
	6	66	201	144
	Total	462	1396	1396

The aim of this study is to check how near in the way to zero energy can we get within plot borders with future plot density conditions? Can we ameliorate the approved plot design in terms of energy consumption and electricity generation within plot borders?

The approved option presented in this paper shows the design alternative by Yashar Architects Ltd. This alternative contains three building block types (Figure 3). The first one is an eight-story long type building (Type 1), the second one is a 30-floor tower with eight floor base on the lower levels (Type 2). These two types appear one time on plot number one within the case study area. The third block (Type 3) is six story building connected to the 25-floor tower and appears 5 times at plots number 2, 3, 4, 5 and 6. In this case the potential surfaces for PV panels' installation are reduced and unclear because of mutual shading.

The proposed option was designed to increase on plot solar yield potential. The plot designed to enable maximum roof surfaces fully exposed to solar radiation and maximise on-site electricity production. As the previous alternative, it contains three building block types. Two blocks of eight story buildings connected to two 20 floor towers above (Type 1, 2). These blocks have minor geometry differences due to actual plot borders. They appear once at the northern plot (number one) to maximize towers south façade exposure to solar radiation and to prevent any shading on other on plot buildings' roofs. Third, a European block (Type 3), appears five times on plots 2, 3, 4, 5 and 6. This block is nine story building with flat roof fully exposed to sun radiation (Figure 3).

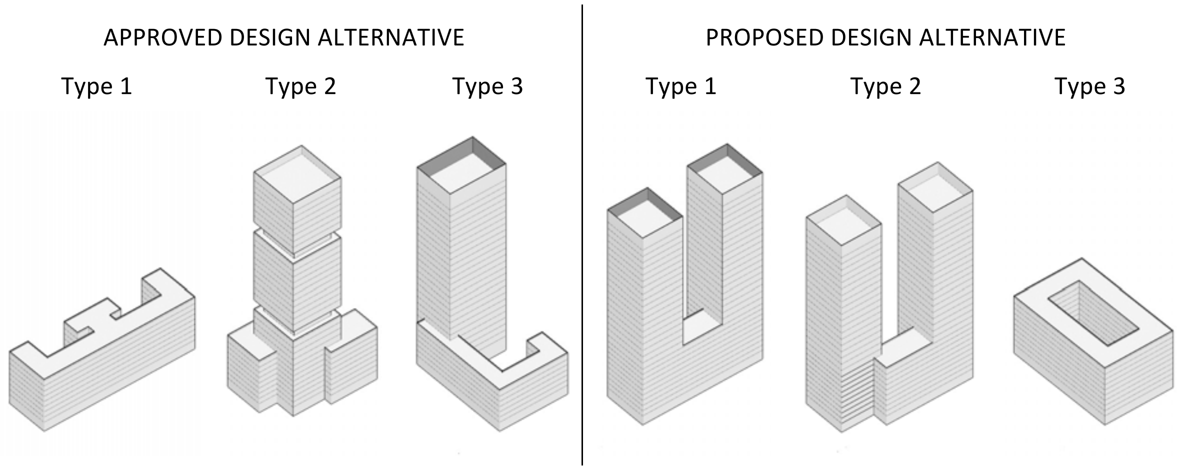

Figure 3. Building block types of "Approved" and "Proposed" design alternatives.

In both design alternatives, the ground floor of all building types was considered as non-residential, public floor, as approved in the original plan. As well, both alternatives aim to maximise on site density conditions but do not consider on plot or neighbour building's solar rights. Design within solar envelope borders to consider solar right of all neighbours will significanty reduce on plot density.

Energy Consumption

Following the previous study method (Kolodiy and Capeluto 2016), the first step for estimating energy plot consumption was to detect buildings' types and identify housing units' types. According to the approved design, there are two main types of housing units in every building block type. Type A apartment, is a unit with single openings' orientation. Its depth does not exceed ten meters to provide basic daylight access and ventilation. Type B apartments are corner units, and have openings in two different directions. These two base types, A and B, has many subtypes that vary in unit's area, orientation and number of external walls.

The second step, was to perform energy simulations (Kolodiy and Capeluto 2016) using Energy UI based on Energy Plus simulation engine. The energy model was built as a tower type building to assess maximum number of unit types with minimum calculation times. Units' windows in energy model were set according to the Israeli Energy Rating of Buildings Standard (ST 5282-1, 2011), namely 15% of the floor area. Although, in Energy Rating Standard openings' sizes varies according to facade orientation, the maximum allowed size was applied to each unit according to Israeli residential design habits.

According to the results, south oriented A and B units have better energy performance results than north oriented. West and east oriented units have slightly higher energy consumption compared to north and south, while the west oriented units are the worst.

The study shows that in case of tower type building with a central core and housing units around it facing all directions, orientation has no significant effect on its overall energy consumption. However other building types, as a long type or European type, are better to be north-south oriented. These buildings' energy consumption decrease as much as more housing units are south or north oriented. According to the study, the total energy consumption of both, approved and proposed, alternatives is similar. The proposed design option, has slightly higher results because of type 3 building elongated block's east-west orientation.

Electricity generation

A PV system was chosen for electricity on site production. To identify suitable surfaces for PV panels' installation, solar radiation simulations were conducted with DIVA for RHINO. Simulations were applied on both plot design alternatives.

As a result, we detected the total annual solar radiation amount which reaches each building's surface. For calibration purposes, the simulations outcome was compared to the solar radiation data from the Design Guide for PV Systems in Israel`s Cities (Faiman et al, 2000). According to solar simulations results, radiation values on surfaces were similar to data that appears in PV Guide (Table 2). For final calculations, the guide radiation data was used as highest radiation value.

Table 2: Solar radiation on various surfaces in Tel Aviv
(Faiman et al., 2000).

Plane orientation	Plane Tilt	Solar Radiation (kWh/m²/year)	DC Output (kWh/1kWp/year)	Solar Radiation Simulation Result (DIVA) (kWh/m²/year)
	Horizontal	1862	1422	from 1840 to 1873
South	Vertical	1244	828	
South-East	Vertical	1337	889.9	from 1345 to 1289
West	Vertical	1125	778.1	
South-West	Vertical	1244	860.7	from 1205 to 1166
East	Vertical	1036	805.3	

In addition to fully exposed areas, shaded surfaces were checked. If obtained radiation was lower than the basic, fully exposed value, annual electricity production was calculated relatively to the PV Guide data. If annual solar radiation on surface was less than 1000 kWh/m²/year, similar to minimum value presented at table 2, it was not considered as suitable for PV array installation. It was found that about two thirds of roof surfaces of the Approved alternative receive up to 1600 kWh/m² annual radiation and are then suitable for PV array installation. Additionally, upper levels of south oriented facades exceed 1000 kWh/m²/year and can be therefore be considered for energy generation. However, west oriented facades, were not considered due to low radiation results on then resulting from plot's slight rotation to the north.

Typically, tower's roofs are occupied by technical equipment and PV arrays cannot be installed. Therefore, tower type buildings' roofs weren't considered as surfaces for potential energy production. In addition, the three lower floors of each building weren't considered for PV potential. Lower, public floor usually has glazing façade with no opaque surfaces for PV installation, and partial or constant shading can be caused by urban infrastructure as trees, street lights, traffic signs and others.

Results and Conclusions

According to the comparison between the case study plot energy consumption and electricity production within buildings' borders, near zero energy goal can be achieved for certain density and technological conditions (Figure 4).

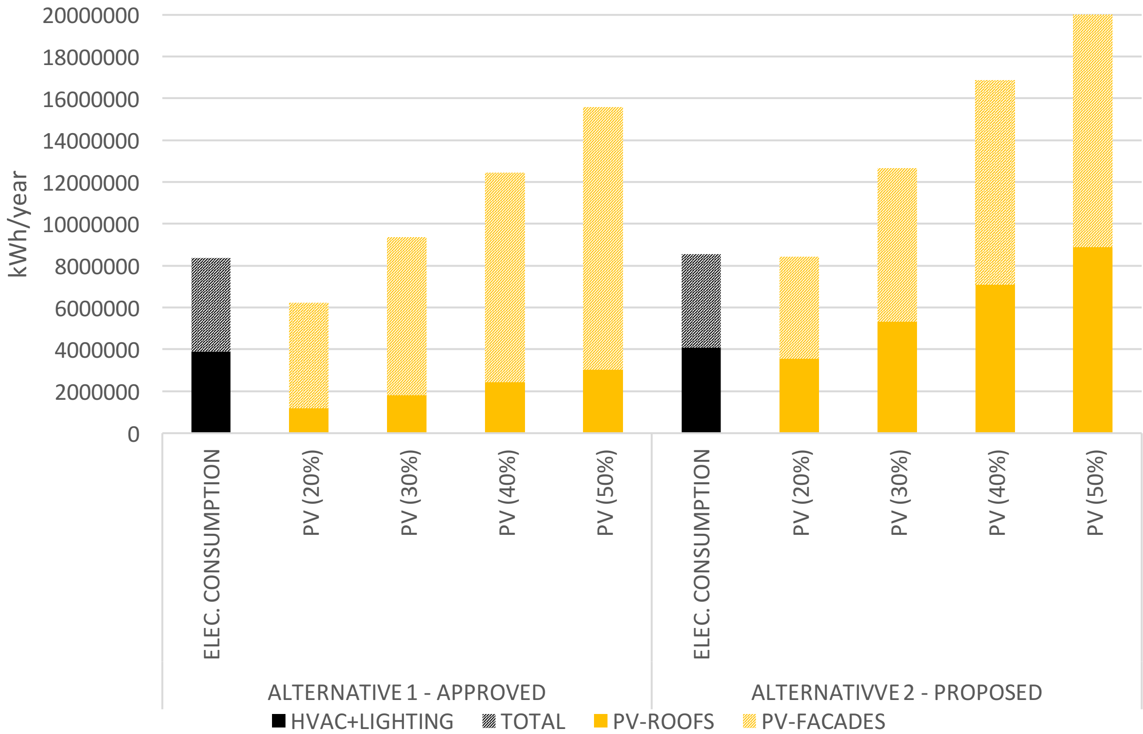

Figure 4. Case study plot various design alternatives' electricity consumption compared to energy production by PV roof and façade installation with various efficiencies.

In case of the approved alternative, big vertical PV array systems can be implemented due to the large façade areas of tower type buildings. However, roof surfaces are small and mostly shaded, therefore PV production potential cannot be maximized. In this alternative roof electricity generation is about 20% of total on plot production.

On the other hand, the proposed alternative offers larger, fully exposed roof areas for maximum electricity production. In this case, PV roof array with 20% efficiency, can provide more than 80% of the total plot energy used for HVAC and lighting, and depends less on facades. Facades surfaces area is slightly smaller than in first alternative so as electricity production from PV array implemented on them. The proposed design enables to produce more energy, although its energy consumption is slightly higher than in case of the approved alternative.

As noted before, horizontal roof PV installations have less impact on building appearance. Roof systems are easier to install and provide future maintenance. If PV array on façades is implemented, further aesthetical design issues should be considered:

- Façade surfaces covered by PV requires flat, fully exposed facades design. Shading elements or balconies will decrease on facade energy production potential.
- PV façade array implementation, limits the cladding material variety. In addition, PV cladding increases expenses of the finishing material and its maintenance. Future developments in PV field may provide more colors, shapes and textures for more various façade designs.

The study shows that zero energy or near zero energy goals is difficult to accomplish if urban and building design relies mainly on façade installation as in the proposed option. It is important to implement solar oriented design on urban level as much as on smaller building scale in order to reduce energy consumption and maximize energy on-site production. In the future, with increased efficiency of photo-voltaic panels and proper design at urban and building scales, zero energy should be reachable goal for presented density developments.

Further studies should examine the limitations of zero energy design for higher urban densities with increased mutual shading, and for lower solar radiation in different countries around the world.

Heated living: Residents' evaluation of heat(ing) in low carbon architecture

Sonja Oliveira[1*], Bill Gething [1], Elena Marco[1], Michelle Agha-Hossein[2] and Tassos Kougionis[2]

[1] Department of Architecture and the Built Environment, University of the West of England, Bristol, UK
[2] BSRIA Sustainable Construction Group, BSRIA Limited, Old Bracknell Lane West, Bracknell, UK

Abstract: Low carbon homes are often designed to accommodate advanced heating control technologies. These technologies are expected to contribute to better performing buildings and a comfortable indoor environment. Recent research focusing on the role of the occupants' interaction with heating controls has identified a number of areas that can influence the in-situ performance of the heating systems installed. Complex interfaces, non user friendly programming instructions, poor functionality as well as badly located controls can all lead to poorly performing homes and reduced indoor comfort. Whilst increasing efforts have been made to better understand residents' engagement with heating control systems in a range of housing types, there is a lack of evidence on the ways residents manage and adapt comfort in a low carbon homes taking into account the wider context of a development. This paper draws on residents' experiences across 40 dwellings in a recently completed innovative low carbon residential development in the UK. The study seeks to extend existing knowledge on ways residents manage comfort in their homes with a specific focus on heating practices in low carbon developments. Implications of the research are twofold. First, the study contributes to a better understanding of the emerging roles of motivations, expectations and mitigation patterns in living in domestic low carbon environments. Second, there are implications for design professions to take account of the potential implications specific physical 'prompts' such as windows, balconies and wallspace can have on the ways comfort is 'controlled' within a home. There are also implications for national and international energy policies on low carbon developments specifically in relation to heating.

Keywords: controls, energy, heating practices, housing, low carbon architecture

Introduction

Almost half of the energy consumed in the UK is generated by space heating, most of which is from the domestic sector (Chaudry et al 2015). A series of policy initiatives aimed at decarbonising heat highlight either the need for new low carbon homes (HM Government 2011), new heating systems (CCC 2016) as well as better management and control of existing systems and technologies (DBEIS 2016a). Moreover, a diverse range of energy systems' scenario modelling have also been undertaken analysing pathways towards 80% reduction of emissions by 2050 (Chaudry et al 2015). UK policy largely focuses on technical solutions via energy efficiency measures and renewable energy. For example, the energy white paper (DTI 2007) includes an analysis of all UK sectors and the likely carbon emission reduction to be achieved in each sector by 2020. The list of measures mentioned is largely based on energy efficiency improvements, more efficient generation and generation from renewable and nuclear sources. Often the context of the technology is viewed in isolation of type of home, location and climatic conditions within which a home is situated as well as age, condition and occupancy patterns within a home. Also, the potential contribution from behavioural changes is not mentioned in the document, neither are policies that encourage such behavioural shifts.

Adding to a growing number of policy initiatives, industry reports and academic discussions have been examining the underlying implications of residents' approaches to new low carbon homes, technologies and systems. Several scholars focus on explaining why and how above average consumption of energy and heat specifically can occur. In most cases this is found to be down to residents' 'lack of control capability' and poor understanding of manuals and handover packs (Gill et al 2010) as well as badly located controls with complex interfaces, often inaccessible with non user friendly programing (Stevenson et al 2013). Devine-Wright et al (2014) analyse how older adults engage with new heating technologies post installation finding how their practices become influenced by pre-existing meanings associated with the 'making of a home'. Whilst some scholars have focused on interaction with particular technologies such as controls; others emphasise the need to study heating as constituted within 'meanings of culture, spatialities, technologies and bodies' (Fennel 2011).

Despite the growing diversity and growing quantity of academic discussion dedicated to analysing heating in traditional and low carbon homes, few studies examine how residents perceive heat in their indoor environments beyond 'interacting with technologies'; and the ways they manage and adapt to new ways of heating within the spatial, cultural and technological contexts of their home, street and wider community. The present paper builds on research that views heating as intertwined with cultural, sensory and spatial factors by examining residents approaches to 'heat' in a recently built low carbon development in South West England. In particular, the paper is interested in what and how residents manage their 'heated' environment and respond to both delight and difficulties they may encounter when moving into a low carbon home both within the confines of their home but also at the scale of the development.

Heating controls, manuals, systems and residents

How well a home performs has been suggested by a growing body of research to be dependant amongst many issues, on how users approach their indoor domestic environment particularly in relation to controls. Controls and their usability have been a topic of an increasing number of discussions particularly in low energy homes where there may be a number of advanced control technologies installed.

Problems with controls have been described in terms of mainly technical issues including the growing complexity of confusing interfaces, inconvenient location in homes (Stevenson et al 2013), increasing number and range related to different aspects of comfort, poor functionality (DECC 2014, DBEIS 2016b) and issues with slow or no feedback (Peffer et al 2011). In addition, studies have begun to highlight some of the social and cultural difficulties in communication between users and designers, poor handover practices, lack of knowledge amongst both users, site managers, contractors and designers (Andersen et al 2016; Bell et al 2016) and at times lack of interest to improve current practice across the built environment (Leaman 2012). Also, a number of studies have suggested particular research methods used such as questionnaires tend to overestimate users' understanding of controls thereby at times ensuring socially acceptable responses (Monahan and Gemmell 2011; Shipworth 2000)

In low carbon developments in particular users tend not to make adjustments to controls due to complex technology or unfamiliarity leading to uncomfortable conditions in indoor environment (Bell et al 2010). In addition, often low carbon developments include separate controls for different services complicating management of homes further (Monahan and Gemell 2010). For some scholars key difficulties lie in poor handover practices and often very complex manuals that are difficult to understand (Pett and Guertle 2004). Stevenson and Rial (2008) suggest difficulties lie in poor knowledge and understanding can be found across the design team. Discussing the post occupancy survey carried out for the Sigma house, Stevenson and Rial (2008) observe how Housing developer's representatives were not always familiar with the more complex controls, referring the user to the induction guide book.

Heating as constituted through culture, specialities, technologies and bodies

Whilst an established area of research focuses on improving usability of controls, recent work by Hellwig (2015) suggests greater attention needs to be placed on exploring perceptions of the environment 'being controlled'. The environment can include broader social and cultural issues as argued by Fennell (2011) whose study of heating enables a greater understanding of the relation between heating and culture, spatialities, technologies, and bodies. In her ethnographic study conducted in Chicago public housing, she finds that heating is intertwined with class and race dynamics, politics and the bureaucratic regulation of a common sensory regime. Using a similar approach, Cupples et al (2007) discuss heating as constituted within national identities and notions of masculinities. Embedded widespread and common practices of using log burners and open fires to heat homes, despite leading to significant air pollution in Christchurch, were found to be deeply tied to notions of 'bearing the cold' and cultural identities linked to the colonial past.

Hards (2013) discusses ways that domestic energy practices reflect status and stigma, noting how the adoption of wood-burning stoves – defined as 'positional goods' – in the United States in the early 19th century was a form of conspicuous consumption. The argument presented by Hards suggests that energy consumption is both a way of conferring status, through conspicuous consumption, or stigma through a person's inability to conform to societal norms with regard to energy consumption. The mobilisation of different forms of capital, including social, economic, cultural and symbolic is important here in both establishing one's status position, but also in avoiding stigma (Hards 2013). Devine-Wright et al (2010) suggest that perceptions of cosiness in a home occupied by older adults led to installation of wood burning stoves and fake fireplaces despite the installation of highly efficient low carbon thermal technologies.

A deeper understanding of how cultural factors mediate sensory experiences and practices is believed by some to be crucial for the development of sustainability-driven policies, especially in light of common discourses on climate change and energy security (Harrison and Popke, 2011; Hitchings and Day, 2011). However, the scarcity of approaches on the experience and attitude towards heat within and outside a 'low carbon home' as well as beyond the systems and technologies that enable it is striking. Whilst the studies discussed in this section of the paper discuss housing and heating broadly, they enable an important understanding of how heating and comfort are positioned within a wider set of relations between status, stigma (Hards 2013), national identity and notions of masculinities (Cupples et al 2007) as well as concepts of cosiness and glow (Devine-Wright et al 2010).

Research setting and methods

The research setting is based on a recently built low carbon development in South West England consisting of over 185 homes ranging from one-bed flats to five-bed houses. The homes were originally designed to be zero carbon in accordance with Level 6 of the Code for Sustainable Homes (CSH).

Research methods- data collection and analysis

Data collection commenced in June 2016 and was completed in Jan 2017 with analysis and literature reviews overlapping. Interview and focus groups sessions involved a total of 48 participants. Initially 5 focus group sessions were held with groups ranging from 6-12 participants. During the focus group sessions, questions probed issues surrounding residents' expectations of the development when moving in, reasons for choosing to live in the development as well as circumstances that led to the decision to purchase a home in the development. In addition, questions were concerned with approaches to controlling heat in their indoor environment, daily routines, meanings, as well as changes to expectations and experiences in their home and wider development. Following the focus group sessions, in-depth semi-structured interviews in 10 homes with 12 participants of diverse ages and backgrounds were held to explore particular aspects that emerged in the focus group discussions. Houses varied from flats, coach houses, 2 bed, 3bed and 5 bed houses located throughout the development. In addition, two homes were shared ownership with the housing association, whereas others were fully privately owned. These were complemented by interviews with housing association managers, site managers and designers where relevant. The research was mindful of ethical issues and was conducted on an entirely confidential, anonymous and consensual basis.

Analysis of the focus group and interview data was informed by thematic analysis (Braun & Clarke, 2006). Data were initially coded into 3 main categories (Background and reasons for moving to development; Experience of living in the development; Views on the indoor thermal environment and how it is adjusted) with more than 30 subcategories; and the main themes presented here stem from a subsequent round of analysis probing issues of heat, control and mitigation strategies as they emerged across the dataset, from which the findings laid out below were drawn. Emergent thematic categories included: ***Justifying investment in home***, ***Managing discomfort*** and ***Learning what a home needs***. Care is taken in the following discussion to bring out differences between the home contexts (where these are significant), alongside identifying areas of commonality. As reiterated above, the authors are not seeking to generalize from this limited set of cases. Rather the thematic analysis is used to identify some of the key considerations relevant to thermal experience in diverse home settings in a low carbon development, whilst recognizing that these will be manifest differently in other settings.

Findings

The findings are discussed across three key 'Activity' themes: ***Justifying investment in home***; ***Managing discomfort*** and ***Learning what the home needs*** (see Figure 1). In all themes discussions centre around physical and social 'prompts' (within the home as well as outside in the wider development) as well as symbolic notions centering around types of control engagement.

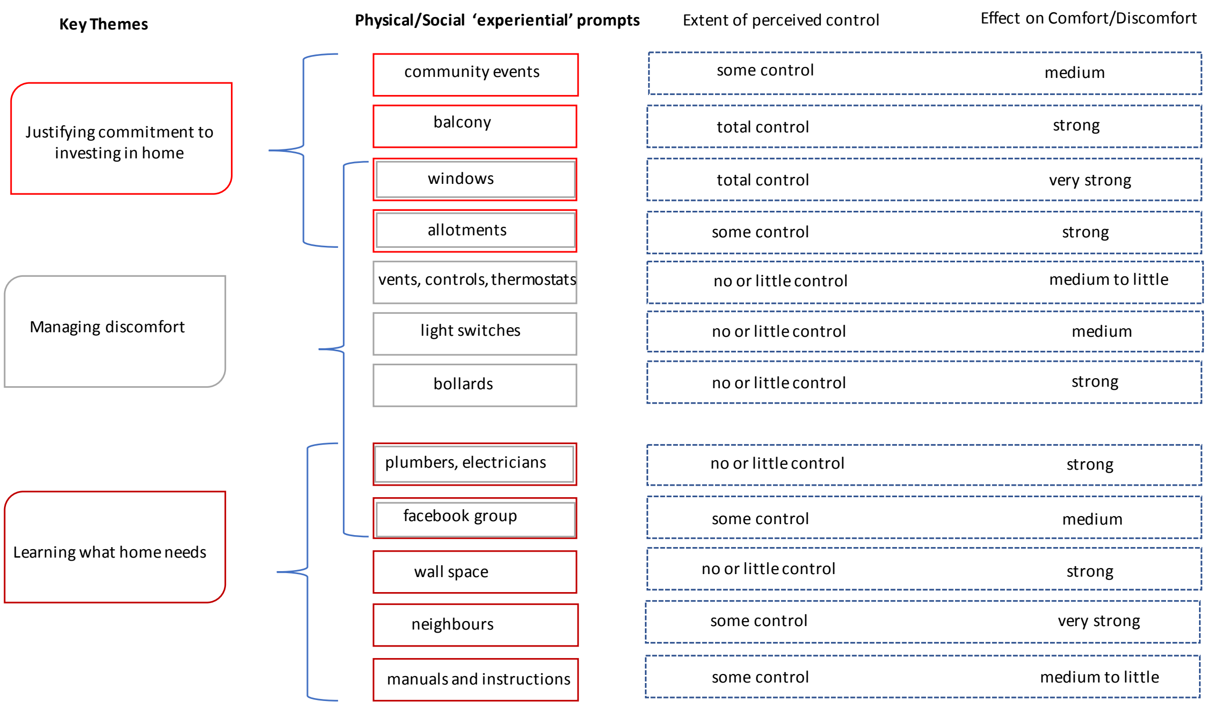

Figure 1 Overview of key themes

Justifying investment in home

In most cases residents interviewed found the development by chance; in magazines, portals or local adverts whether moving from elsewhere in the country or elsewhere within the city. In many cases residents chose to live in the development in order to be save money; seeing the key attraction of the homes in promoted low running costs. In some cases, residents were drawn to the advertised 'sense of community' and in some cases the eco features promoted in the sales leaflets such as 'rainwater harvesting', 'solar panels' or 'recycling'. In most cases residents were moving from conventional homes located within a street and had never lived in an estate type development or a new build home. In very few cases did the sustainable ethos of the development play a major part in residents deciding to purchase a home on the site.

> "We moved to the development because we needed to downsize and needed to be frugal with money…obviously its reduced bills here…"(Linda and Richard)

For most of the residents, the move was about a transition to a new stage of life such as retirement, being divorced, 'children moving out' and left on own or 'children staying at home' and needing more space. Whilst most residents did not choose to live in the development because of its low carbon credentials, many were drawn to the idea of a 'created community'. Residents, having described how they moved to the development would often begin to discuss features of their home or development that were unexpected or disappointing. 'Buying into' a community and finding that most residents were not 'eco' or did not share the promoted ethos of the development was often reflected upon.

Dalia moved into the development having lived in the city most of her life and being familiar with the area. Though she wasn't planning to buy she did note how she 'stumbled across' the show home and was offered to buy on the condition 'she sold hers by 5pm that night'. She chose her particular home because it had a kitchen window on the corner, allotments nearby and a balcony 'so the dog could watch people come and go'. However, she was to find a type of community (her home was close to what she described as the social housing bit) she did not expect and a home which she felt she 'did not have what it needed' in terms of 'knowing what to do and how to use it'.

> "I hadn't quite realised the impact of living here as there is quite a lot of drama; sometimes its like living in the middle of Eastenders with the bailiffs, police, paramedics, fire engines. You can get them all in one night, all outside my own house…" (Dalia)

Despite being disappointed Dalia goes on to justify the fact the home is invested in already (emotionally as well as financially) by reflecting upon the 'community as being lovely and a 'microcosm of the country' as well as observing how 'a home is somewhere you have to love' reminding us of the fact her house has 'lots of light and that extra kitchen window; a corner window'.

Managing discomfort

When discussing how they found their indoor environment in terms of comfort, most residents noted long periods of adjustment, 'not having what the home needed' and not knowing were things were or how they worked. The home was described by one resident as needing a particular set of skills and knowledge (that she perceived was lacking).

> "Initially they (the developers) just wanted your deposit down…bear in mind I'm blonde and I'm artistic…and to live here you need to have mathematical brain…and preferably a partner"…(Jasmine)

In most instances residents describe their home as too hot, reflecting upon the vents 'as being everywhere', the balcony 'as a social corner and chance to breathe'. When prompted to describe how they 'cool their home' in most instances 'windows are left wide open' and 'vents are not touched'. One resident noted how 'heating controls had a life of their own' and controlling them meant "tak(ing) a glass of sherry, cross(ing) my fingers and press(ing) the buttons". For some, the sense of helplessness in managing the indoor home environment was conflated with a sense of social isolation and being 'on your own'.

In some instances residents (particularly those seeking an eco community) viewed themselves 'knowing something others don't'. Yvonne and her husband live in a 2 bed house, having already lived in a similar 'eco development up north'. The described their knowledge and interest in eco living as being familiar and long established. They also describe how they learn of 'others who don't seem to realise the MVHR needs maintaining' or the solar panels need cleaning'. They also discuss how a lot of time was spent 're-specifying the house' so light switches were zoned as built.

Discomfort of the indoor environment was often reflected upon through other disappointing features within the home such as a 'lack of wall space being occupied by doors and technology', or 'light switches in strange places such as behind the door' as well as outside the home such as bollards 'that no one warned us about'. Bollards were viewed as being installed without resident consultation (post completion) and were viewed as obstructing the ways residents could use the 'front of the house' such as opening of front doors for 'cross ventilation' as they might 'encourage cars to get closer to the front door'.

Learning what the home needs

Whilst discussing adjusting to their new home environment, residents often described a long process of learning over periods of 2-4 years as an unexpected issue. In many instances, welcome packs and instructions were described as 'being wrong', 'referring to a different type of control' and not giving enough of an insight into the 'type of lifestyle this needed'

> "I was a little bit of a guinea pig….so they showed me a building and asked me what questions I had, but they didn't handover much, apart from a generalistic pack, so I had to find out myself. They also said some things that were utter rubbish; they said don't ever touch the ventilation system which is utter rubbish as you obviously have to change it to summer mode…"(Dalia)

For most residents learning involved reliance on others whether a next-door neighbour, an electrician *'who visited and fixed the controls'* or wider community social media such as a Facebook page or manual. In many discussions, a manual produced by one of the residents on use of controls and maintenance of systems would be brought up or the Facebook page where residents could post their issues with the development or their home. Most residents, however, did not seek to question difficulties encountered or complain to the developer or housing association in the first instance. Instead residents noted how they had used controls before and 'it should not be that difficult'. In some instances, residents did not alter the programming since moving in finding themselves often opening widows throughout the day and night as their home was too hot.

Active learning meant seeking advice from plumbers and electrician, who often 'simply could not help'; 'or did not know'. In two instances, residents bought an alternative thermostat 'because another resident has done it'.

Discussion and conclusion

Extending Shove's argument (Shove et al 2009), findings in this paper similarly suggest a need to analyse the dynamics of domestic energy use as intertwined with and through different aspects of everyday life. The study reported in this paper, however, highlights the possibility of understanding how adaptation, use of physical and social prompts lead to particular outcomes. How can placement, use and spatial relations of physical/social prompts such as community events, windows and light switches motivate behavioural learning or adaptation? It has been established for some time in anthropology that the built environment can hold repositories for social meaning, physical bodily orientations and identities (Fennell 2011). In addition, research in the built environment has observed detailed relationships between comfort and clothing (Cupples et a 2007), furnishings and openings (Raja et al 2001; Nicol 2001). This study extends this work by highlighting how the use of prompts (both physical and social) within and outside the home obstruct or enable particular approaches to heat and heating in low carbon homes.

Within UK policy, the concept of a zero or low carbon house has been (re)defined several times. Currently, three elements are required for a house to be classified as low carbon: 1) the energy demand must be reduced to comply with the Fabric Energy Efficiency Standard (FEES); 2) any remaining carbon emissions must be below the Carbon Compliance Level; and 3) any remaining carbon emissions must be offset through investment in Allowable Solutions projects such as offsite renewable energy sources (ZCH, 2014). Missing are broader implications of physical placements of home components- vents, switches, windows, balconies as well as positioning of outdoor elements such as bollards and allotments. Instead too often the focus is on the technological components of heating systems such as valves, controls, thermostats or boiler inaccessible technology and users lack of preparedness or understanding. Further research is need to better understand the ways physical and social components of a home environment (both inside and outside) help shape how heat is approached, controlled or ignored. There are implications in his paper on designers of both homes as well as the environment that surrounds them (the gardens, landscaping and parking) and the potential importance they play in the way decisions on comfort and heating in particular are made by residents.

New insight on passive ice making and seasonal storage of the Iranian Yakhchal and their potential for contemporary applications

Hareth Pochee[1], John Gunstone[1], Oliver Wilton[2]

[1] Max Fordham LLP, London, UK, h.pochee@maxfordham.com
[2] The Bartlett School of Architecture, UCL, London, UK, o.wilton@ucl.ac.uk

Abstract: The Yakhchals of Iran are a type of ancient structure and system used to produce, harvest and store ice for cooling uses later in the year. In this paper, the authors present an explanation of how Yakhchals are understood to have operated and then go on to present analyses of aspects of the ice making and storage processes. A transient 1D heat transfer model is used to predict of how much ice could be made over the course of a year. A second transient heat transfer simulation is used to predict the amount of ice that could be retained (not melt) over the storage season. Finally, the potential for a modern day application of passive ice making and storage for space cooling in an ultra-low energy office is explored.

Keywords: Yakhchal, ice, passive, cooling, simulation

Introduction

The Yakhchals of Iran are relatively well-known (Hosseini & Namazian, 2012) and their method of making and storing 'ice in the desert' via passive means has influenced the current generation of passive and low energy designers. The use of ice from Yakhchals for cooling drinks and food was reported to be common in Iran by John Fryer in the late seventeenth century (Beazley, 1977) and some Yakhchals were reportedly still in active use as recently as the 1960s (Jorgensen, 2010). Yakhchals are found across Iran in areas where the climate enables the freezing of ice on site in winter, or where ice and snow could be brought from nearby mountainous areas (Hosseini & Namazian, 2012).

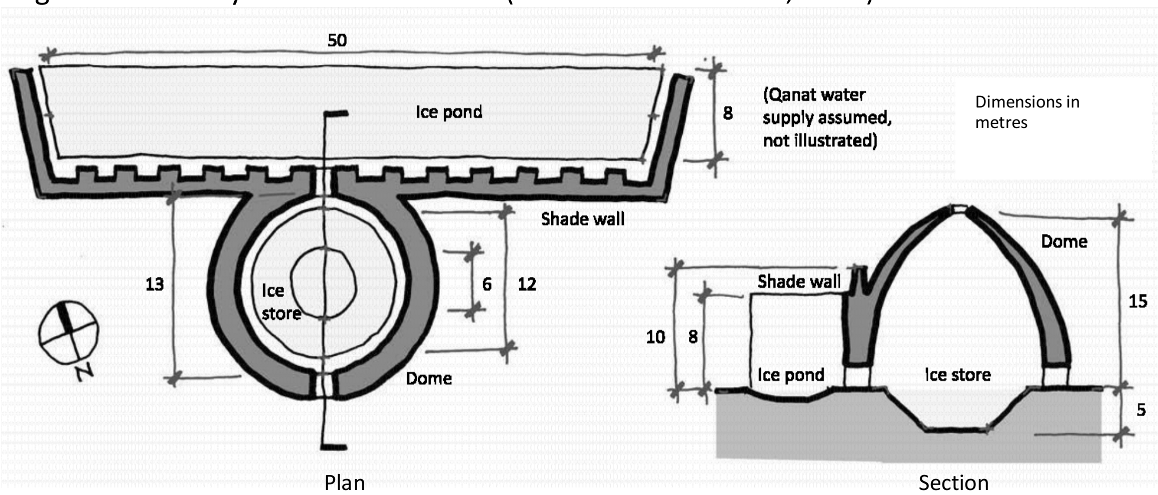

Figure 1. Meybod Yakhchal. (Adapted from Ghobadian, 2001 as referenced in Hossieni and Namazian, 2012)

Figure 1 illustrates a particular large, dome type Yakhchal in Meybod, in the province of Yazd on the Iranian plateau, which is reported to be around 400 years old and has recently been partially restored. The complex includes an ice production pond, which is protected from the low winter sun by a shade wall, and a store where ice is kept for use in the warmer months. The shade wall and dome structures are typically made of mud bricks or adobe, sometimes made using soil extracted from the local ice pond and store excavations (Jorgensen, 2010).

In this paper we present the results of analyses of several building physics aspects of the large dome type Yakhchal and ice pond structures within Yazd climatic conditions. There are several aims; to understand and simulate the heat transfers used to form ice; to make predictions of the amount of ice that could be produced; to understand and simulate the physics of the ice storage process; to make predictions of the amount of ice that could be retained (not melt) from winter to summer; to understand how the architectural designs of the structures contributed to these effects; and to investigate if passive ice making and storage could be made use of in a modern architectural context.

Anecdotal evidence from historical accounts regarding quantities of ice production vary, CJ Wills describes the ice production process in Shriaz in 1891; "A few inches of still clear water is collected in the pond, by morning it is frozen; at night the water is again admitted, and another inch or two of ice made. When three to six inches thick, the ice is broken and collected for storage in a deep well on the spot : and so day by day the process goes on during the short winter until the storehouses are full" (Wills, 1891).

Other physics based analyses have been carried out; Jorgensen presents an ice yield estimate from the Abarqu ice pond in Yazd district of 100cm/yr. However, having reviewed this work we feel that the work over estimates both the ice formation rate at a given temperature and the extent that Yazd's climate resides at sub-zero temperatures leading to a gross over prediction of ice yield. Zare et al derived an expression for the thickness of pond ice produced based on climatic conditions (Zare & Davoodmoosavian, 2015). The same paper presents an analysis of dome shaped stores concluding that dome shaped stores absorb less solar radiation than flat roofed equivalents.

Climate Data

The climate of Yazd is very dry, with hot summers and cool winters. The average annual precipitation is less than 100mm/yr. A TMY hourly climate data set (IRN_Yazd.408210_ITMY) is available for Yazd (Energy_Plus_Weather_Data, 2005). Figure 2 illustrates the hourly dry bulb temperature for this set showing that summer temperatures occasionally exceed 40°C and winter temperatures occasionally drop below -5°C. TMY data sets use a cut and paste approach from many years of data to synthesize a "typical" year's climate data. The Yazd TMY year uses data from 1961 to 2004.

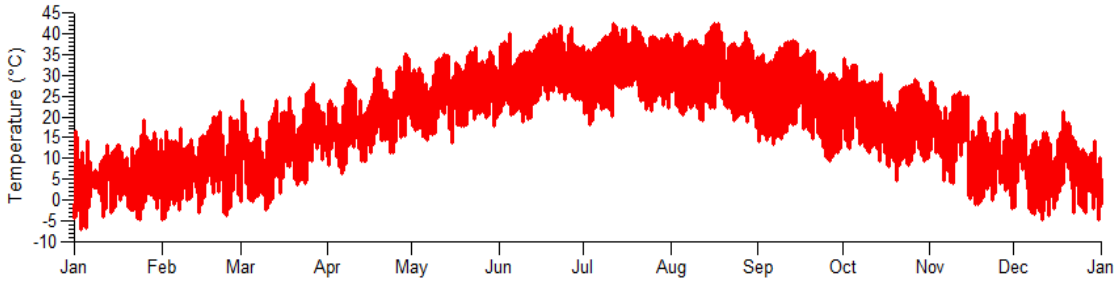

Figure 2. hourly dry bulb temperature from the Yazd TMY (Typical Meteorological Year).

Ice Production Modelling

A 1D numerical model (the "MF Pond Ice Model") was created to simulate the heat transfer processes in the Meybod ice pond.

Figure 3 illustrates the pertinent model parameters. The model uses the Yazd TMY hourly climate data set for the external variables. The convection, sky radiation, and evaporation models implement the methods proposed by Tang and Etzion (Tang & Etzion, 2005) and Hamza (Hamza, 2007).

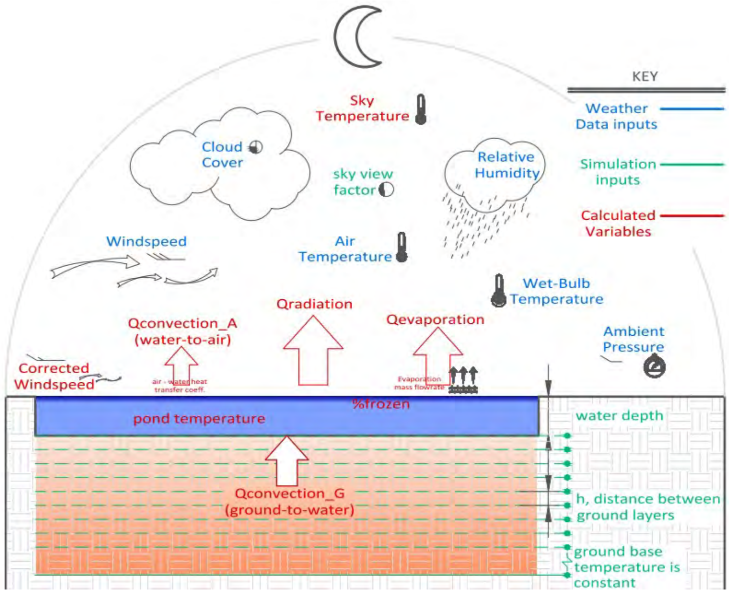

Figure 3. Ice making model features and parameters. "Q" is used to represent heat transfer

The ground below was modelled as 5m thick layer with a base temperature fixed at 19°C (the annual average air temperature). The ground thermal conductivity used was $0.3Wm^{-1}K^{-1}$, a value for dry clay soil 5% m.c. proposed for Yazd by (Dehghani-sanij & Sayigh, 2016). The ground initial temperature was modelled with a spatial distribution defined by the method provided by Kasuda (Kusuda & Achenbach, 1965) which results in a temperature of about 4°C at the pond base and 19°C at 5m depth.

The pond itself was modelled as a homogeneous medium 100mm thick with the thermal properties of either liquid water, or ice depending on its temperature. The freezing (or melting) phase change was modelled by keeping track of the amount of energy in a theoretical "latent store" Using this procedure, when the pond reaches 0°C and receives further cooling the temperature of the water is fixed to remain at 0°C and energy is subtracted from the latent energy store, which when fully depleted signifies a complete phase transition from water to ice for the whole pond. For intermediate states, the thickness of ice layer is assumed to be equal to the total pond depth multiplied by the % that the latent store is empty.

The pond area was assumed to be $416m^2$, estimated from drawings of Meybod (Figure 1). It was assumed that each evening in winter, at 9pm the pond is filled with 100mm of water with temperature equal to the external air temperature at that time. The ground temperatures below the surface are calculated from the results of the previous day. After 11 hours of simulation any ice >3mm thickness predicted to have formed is "harvested" and the process repeats again for the next day. The assumed view factor from the pond to the sky was 0.7. The simulation was run for 3 years using a 5 minute time step. The results presented are for the final year of the run.

MF Pond Ice Model Results

Figure 4 illustrates the predicted daily ice yield. The maximum predicted ice yield is 12mm/day. The total predicted yield is $49m^3$/yr, equivalent to a total thickness of 120mm and a latent coolth store of 4.3MWh. Figure 5 shows the predicted average hourly heat transfers for the coldest week of the winter (in January). Radiation heat loss to the sky is found to be the dominant cooling mechanism, but the modelling shows that evaporation is also significant, much more so that convection to the external air. Convection heat gains from the relatively warm ground are also small in comparison to the losses from radiation and evaporation.

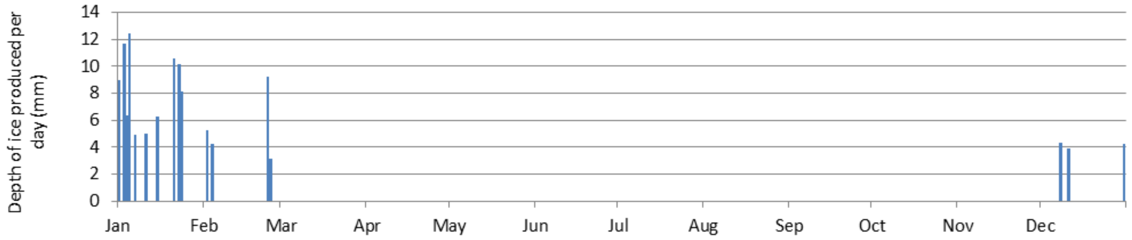

Figure 4. MF Pond Ice Model results of daily ice production in the Meybod ice pond.

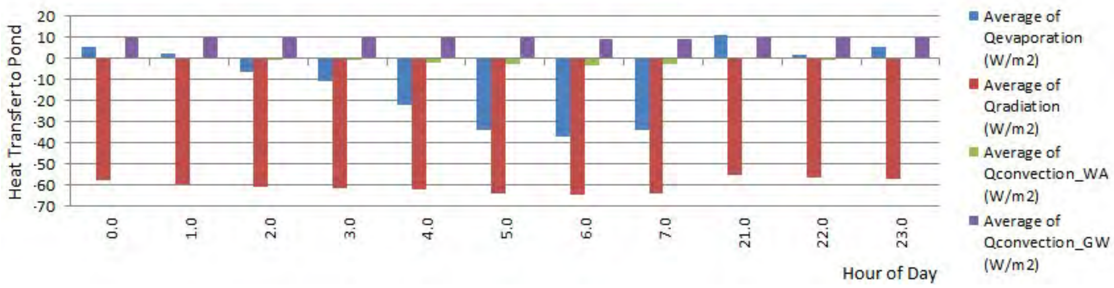

Figure 5. Model results of heat transfers in the Meybod ice pond. The values are the average value at the stated time for all the days of the coldest week.

Ashton Ice Formation Model

The Ashton Ice Model is an empirical model proposed for thin layers of ice on open fresh water bodies (Ashton, 1989). It depends only on the duration of cold air temperatures, expressed as freezing degree days (FDD) and empirical constants. The Yazd TMY data set has 20 FDD, for which the Ashton Ice Model predicts 70mm of ice.

Ice Storage Modelling

Heat transfers within a typical dome Yakhchal have been modelled using a 3D dynamic thermal simulation with the Virtual Environment software by IES (IES VE, 2015) using the hourly Yazd TMY climate data. The model geometry and pertinent model parameters are illustrated in Figure 6. For the walls and the ground the model implements a layered 1D transient conduction model, allowing temperature penetration depth and time lag effects to be represented.

(Hosseini & Namazian, 2012) report that straw, or thatch insulation was placed around and within the ice packs and also on the outside of the dome. They also state that the layer of straw insulation over the icepack top surface could have been 1 to 2m thick. The model material properties are given in Table 1. The initial run used 0.5m of thatch insulation in all locations.

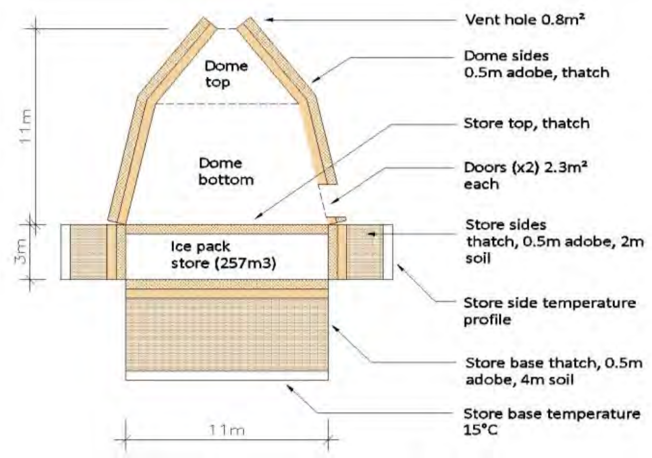

Figure 6. Ice storage model parameters

Table 1: Ice storage model material properties

Material	Thermal Conductivity (W/mK)	Density (kg/m^3)	Specific Heat Capacity (J/kgK)
Adobe	0.6	1700	900
Thatch	0.1	250	1800
Soil	0.3	1000	1900

The store side and base temperatures were estimated using the Kasuda equation for ground temperature with an estimated correction for the long term cooling effect of the presence of the ice store. The base temperature was kept fixed at 15°C. The store side temperature profile was set to vary according to the season in the following way J,F,M: 8°C; A,M,J: 16°C; J,A,S: 30°C; O,N,D: 16°C. The model was started with an initial temperature of 10°C. The IES model uses the climate data to simulate the effects of solar radiation, longwave sky radiation and convection to the dome external surfaces.

The ice pack was modelled as a zone with a (variable as needed) cooling load applied to keep the temperature at 0°C. The store volume was assumed to be full of ice. The model calculates the conduction heat gains into the store from the dome and surrounding ground. The amount of ice melted is calculated from the total seasonal heat gains (cooling load) into the ice pack store.

Ice Storage Modelling Results

Figure 7 shows the predicted internal dome (bottom) temperature for a scenario called Store_10 which has the doors closed, the top vent unshaded and open for ventilation and the thatch 0.5m thick. The annual total heat gain (cooling load) of the ice store is predicted to be 4.6MWhrs which equates to 52m^3 of ice melt or 20% of the total store volume.

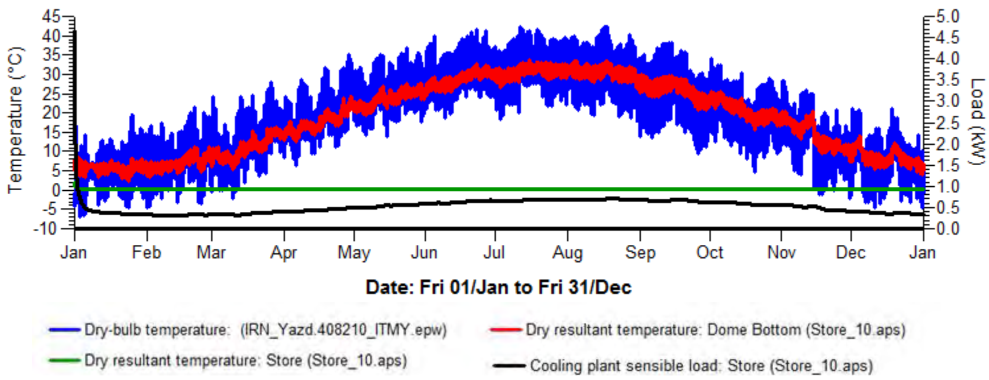

Figure 7: Store_10 scenario ice storage modelling results.

The distribution of annual heat gains into the store for Store_10 is found to be 15% through the floor, 15% through the sides and 60% through the top surface to the dome; which shows that the dome's ability to keep cool could significantly affect how much ice melts. However, it should be noted that this work assumes soil with a very low thermal conductivity, which keeps the heat gains from the ground to a low fraction of the total.

Several other scenarios have been simulated to investigate how the system could perform in both the past and the present. It was found that adding shading to the top vent so that the dome solar gain is zero has negligible effect on the store heat gains. However, employing a ventilation manager (in either human or machine form) to open the doors whenever the external temperature is lower than the internal dome temperature reduces the melt losses by 1%. Removing the thatch on the dome exterior causes melt losses to increase by 1%. Most benefit can be gained by investing in store insulation; if 1m of thatch is used at the base, sides and top of the store the melt losses are reduced to 13%. If 0.5m thick of polyurethane foam (with k=0.02W/mK) is used the melt losses are predicted to be 6%.

Contemporary Application: An Ultra-Low Energy Office

A concept ultra-low energy office has been modelled using IES VE with the Yazd TMY climate data. The concept design is one that minimises the cooling load. The model geometry is illustrated in Figure 8. Other key features of the model were: 10m^2/person occupancy from 8am to 6pm. High thermal mass floor, walls and ceiling. Windows sized to provide 2% daylight factor with solar control glazing and external shading that automatically deploys to block 80% of direct sun. Lighting and computer heat gains of 4W/m^2 and 5W/m^2 during occupied hours; an additional heat gain of 2W/m2 all the time and ventilation at 8l/s/p of fresh air when occupied. The design and model also included additional free cooling ventilation providing 20ac/h of external air whenever beneficial. A cooling system is included that attempts to cool to 26deg C but is limited to 8W/m^2 (1kW) peak output.

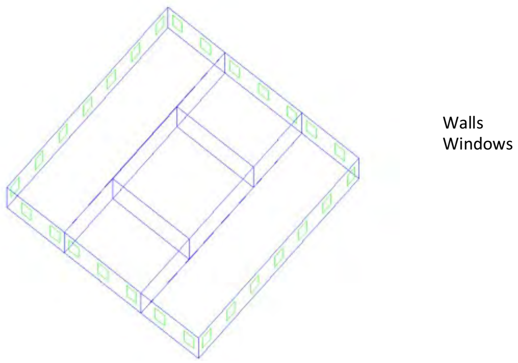

Figure 8: Ultra low energy office model. Single storey with 400m^2 floor and roof areas.

Ultra-Low Energy Office Model Results

The results of the modelling for the west facing side of the building are illustrated in Figure 9. The peak cooling output is limited and results the internal temperatures shown. The model predicts that a typical hot day has an internal temperature of about 33°C when the external temperature is 40°C. The total annual cooling demand is 3.5MWhrs.

An assesement of thermal comfort was made using the adaptive thermal comfort method descibed by (Mohammad & Shea, 2013) which, for the Yazd climate data defines the following monthly comfort temperatures; May 28°C, Jun 30°C, Jul 31°C, Aug 30°C, Sep 29°C. The results showed that comfort temperarures were exceeded in 20% of occupied hours.

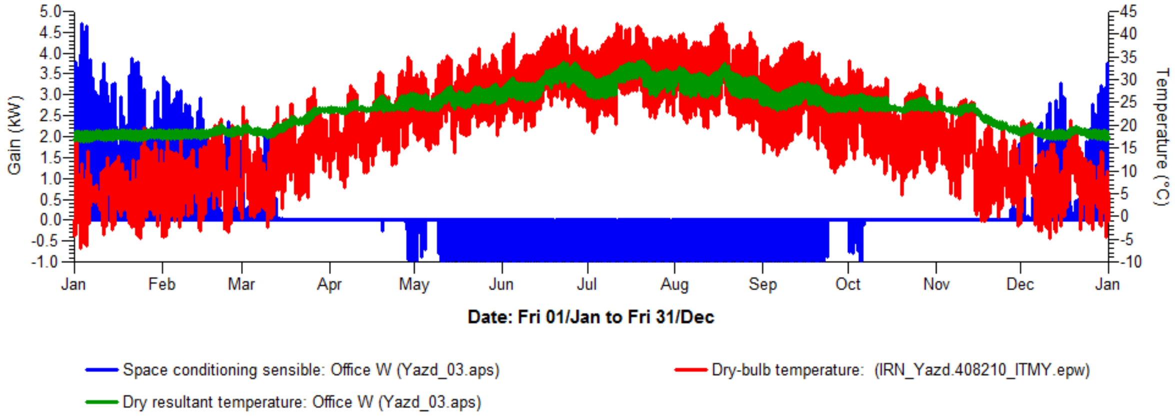

Figure 9: Ultra low energy office model results

Discussion, Insights and Conclusions

Ice Production

A 1D transient heat transfer MF Pond Ice Model was developed. When used with Yazd TMY climate data the model predicts the amount of ice that could be made in a sun shaded pond over one winter to be 120mm total thickness. This was in general agreement with the Ashton Thin Ice Model which predicts 70mm for the same climate data. A lower yield from the Ashton method is expected since the Ashton empirical constants were measured for lakes subjected to solar radiation. Whereas, due to their operation at night and shading structures, the Yahkchal ice ponds receive little or no solar radiation.

As expected, sky radiation was found to the dominant cooling mechanism but evaporation was also found to be significant. For the coldest week in the data set The MF Model predicts typical night time average pond heat losses of 60W/m^2 for sky radiation, 20W/m^2 for evaporation, 1W/m^2 for convection to air and 8W/m^2 heat gain from the ground. The MF Model assumes that evaporation effects are always active (even when ice has formed), in this respect it probably over predicts the ice formation rate. However, including evaporation always is a reasonable approximation if the water is gradually applied in layers on top of an existing ice sheet. This is mode of operation is therefore recommended to maximise yield and there are historical reports in the literature that suggest this was indeed done.

The simulation work also showed that harvesting ice each morning was more beneficial that leaving it out. This was because, even with the shading wall in place the amount of diffuse solar radiation heat received was greater than additional available daytime cooling.

The estimated size of the Meybod ice store is 200m^3. The predicted winter ice yield from the 416m^2 production pond was 49m^3, 25% of the size of the store. There are several possible explanations for the predicted low fill fraction including one or more of the following; the pond may be genuinely undersized compared to the store; the physics model may be deficient; the assumptions for model inputs may have been flawed; the TMY climate data may not provide a good representation of ice making conditions compared to reality (either now or in the past).

Ice Storage

A numerical model was used with the Yazd TMY climate data to simulate the heat transfers within a large dome type Yakhchal similar to the one at Meybod. The model used a 1D approximation of heat transfers from the below ground store into the surrounding soil. The model assumed a 257m^3 underground store packed full of ice surrounded by a layer of insulation. The modelling results predicted annual melt losses of 20% for 0.5m thatch insulation, 13% for 1m thatch and 6% for 0.5m of modern polyurethane foam insulation.

Potential Contemporary Application

A concept single storey 400m^2 ultra-low energy office in Yazd was modelled using a dynamic thermal simulation. The model included very high standards of passive design along with a maximum active cooling output of 8W/m^2 resulting in an annual cooling load of 3.5MWh (9kWhr/m^2/yr). The Ice Production analysis predicted an annual ice yield of 120mm/yr. Therefore, siting a pond over the whole 400m^2 office roof could produce 48m^3 of ice per year which could be stored in an insulated pit under the building. Allowing for 10% melt losses, the avaialble latent coolth from the ice store would be 3.7MWh, i.e. slighly more than the annual space cooling demand. However, it was found that internal condictions within the office were not always comfortable; comfort temperatures were exceeded in 20% of occupied hours. Convieniently ignoring cost or any other feasibility issues, the work has shown that using passive ice making and seasonal storage alone can, in principal meet a significnt fraction, but not all of the space cooling demand in a contemporary single storey ultra-low energy office. The cooling capacity of the system could be enhanced by also making use of summer roof pond cooling such as the type descibed in (Tang & Etzion, 2005) which, when combined with the seasonal ice harvesting might be possible to meet 100% of the building cooling load.

Abstract: Colegio Rochester is school in Colombia with a strong vision for sustainability. This vision permeates the new school building which was the first school in Latin America to be awarded a LEED Gold certification. This article uses Colegio Rochester as a case study to understand how the individual roles and interactions between stakeholders, including pupils, shaped (and still shape) the energy performance of the building. Primary qualitative and quantitative data have been collected including interviews with the LEED consultants and multiple users, and a detailed analysis of the energy performance figures. The data was used to map users and the key connections between them, developing an understanding of the inputs that different users have had throughout construction and use of the building, and the drivers and impediments that have characterised the project. The energy performance in use was also compared against the modelled energy consumption predicted at design stage, showing a strong alignment with the real figures, in fact, lower than those predicted. The result of this case study is a detailed insight into how a project was delivered with a negative performance gap, with recommendations as to how this approach can be replicated across the Global South and the rest of the planet.

Keywords: school building, building users, performance gap, LEED, holistic sustainable building design

Introduction and background

The influence that a healthy, positive and comfortable built environment in schools has on students achievement and behaviour is not new (e.g. Earthman and Lemasters, 1996). However, in a world where global warming and climate change threaten the global environment with potentially disastrous catastrophes, such optimal learning environment must be achieved in an energy efficient manner.

Energy efficiency in schools is generally investigated from the perspective of a specific measure, be it a low-energy technology, an energy reduction measure or a passive design strategy. For instance, Becker et al. (2007) investigated design solutions for schools in Israel that would maintain good levels of thermal comfort and indoor environmental quality whilst being at the same time energy efficient, what they called the EE-TC-IAQ dilemma.

Theodosiou and Ordoumpozanis (2008) addressed the same 'dilemma' for nurseries and elementary school buildings in a cold climatic zone of Greece. Their results indicate that main causes for energy inefficiency are to be found in the building envelope, the lack of apt legislative measures, and an improper control of lighting and heating systems – among others (Theodosiou and Ordoumpozanis, 2008). Dimoudi and Kostarela (2009) monitored the energy consumption and assessed the energy conservation potential of school buildings also in a cold climatic zone in Greece. Their monitoring and simulations revealed that in that context improved thermal insulation has the greatest benefit on the reduction of energy consumption, followed by increased wall thickness and better airtightness (Dimoudi and Kostarela, 2009).

Sekki et al. (2017) investigated the effect of energy measures on the values of energy efficiency indicators for school buildings in Finland. In the cases they studied, the most savings in energy consumption can be achieved through investments in technical measures or by operating an automated building management system based on the actual occupancy of the school (Sekki et al., 2017). Research on energy efficiency in schools has evolved greatly given the continuous increase in computational power and refined software tools. One such example, is the work of Zhang et al. (2017) that employed a simulation-optimisation approach based on multi-objective genetic algorithm to improve thermal and daylight performance of school building in China. The authors adopted a parametric approach related to spatial configurations and found that the best design could lead to a 28% energy reduction (Zhang et al., 2017). Schools have also been analysed from a life cycle perspective, in order to understand how minimise material use and waste generation. For example, Pons and Wadel (2011) looked at prefabricated timber, steel and concrete structures. Depending on the technology used, they found that CO2 emissions could be reduced by 50% or waste generated during the school building's life cycle cut by 40% (Pons and Wadel, 2011).

Not only do such interventions on a school building foster a healthy and comfortable educational environment, they also have a further, beneficial and often untapped potential: that to educate and promote sustainability amongst future citizens (Hertzberger, 2008). Whilst this has been already noted and pointed out in the literature on energy efficient schools (e.g. Theodosiou and Ordoumpozanis, 2008) there currently is a lack of research on the benefit and impact of a more holistic approach to school design, with a focus on the roles that different users and stakeholders have. This is therefore the focus of this paper, which will use a K-12 school in Latin America as a case study to reflect on the role of a school building as a living textbook and understand how the individual roles and interactions between different users, including pupils, shaped (and still shape) the energy performance of the building.

Colegio Rochester

Colegio Rochester was established in 1959 as a K-12 private educational institution teaching English as a second language in Bogotá, Colombia. In 2000 the School Board set out to develop a wholly new educational facility with open areas, a good infrastructure for the arts, a swimming pool to promote a wider range of sports, and innovative classrooms to facilitate learning and teaching. The new facility also had to embed sustainability at its core and promote environmentally friendly strategies throughout design, construction and use (Colegio Rochester, 2014). The very ambitious idea was to use the new school site as a living text book, and even more, to make it a tool to transform society in Colombia (Medina Campos, 2015). Many successful initiatives have been organised, that involved not just the school's users such as teachers and pupils but the wider society as a whole, through families of the pupils and the members of the neighbourhood where the new school site sits. This holistic approach to sustainability, in addition to excellent design and environmental management has led to Colegio Rochester receiving the LEED Gold Certification in January 2014, being the first school in the whole Latin America to achieve such accomplishment (Colegio Rochester, 2016). Colegio Rochester has been recognised by national and international organizations such as the Kimberly Clark Foundation Ekco-Awards recognition in 2013 for Exceptional Places to Work, BIBO-WWF in 2014 and as “Academy – Best Environmental Practices” and “Green Project Challenge - 2014”. In 2016 EU press included Colegio Rochester as one of the 50 world’s most innovative schools (El Tiempo, 2016). Since 2012 Rochester School is leading “Green Apple Day” in Colombia and “Our Choice”, an integrative K- 12 networking initiative based on sustainability educational strategies for schools since 2014. In 2016, the WWF awarded Rochester for the protection of the environment (WWF, 2017). Given the remarkable achievements across the whole sustainability spectrum, Rochester made therefore an ideal case study to understand the implicit and explicit aspects that led to such a successful project.

Data collection

Primary data were collected by the authors, starting in May 2016 and continuing through to 2017. Data collected were both qualitative and quantitative. The former consisted in exploratory interviews with LEED consultants as well as semi-structured interviews with school stakeholders. The latter resulted in modelled and measured energy consumption to assess whether and to what extent the low energy technologies employed in the school design had had the expected positive impact. The interviews were realised with:

- Two senior members of the school management
- Two environmental managers
- Two teachers
- Two technicians, and
- Two students

Energy figures were obtained from the energy simulations performed in 2013 as a requirement for the LEED certification. This consisted in carrying out a computer based energy use simulation of two buildings, the baseline building design according to Appendix G of ANSI/ASHRAE/IESNA 90.1-2007 (ASHRAE, 2007) Energy Standard for Buildings Except Low-Rise Residential Buildings (Performance Rating Method) and the proposed building design that incorporates technologies and alternatives (SES, 2013). Ex-post measured energy figures were obtained from the independent energy audit that monitored real energy consumption from November 2012 to January 2017 (SES, 2016, Colegio Rochester, 2017).

The construction materials were evaluated with Design Builder to validate the thermal behaviour, and finishing materials with high surface albedo were chosen. In terms of ventilation, a mixed mode with fresh air intake operates throughout the building and all classrooms are equipped with temperature and CO_2 sensors. The water centre instead fully relies on a natural ventilation strategy with relative humidity of 65% and temperature in the range of 24-30°C. The Colegio also benefit from a range of renewable systems, including 92 PV panels for a total of 24446 kWh/year, solar thermals for hot water and pool hearing, and daylighting system (i.e. Solatube).

Results and discussion

The first result that was produced from the analysis of the interviews has been a flowchart mapping all stakeholders that have influenced and participated in the project across the different stages (pre-executive design stages have not been considered, e.g. planning permissions). This is shown in Table 1.

Table 1 - Stakeholders across different stages of the project

SUPERVISING ALL STAGES

- School Board (General Manager)
- Sustainability and LEED Consultants
- Commissioning Authority
- School Sustainability Director
- Architectural Firm specialised in schools

DESIGN PHASE STAGE 1	DESIGN PHASE STAGE 2 and CONSTRUCTION PHASE STAGE 1	CONSTRUCTION PHASE STAGE 2	OPERATION and FACILITY MANAGEMENT
▪ Architect ▪ Design builder modeller ▪ Energy modelling consultant ▪ Wastewater treatment consultant ▪ Ventilation system design engineer ▪ Lighting design engineer ▪ Acoustic design engineer ▪ Structural engineer ▪ Environmental consultant ▪ Renewable energy consultant	▪ Renewable energy design consultant and contractor ▪ Hydraulic consultant and contractor ▪ Landscape design consultant and contractor ▪ Construction firm	▪ Ventilation system contractor ▪ Electrical and sensors contractor ▪ Wastewater treatment system contractor ▪ Flooring contractor ▪ Ceiling contractor ▪ Windows contractor ▪ Solar tubes contractor ▪ Lighting contractor	▪ School sustainability director ▪ Environmental manger ▪ Sustainability consultant ▪ School facility manager ▪ Teachers ▪ Pupils ▪ Technicians ▪ The wider community

Table 1 reveals some interesting aspects. Firstly, the boxes and arrows show those key actors that have supervised the project across all stages as well as being directly involved in some of them. These are: the environmental and sustainability consultants who played different roles throughout the project, also acting as LEED consultant, the school sustainability director who is actively involved in managing and overviewing the school buildings' operation as well as in supervising the facility management, and the commissioning authority currently acting as facility manager.

Once the building has been completed, it was immediately used as a living text book to engage pupils in all grades and let them have a real feel for what sustainability is about in practice. For example, as a student reported in the interview, visits to the school's wastewater treatment plan (which is the most critical element) helped them understand the purpose of having solely biodegradable soaps and washing up liquids. Additionally, and more importantly, the pupils understood the effects (both positive and negative) that virtuous or vicious behaviours could have on the whole system. Both students in the interview showed an admirable awareness of their roles as sustainability champions, and this was in fact a general feeling during the fieldwork at the school; all pupils at all grades were strongly engaged with the sustainability theme and very aware on how they could promote sustainability and contribute to a better environment.

The building has also been used as one of the main elements of the sustainability curriculum which is taught, with the due differences, at all grades. The school has introduced a sustainability area coordinator as a new role to manage and overview the curriculum and its continuous refinement and evolution. In all interviews it emerged that the school's vision and its sustainability curriculum were so forward-thinking that they actually started driving cultural change. However, as some interviewees have revealed, this also became problematic when pupils – especially those at lower grades – received a different message at home from their parents. Rather than seeing this as a setback, the school decided to broaden even more its outreach and activities for pupils and their families have grown in number and in scope. This solved to some extent the dual message that children were being exposed to, by "educating pupils as well as their families" as one of the interviewees put it.

A different difficulty was experienced with students at higher grades, which already had their own views and perception about sustainability. In these cases, it was not just the sustainability curriculum that drove change but, equally – if not more –importantly, the commitment of the School Board, the School Sustainability Director and all the teachers. Through a holistic approach and the coherent message, all students successfully and positively engaged with the new buildings, the advanced and low-energy technologies used, and the rationale for doing so. Similar to this was the experience of technicians and other support staff working at Colegio Rochester. For them, the new school site has represented a paradigm change since they "were not educated thinking about sustainability", as reported by one of the technicians interviewed. However, over time, the technicians have become sustainability champions too, they enjoy their daily jobs, and feel part of a bigger system which truly cares about humans and the environment. During the interviews it also emerged the formative roles of the technicians, which have frequent and effective interactions with students in order to show them how systems work, how their use of technologies can be improved or rectified in order to reach together a very ambitious goal.

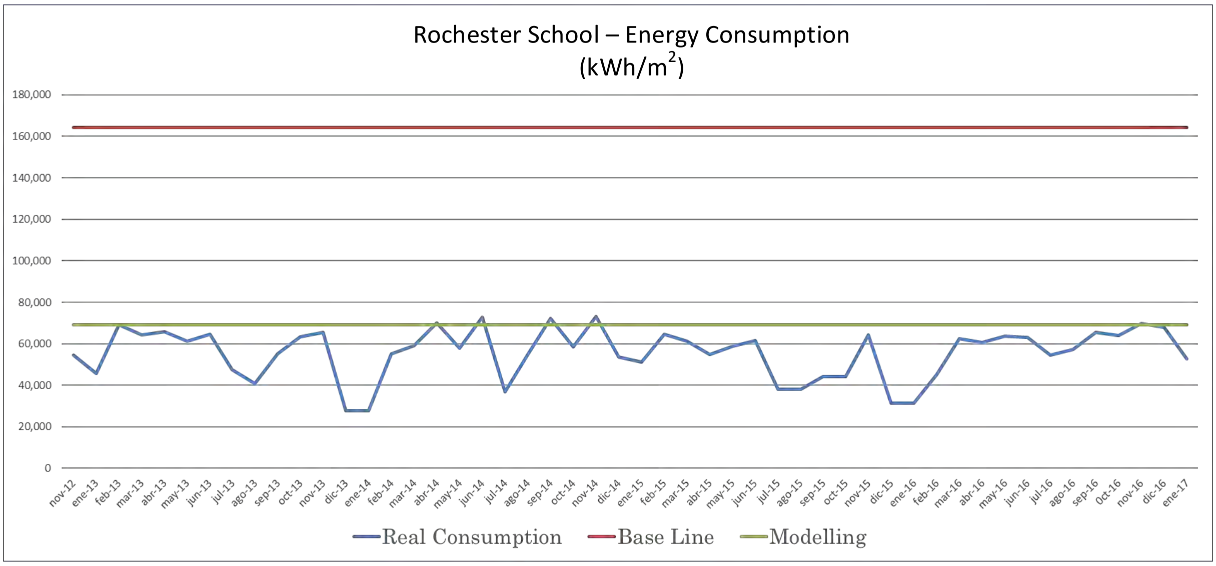

Figure 1 - Modelled vs. measured energy consumption [2012-2017] - Courtesy of Rochester Facility Manager

In addition to an evident positive contribution to promoting social sustainability through the key role education plays, all these activities have had a remarkable impact on the energy consumption of the new school buildings. Figure 1 shows the base line, modelled, and measured energy consumptions from November 2012 through to January 2017. Real figures on energy consumption were collected from the CODENSA (Colombian Energy Supplier) energy bills for all months covered in the chart.

It can be seen that when the measured energy is compared against the modelled energy consumption predicted at design stage, it shows a strong alignment with the real figures, in fact, lower than those predicted. This is a noteworthy achievement, particularly at these times where a big performance gap seems to be the norm in buildings' projects (Forman et al., 2017). Colegio Rochester has fully realised that building users play a crucial, yet "poorly understood and often overlooked role in the built environment" (Janda, 2011 p.15), and has therefore put them right at the heart of the building energy consumption. Not only Colegio Rochester performed very well against the modelled energy figures, but it also performed brilliantly overall compared to schools' energy consumption. This is can be seen in Figure 2, which shows the Energy Intensity Index based on Energy Star.

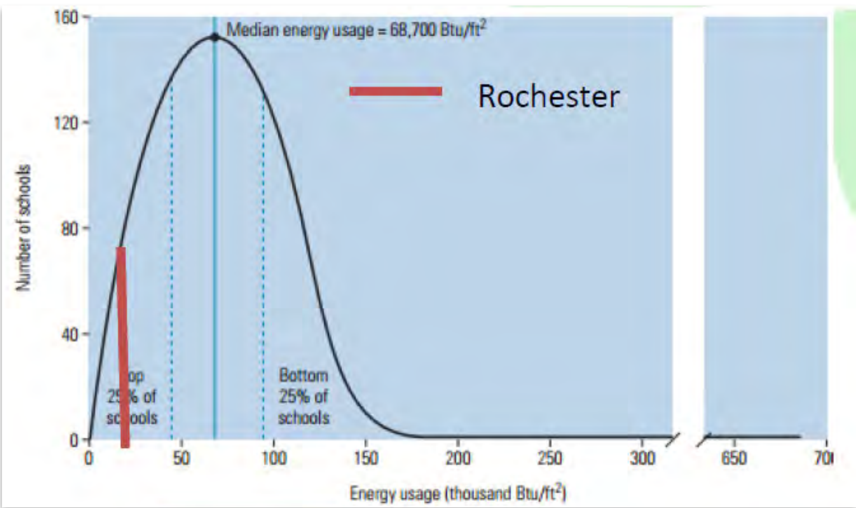

Figure 2 - Colegio Rochester's energy performance compared to other schools - source: SES (2016)

Colegio Rochester is located in the upper bound of the schools with lowest energy consumption. The energy audit conducted in 2016 other than assessing how the building had performed in the previous four years was also an opportunity to re-assess the modelled energy figures and evaluate further energy reduction and optimisation measures. Despite a strong agreement between modelled and measured energy (Figure 1), the energy audit has revealed that individual energy loads could be better modelled (e.g. there had been an overestimation of the ventilation loads and an underestimation of the lighting loads). The energy modelling has been adjusted in light of real figures and therefore the predicted energy consumption in the future will be even more accurate.

The energy audit has also recommended further interventions for energy reduction, which have then been evaluated by the School Board and Facility Managers to evaluate their implementation. Two such examples are lowering the operational temperature for the aquatic centre pools and the elimination of lighting parasitic loads. The former was rejected because pools temperature is set according to national and international norms for comfortable swimming and therefore the energy saving intervention would affect the pupils. The latter instead could be implemented, after checking with the Security Manager that adjusting lighting timers would not pose any increased security risk. Even in these two cases it can be seen that pupils are always placed at the heart of building-related decisions, after all the school exists for and because of them. It shall not surprise that when they are given so much consideration, their behaviour in return is fully committed to achieving a low-energy, sustainable building.

Conclusions

Colombia, like other countries in Latin America, faces great challenges related to the inclusion of sustainability principles and to social and economic development (UNEP, 2014). Education can play a key role in many different aspects, and can certainly help promote paradigm shifts amongst new generations that will be the leaders of tomorrow. This is true across the whole sustainability spectrum, which includes sustainable buildings. This paper has shown how a school building can become a living text-book and give pupils a very concrete experience on how sustainability in the built environment is designed, practically implemented, and managed.

Colegio Rochester is not only an award-winning school but a social phenomenon that has successfully engaged with its many stakeholders across all stages of the building process through to operation and management of the new building site. Pupils have been recognised as key users, and are continuously put at the heart of the school's activities. They are highly engaged with the sustainability theme and have become passionate sustainability champions. As a result, the building has performed better than predicted over the past five years, with measured energy figures lower than those modelled at the design stage. The approach followed, the design utilised, and the technologies implemented are all highly replicable and can be adopted and adapted to different contexts. As such Colegio Rochester could be an excellent model on how sustainability in school can be replicated and achieved across the Global South and the rest of the planet.

Acknowledgements

Funding for this research was received from the Isaac Newton Trust at the University of Cambridge. The authors would like to express their gratitude to the interviewees, the staff, and the senior management at Colegio Rochester for their time. Without their support, opinions, and insights this research would have not been possible.

PLEA 2017 EDINBURGH
Design to Thrive

Productive facade systems for energy and food harvesting: A prototype optimisation framework

Abel Tablada[1], Vesna Kosoric[1], Siu Kit Lau[1], Chao Yuan[1] and Stephen Lau[1]

[1] Department of Architecture, School of Design and Environment, National University of Singapore, Singapore.

Abstract: Building facades in tropical low-latitude regions usually receive ample sunlight; hence, the integration of solar and farming systems may greatly contribute to the productive role of buildings. This paper discusses the development and optimisation of modular productive solar facade (PSF) prototypes suitable for residential buildings involving the implementation of Building Integrated Photovoltaics (BIPV) and Building Integrated Agriculture (BIA) systems. Design alternatives are created by means of an integrated design process (IDP); whereas the VIKOR multiple criteria decision analysis (MCDA) method is applied for a holistic assessment and for the selection of the optimal design alternatives in view of the conflicting criterion categories: architectural quality, production performance and financial performance. Owing to the complexity of PSF integration, in addition to the final food and energy yield, the design optimization considers the impact that arrangements, geometrical forms and types of facade elements may have on the indoor daylight conditions, shading and thermal performance, and wind permeability. At this stage, preliminary results regarding the optimal BIPV on north and south facades, as well as vertical farming arrangements are available. Two optimal facade prototypes for each orientation will be installed and tested at the Tropical Technologies Laboratory (T^2 Lab), at the National University of Singapore campus.

Keywords: BIPV, vertical farming, residential buildings, carbon neutrality, tropical architecture

Introduction

The transition to carbon-neutral societies requires a gradual paradigm shift in lifestyle and building design. Buildings and urban landscapes should become a primary source of energy, food and water, instead of being merely the receivers. As cities extend and their life intensifies due to the rapid growth of urban population in Asia and in tropical regions, a high degree of self-sufficiency in terms of energy, food, and water supply should be guaranteed in order to achieve such transition, while also adapting to climate change and mitigating its effects. Tropical low-latitude regions have ample sunlight; therefore, building facades could greatly contribute to the productive role of buildings by implementing Building Integrated Photovoltaic (BIPV) and Building Integrated Agriculture (BIA) systems.

Several studies have been conducted on the integration of Photovoltaic (PV) panels on building facades in Singapore. Wittkopf et al. (2008) report on the BIPV design development, final designs specifications, and tender assessments of the Zero Energy Building at Building Construction Authority (BCA) Academy in Singapore that includes BIPV as shading devices. However, no details are provided regarding their performance. Saber et al. (2014) studied the PV performance and energy yield predictions of the BCA Academy in Singapore. Through data-collection and simulations, Saber et al. (2014) concluded that a 30° slope is the most effective angle for PVs in Singapore. Mandalaki et al. (2014) compared different shading systems that incorporate BIPV in terms of visual comfort and energy yield. They concluded that the brise-soleil and the single-inclined overhang perform well in terms of energy production and visual comfort. However, their study refers to Mediterranean climate were sunray angles are on average lower than in tropical latitudes. Luther and Reindl (2014) made an estimation of the potential PV area to be installed on Singapore's building facades in order to achieve energy yield equivalent to that provided by 4 km^2 of roof-top PV panels facing the sun at an optimum angle.

Most studies on BIA focus on the rooftop as the potential farming area (Lim and Kishnani, 2010). Other studies on vertical farming concentrate on indoor farming with air conditioning systems and electrical light being used (Despommier, 2013). The application of farming systems on building facades from the construction point of view was reported by Suparwoko and Taufani (2017). However, only Tablada and Zhao (2016) thus far investigated the integration of both solar and farming systems on building facades on an urban scale.

In order to achieve a successful architectural integration, the complexity and dynamics of PV systems design require a holistic multi-disciplinary approach (Hestnes, 1999; Kosorić et al., 2011; Munari Probst, Roecker, 2012) as well as the application of integrated design process (IDP). Solar facade prototype enables fine-tuning of different functions and it balances production performance with architectural qualities (Zoltan et al., 2016). The development of a productive solar facade (PSF) prototype involving BIPV and BIA systems that accomplish multi-dimensional functionalities is an iterative process that includes multiple and often conflicting quantitative and qualitative parameters. The optimal solution should meet specific architectural and techno-economic requirements while at the same time complying with a number of different constraints (safety, accessibility issues, etc.). Therefore, this paper focuses on the development of a multiple criteria decision analysis (MCDA) framework which will be used for the design optimisation of the PSF systems to be installed at the Tropical Technologies Laboratory (T^2 Lab) at the National University of Singapore (NUS) campus. Two modular facade prototypes per orientation suitable for residential buildings will be developed: (1) facade wall and (2) facade with balcony (or corridor).

The VIKOR method (Opricović and Tzeng, 2004; Opricović and Tzeng, 2007) is increasingly applied in areas related to sustainability and renewable energy (Mardani et al., 2016). Regarding the integration of active solar systems into buildings, the VIKOR method can be successfully applied to enable comparisons of otherwise incommensurable or conflicting requirements and to provide greater modelling flexibility according to the preferences of the decision-maker (Kosorić et al., 2011; Krstić at al., 2012). In this paper, MCDA VIKOR method is applied in order to provide a comprehensive evaluation and selection of the optimal design alternatives. In addition to food and energy yield, the optimisation method considers the impact of the facade design on the building thermal and visual performance, functionality, and costs. The research is based on the hypothesis that the performance of building facades should exceed the traditional indoor–outdoor boundary functions and climate regulation by also providing a portion of energy and food that residential buildings require. The benefits that each BIPV and vertical farming system can provide are two-fold: on one hand, they enable the production of electricity and food;

on the other hand, as passive devices, they reduce solar gains as well as improve indoor visual and thermal comfort.

Optimisation framework

Figure 1 shows the overall framework of the MCDA applied in this study. The first step was to define the potential BIPV facade components, vertical farming and fenestration or openings. For each system a series of preliminary simulations was conducted and the technology was selected based on the available reference literature. Thereafter, the decision goals were identified considering the potential integration of PSF in residential buildings. The result of considerations is a simple rectangular form of SPF with a relatively neutral appearance. Key parameters such as: production outputs, installation and maintenance costs, user comfort, accessibility, and aesthetics, also have to be balanced. Design alternatives are then generated to be applied on two facades types: (1) facade wall and (2) facade with balcony. Both facade systems are analysed separately for four orientations: north, south, east and west orientation.

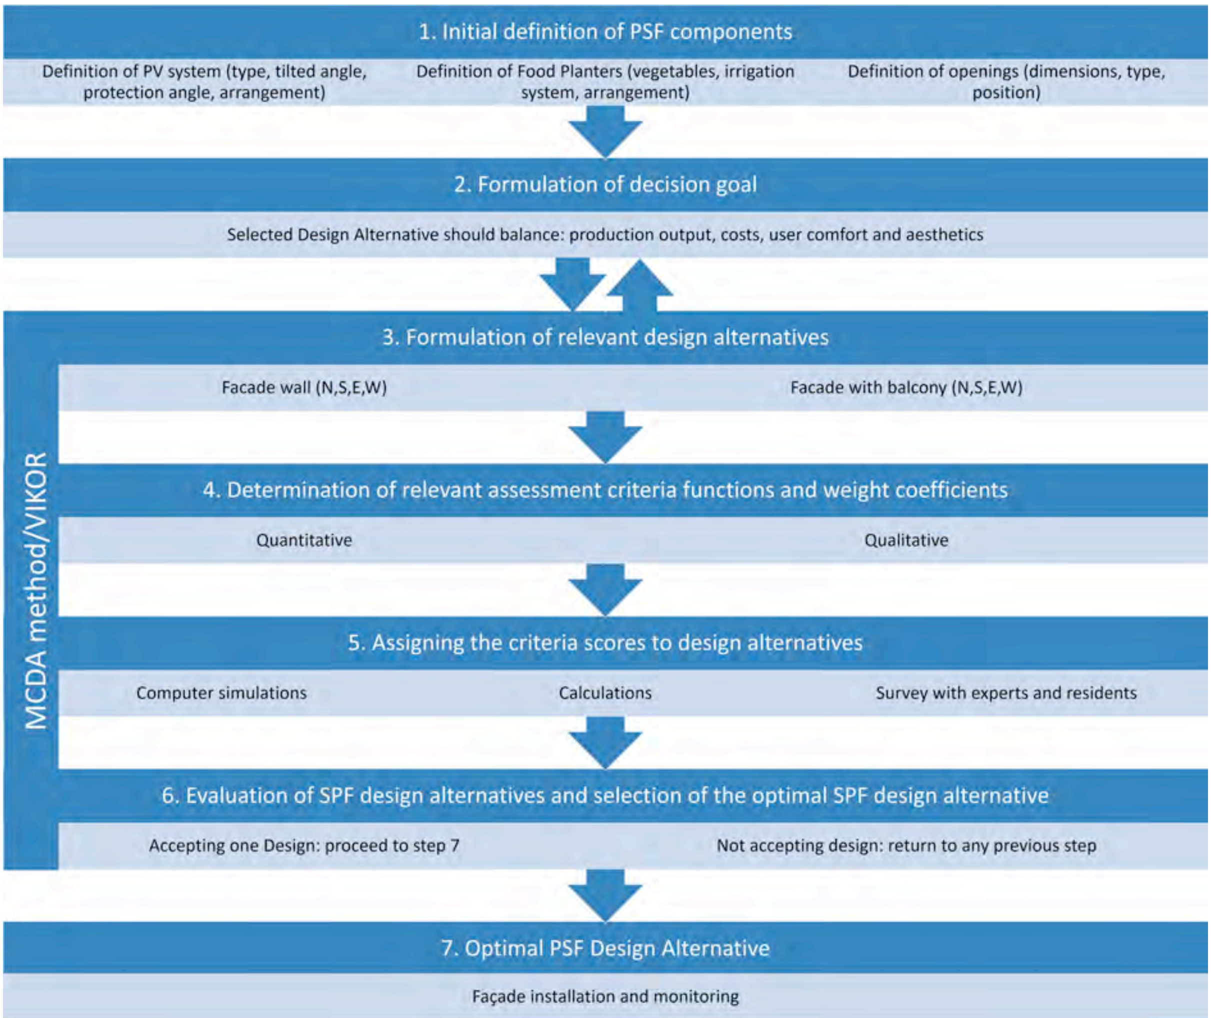

Figure 1. Productive Solar Façade (PSF) systems development and optimisation methodology

Design alternatives

Figure 2 shows a selection of design alternatives highlighting variables such as: the PV tilt angle, angle of protection, and planter's arrangements. In total, there are 980 design alternatives, 240 for the facade wall and 740 for the facade with balcony. The PV panels and planters serve as shading devices reducing solar gain. Planters with vegetables and herbs may also be used as wind-permeable railing of a balcony or corridor.

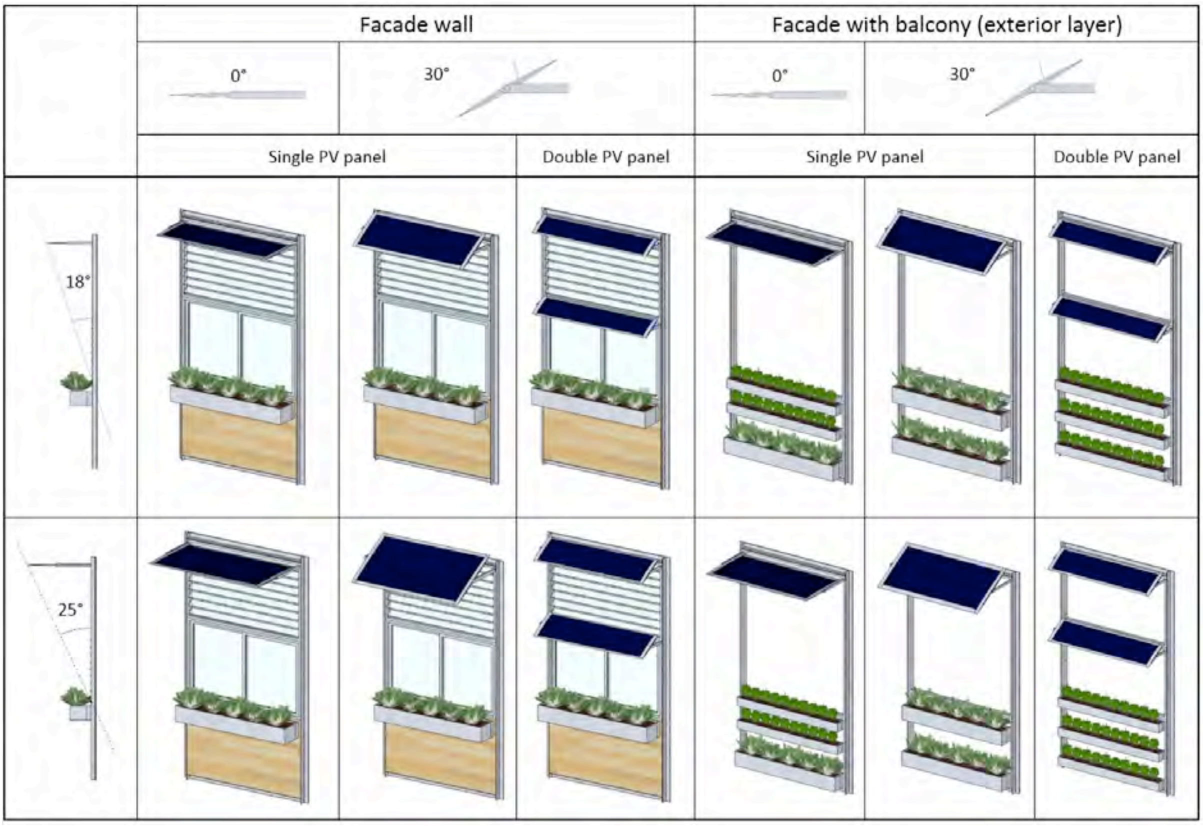

Figure 2. Selection of design alternatives for the application on the facade wall and facade with balcony. Total number of design alternatives: 980.

In terms of criteria functions such as the production yield, simulation models replicate the facade assessment for at least one level above. This is necessary since the effect of upper levels planters or BIPV on the availability of sunlight should also be taken into account. The prototype is a generic proposal; therefore, at this stage, only a low angle obstruction is considered rather than a more realistic urban morphology comprising middle/high-rise residential buildings in close proximity to the facades.

Design strategies and criteria

The MCDA comprises 10 criterion functions referring to three main criteria categories: architectural quality, production performance and financial performance (Table 1). In the first optimisation, criteria function groups are given the same weight coefficient (ω_i) (0.1 each). Metrical units used in evaluation are also specified as well as the expected best performance (Ext, Minimum or Maximum).

Since the facade prototype is to be installed at a test-bed facility, the ease of transportation and installation is also considered. This aspect is aligned with the need for the systems to be installed as a retrofitting measure in existing buildings. Other features such as: usability, acceptance, and aesthetical value, aim to address user-oriented aspects also pertaining to the actual use and success of the proposed systems.

Table 1. Criteria categories, criteria function groups and individual criteria functions for PSF design alternatives evaluation. 'ω_i' and 'Ext.' refer to the weight coefficient and to expected best performance respectively.

Criteria categories	Criteria function groups		Individual criteria functions	f_i	Units	ω_i	Ext.
Architectural quality	Functional quality	Daylight performance (0.1)	Daylight Autonomy (indoors)	f_1	%	0.05	Max
			Energy on lighting (indoors)	f_2	KWh	0.05	Min
		Thermal performance (0.1)	Envelope Thermal Transfer Value (ETTV)	f_3	(W/m^2)	0.1	Min
		Natural Ventilation (0.1)	Ventilation rate	f_4	m^3/s	0.05	Max
			Wind speed	f_5	m/s	0.05	Max
		Views quality (0.1)	Angle of view/opening	f_6	degrees	0.1	Max
		Usability & Acceptance (0.1)	Accessibility	f_7	qualitative (1-5)	0.05	Max
			Residents' acceptance	f_8	qualitative (1-5)	0.05	Max
	Aesthetic quality (0.1)		Aesthetic quality of the element	f_9	qualitative (1-5)	0.1	Max
	Constructive quality (0.1)		Components' weight	f_{10}	kg	0.05	Min
			Ease of assembly/disassembly	f_{11}	qualitative (1-5)	0.05	Max
Production performance	Energy yield (0.1)		PV electricity generation per year	f_{12}	KWh	0.1	Max
	Food yield (0.1)		Total value of produced food	f_{13}	SGD	0.1	Max
Financial performance	Costs (0.1)		Installation costs	f_{14}	SGD	0.05	Min
			Maintenance costs per year	f_{15}	SGD	0.05	Min

In terms of the production performance, criteria were defined per energy yield and food yield. For energy generation, the standard metric unit used to assess the BIPV performance is the total electricity in KWh. In terms of food production, rather than the total weight (kg), the total value of the produced food (SGD) was considered to be more relevant seeing how, while herbs and vegetables may not be very heavy, they still constitute a valuable output for residents and provide a significant incentive for cultivation.

Safety was another criterion under consideration; however, since all design alternatives should comply with minimum safety standards, it was not included in the MCDA. Once the SPF prototype optimisation is resolved, the criteria and weight coefficients will be chosen by authors in cooperation with the local building authorities and experts from the PV industry and research institutions. Grasshopper's plug-ins software is used for the calculations of the criteria functions values related to daylight performance, thermal performance, natural ventilation, and electricity production. A numerical grade on the scale from 1 to 5 is assigned to design alternatives with regards to qualitative criteria such as: accessibility, residents' acceptance, aesthetic quality and ease of assembly/disassembly. Also, the component's weight and costs will be estimated. With regards to design alternatives aesthetic qualities, a survey will be carried out among public housing residents, university staff, architects, engineers, and PV experts.

Selection of optimal design alternatives

The VIKOR method relies on the weight coefficients of the criteria functions to model the preferred structure of a design strategy. The selection of the optimal design alternative refers to the value Q_j, Eq. (3), as the value that ideally approximates the balance i.e. the compromise between two decision-making strategies:

(1) Maximum group benefit (better alternatives are good according to the majority of criteria) - as defined by S_j, Eq. (1) and

(2) Minimum of maximum deviation of ideal value (better alternative must not be very bad according to any criteria) - as defined by R_j, Eq. (2) (Opricović and Tzeng, 2004).

The VIKOR algorithm (Opricović and Tzeng, 2004) follows several steps in order to reach a compromise between J alternatives: $A1, A2, \ldots, A_J$ as per the established n criteria functions f_i and their relative importance stated through criteria functions weight coefficients ω_i.

The first step determines the best f_i* and worst f_i^- values for each criteria function. The second step calculates values S_j, R_j and Q_j in the manner stated below:

$$S_j = \sum_{i=1}^{n} w_i \left(f_i^* - \mathrm{f}_{ij}\right)/\left(f_i^* - \mathrm{f}_i^-\right), i = 1,2,\ldots,n,\ j = 1,2,\ldots,m, \tag{1}$$

$$R_j = \max_i [w_i \left(f_i^* - \mathrm{f}_{ij}\right)/\left(f_i^* - \mathrm{f}_i^-\right)], i = 1,2,\ldots,n,\ j = 1,2,\ldots,m, \tag{2}$$

$$Q_j = v(S_j - \mathrm{S}^*)/(S^- - \mathrm{S}^*) + (1 - \mathrm{v})(R_j - \mathrm{R}^*)/(R^- - \mathrm{R}^*),\ j = 1,2,\ldots,m, \tag{3}$$

whereas

$$S^* = \min_j S_j, S^- = \max_j S_j,\ j = 1,2,\ldots,m, \tag{4}$$

$$R^* = \min_j R_j, R^- = \max_j R_j,\ j = 1,2,\ldots,m, \tag{5}$$

Value v represents the weight relative to the maximum group utility strategy and *(1-v)* stands for the individual regret weight. Based on the above calculations, three ranking lists are obtained that determine the order i.e. the rank of the alternatives. The lists are sorted according to the descending values of *S*, *R,* and *Q* values. The compromise solution is the alternative with the lowest Q value indicating “acceptable advantage” and “acceptable stability” (Opricović and Tzeng, 2004).

The VIKOR method allows both the criteria and weight coefficients to be changed relatively easily. This also helps analyse the criteria and weight coefficients impact on the compromise solution, and provides a clearer insight into the selected solutions.

Preliminary results

Currently, only the preliminary results from an independent evaluation of BIPV and vertical farming systems are available.

With regards to the BIPV on the facade wall solutions, a 30° tilt angle of PV panels that also serve as shading devices, is considered as the optimum angle for north and south facades accounting for the incident direct and diffuse sunlight. This tilt angle applies to all levels of a multi-storey residential building with different sky view factors involved. Horizontal position as the optimum position for obtaining maximum yield, solar protection, and daylight levels is considered only at the top level. As for the arrangement of the PV panels, a double panel system is preferable over a single panel. This is applicable for frameless modules or modules with minimal frames (Ong and Tablada, 2017).

Regarding the application of vertical farming arrangement on the facade with balcony, the best output is provided with three rows of planters, preferably two rows for larger vegetables and one row for smaller ones, not only in terms of the yield, but also in terms of accessibility. Facade arrangements for east and west orientations would require larger overhangs or narrower spacing between louvers in order to provide protection from direct sunlight. However, other important design features such as: daylight, views towards outside, and overshadowing between the BIPV and planters would be affected.

Conclusions

This paper describes the methodology applied in the development and optimisation of modular productive facade prototypes that integrate BIPV and BIA systems in residential buildings in Singapore. The presented framework gives systematic guidelines that lead to optimal SPF solutions. Each facade prototype is analysed for its implementation on the facade wall and facade with balcony and optimised for north, south, east, and west orientations. Facade modules will be installed and tested at the T^2 Lab, at the NUS Kent Ridge Campus.

VIKOR as the MCDA method, is recommended for finding the optimal SPF solutions for four facade orientations and helps understanding how different optimisation requirements influence optimal solutions as well as the reasons behind them. The VIKOR method was applied in order to optimise eleven quantitative and four qualitative criteria functions. Since architectural integration of the optimal element selected is of high importance, the criteria related to architectural quality have greater weight coefficient in terms of the optimisation. Distribution of criteria weight coefficients can however be easily altered and adjusted to meet different project requirements. For instance, the project owner could require that facade costs have a higher weight in comparison to the production performance.

The recommendations given in this study on the optimal arrangements, geometrical forms and types of PSF elements contribute to the discussions on solar architecture and the integration of renewable resources into urban and building design in order to reduce the dependency on fossil fuels and the current carbon footprint in tropical regions.

Acknowledgements

This research is funded by City Developments Limited (CDL), Singapore. The authors would like to acknowledge the collaboration of Thomas Reindl and Veronika Shabunko from Solar Energy Research Institute of Singapore (SERIS) and Hugh Tan from Department of Biological Sciences, NUS. We also appreciate the contribution of Huang Huajing and Ian Chaplin from Department of Architecture, NUS.

Design to Thrive

Seeing the miraculous in the common: Re-mainstreaming the use of sustainable building materials

Dr Keith Baker[1] & Dr Craig Thomson[1]

[1] Built Environment Asset Management (BEAM) Centre, School of Engineering and the Built Environment, Glasgow Caledonian University, Glasgow, Scotland. E. keith.baker@gcu.ac.uk

Abstract: Europe is in danger of losing much of the knowledge and skills needed to sustain the traditional industries that supply natural and sustainable materials and products to architects, the construction industry and housebuilders. This paper describes the outcomes and knowledge developed as part of the Natural Energy Efficiency and Sustainability (NEES) Project, funded by the European Regional Development Fund's Northern Periphery Programme and delivered by partners across Scotland, Ireland, Northern Ireland, Sweden and Greenland. The project focused on the development of the 'NEES Process' to identify and promote fifteen examples small to medium-sized enterprises demonstrating best practice in the use of natural and recycled building materials sourced from Northern Europe. As well as being exemplars of energy and / or resource efficiency the NEES Best Practices were also selected for being sensitive to local architectural heritages, cultures, and traditional industries. As part of this project a number of key opportunities and barriers for increasing the take up of locally-sourced sustainable materials, products and services were identified; including the potential co-benefits to other sectors, the need to stem the loss of traditional knowledge and skills, and the litigious nature of some larger producers of conventional building products and materials. This paper also describes the knowledge and practice gaps that need to be closed in order to reintroduce and mainstream the use of traditional and sustainable building materials into architectural practices and public procurement policies, and from there to re-mainstream their use by local tradespeople and householders. Finally, it questions the value of the government led agenda for innovation in building materials where natural and traditional materials can offer equal, or near equal, levels of energy efficiency whilst providing additional co-benefits to householders, local communities, the environment, society, and regional economies.

Keywords: sustainable, natural, building, materials, energy efficiency

Introduction

The critical importance of realising sustainability and the central role of the built environment in achieving this is recognised at the highest levels (UN Habitat, 2008; European Commission, 2007; WCED, 1987). However, current sustainability assessment protocols are largely confined to assessing the environmental performance of buildings and fail to address their impact on quality-of-life and the interrelationship between the two thus not optimally aligning with the principles of sustainable development. Even within the current environmental focus, the emphasis is often on a narrow range of issues such as energy performance (for example, The Energy Performance in Buildings Directive – European Commission, 2002) and material use ("Environmental Product Declaration" EPD, 2008). As such, sustainability in its widest sense of delivering quality-of-life while improving environmental performance, is yet to be fully operationalised because existing assessment tools and protocols are insufficient for capturing these 'co-benefits' (Pridmore et al., 2017).

In this paper we present the philosophy behind the criteria development and evaluates the results obtained in selecting and accrediting sixteen examples of Best Practice as part of the European Regional Development Fund's Natural Energy Efficient and Sustainability (NEES) Project (NEES, 2016).

Background

Despite their shortcomings, a plethora of sustainability assessment methods (SAM's) have emerged recently. As early as in 2005 Walton et al (2005) identified that there were over 600 tools dealing with one or more aspects of sustainability in buildings. Despite the abundance of tools, the landscape is incomplete in its coverage of sustainability themes, with no one sustainability assessment tool providing complete coverage and the criteria around which the method is developed, often reflecting variations in their interpretation of the concept. Poston et al. (2010) conducted a comparison of the thirty most commonly used SAM's to explore the coverage of their criteria against a holistic interpretation of sustainability. The findings of the survey confirmed the incomplete coverage of criteria against economic, environmental and social themes and confirmed a tendency to focus on environmental impacts often from a technical standpoint, thus failing to account sufficiently for cultural and economic considerations which are important to the aim of the NEES project.

In establishing the basis for an assessment criteria for selecting best practice products and services based on the principles of the NEES project, there was a need to go beyond what is commonly reflected within the criteria used by common sustainability assessment tools. We therefore considered established criteria within common tools, criteria emerging within tools which reflect novel articulations of sustainability, and drew on sustainable material frameworks such as NaturePlus™ (NaturePlus, 2017) for validation.

Method

Our approach drew on the experience of the SUE-MoT research project (SUE-MoT, 2008) involving Glasgow Caledonian University (GCU) which developed a criteria for assessing sustainability of building projects. This criteria was tailored for the context of sustainable materials and cross mapped with the criteria displayed in novel articulations within SAM's (Poston et al. (2010) and drew on a sustainability materials selection criteria developed by GCU with a housing development team and housing association. The emerging materials selection criteria was developed around bioregional principles but was established from the same reductionist approach. The criteria embodied many of the environmental principles reflected in NEES, but a need existed to tailor the criteria to reflect the future potential of the product or service within the market and the context of the Northern Peripheral Programme (NPP) regions (geographic, cultural, economic, skills and traditions). The emerging criteria was validated through comparison with the NaturePlus™ criteria (NaturePlus, 2017) which focused on the technical elements of resource efficiency, environment and health criteria; but were found to lack the wider sustainability, enterprise and scalability criteria important to NEES.

Consultation with the NEES partners and stakeholder experts was an important element of the refinement process with a view to ensuring the emerging assessment criteria met with the principles pursued within the project, best practice and to enable regional variations to be reflected (i.e. Scotland, Ireland, Northern Ireland, Sweden and Greenland). This process aided in establishing a firm understanding of the NEES philosophy and its articulation in the context of the criteria. An expert panel was convened comprising of professionals in sustainable design and construction from the different partner regions. They provided technical input, and ensured that the emerging criteria reflected the latest interpretation of best practice to sustainable materials within their regions.

Emerging from this was an aim for NEES to seek to promote products which “were comprised of a minimum of 85% of renewable raw materials, or mineral based materials which are almost unlimited in their availability”. The synthetic or high-tech components of such products were strictly limited and reduced to the minimum level that is technically possible. Harmful emissions were avoided and on the other, and the use of fossil fuels and limited natural resources were minimised. The origins of the raw materials were carefully checked. NEES also seeks to promote services if they “were based on the use of such products, and their implementation has no or limited environmental impact”.

To ensure that products and services considered for selection as Best Practices meet this philosophy, three ‘gateway’ criteria were introduced to eliminate quickly failing submissions from the process:

- Use of natural and / or recycled materials
- Suitable for retrofitting to improve the energy performance of buildings
- Sourced from the NPP region, or those with main market in the region.

Those products and services that meet all three of the gateway criteria are then scored against five NEES assessment criteria (Table 1). The first two criteria aligned with the NaturePlus criteria, the findings of the SUE-MoT project and the sustainable building materials criteria developed by GCU. The third expands these to cover a wider definition of sustainability incorporating social, cultural; heritage aspects and wider economic impacts, and the latter two are more blunt assessments of success and future market potential. On passing the three ‘gateway’ criteria, representatives of the products and services were asked to submit an application for consideration as a promoted best practice through the NEES website. The application was in the form of an online survey designed according to whether the applicant provides a product or service. The product survey set specific questions designed to draw out pertinent information that may not be obvious to applicants. The initial version of the services survey was simplified following feedback from respondents and the expert panel. The survey then focused on requesting case studies that address the ‘natural / recycled’, ‘energy efficient’ and ‘sustainable’ aims of the project.

Table 1. The NEES Assessment Criteria

Criteria	**Aspects of sustainability assessed**
Resource efficiency	This captures the more quantifiable impacts of the products and services, including life cycle costs, carbon footprint, and energy savings attributable to use
Environment and health	This captures less directly quantifiable impacts such as pollution and any hazards to human health (from installation and use)
Sustainability	This captures socio-economic impacts as well as cultural issues such as sensitivity to regional architectural traditions
Enterprise	This captures the growth, to date, of the product or service (given that all applicants must be SMEs or smaller)
Scalability	This captures the potential for growth, including the sustainability of the product or service if demand were to grow significantly, as well as the value that could be added by involvement with the project.

In line with the Delphi Process (Dakley & Helmer, 1963) the completed assessments were passed to a panel of independent experts (one representing each partner region) to score and evaluate against a standard marking scheme. The results were collated, the highest and lowest marks removed, and the average of the remainder taken. Those scoring above or below 7 under all five criteria are automatically accepted or rejected and the rest were further evaluated at a meeting of the panel, who had the option of accepting, rejecting, or referring a submission back for (specific) information. The whole process is therefore designed to eliminate professional bias, minimise the time needed from experts, and facilitate more detailed discussion where this is needed regarding the characteristics of the NPP regions. The panels were established partly to overcome the research/ information gap surrounding the performance of products and services aligned with the NEES criteria and to ensure professional opinion and experience within the NPP regions was reflected.

Outcomes and Discussion

Table 2, on next page, details the Best Practices and the main reasons for their selection by the panel. In Scotland and Ireland there was observed a high proportion of submissions from small micro-enterprises which displayed limited business skills and resources to grow their product and business. A committed community of architects providing sustainable design services was represented but reported a real challenge finding suppliers within the local area for sustainable materials. Both these regions exist close to large urban areas (central belt of Scotland; Dublin and Belfast in Ireland) which can service this market with products and services resulting in an abundance and dominance of contemporary materials.

In Sweden, the submissions were largely from large companies who have invested in developing products with a view to promoting these on the Swedish and global markets. Due to low population levels the potential for commercial activity servicing a local market is limited and this is reflected in the lack of micro enterprises promoting products and services.

In Greenland, the submissions reflected challenges in obtaining submissions from this region resulting in an inability to identify a successful Best Practice. This reflects the reliance on imported building materials from Denmark and limited economies of scale for local products and services. A lack of local training and investment problems associated with investment levels required for research and development of materials suitable for the Arctic climate were observed. Economies of scale were identified to be a common barrier limiting the potential for growth in all regions. Low population density in Greenland and Sweden restricts the market potential for such products and services at a commercial level locally. Sweden relies on large organisations to invest in the region in order to promote these products to the mass market. In Scotland and Ireland, the focus is on mirco-enterprises and two types of organization were observed with 1) lacking the desire to grow due to the local scale of the business satisfying the needs of the shareholders, and 2) those that have the desire to grow but lack the skills and experience to grow their business.

The process also enabled the identification of some common barriers to mainstreaming sustainable building materials. Simple lack of awareness of their benefits (and co-benefits) amongst the construction industry, housing developers, and the public was a commonly-cited barrier, along with a lack of professional training opportunities for architects and house builders. However, where clients were aware, or made aware, they were reported to have found them preferable for reasons such as being safer for installers and more aesthetically pleasing for occupants. A potentially more significant barrier, and a key finding of the study, was the costs of achieving relevant certification for products manufactured by the smaller companies, and the potential consequences of making claims without that certification. Larger competitors using conventional products and materials were commonly viewed as being litigious towards smaller companies who promote the sustainability of their products and services, and even the risk of legal action was seen as sufficient to deter them from making such claims. This was further compounded by the financial and staff resource costs of achieving relevant certification, and the project produced an example of this.

Table 2. The NEES Best Practices

Name	Country	Materials	Reasons for selection
Advanced Timbercraft	Northern Ireland	Timber; cellulose; hemp; sheepswool; woodwool; wood fibre	Family-run firm specialising in low energy, high thermal performance buildings, using recylable and biodegradable materials
Anu Green	Ireland	Structural materials for roofing; soil / bedding material; plants / grasses	60-100% use of recycled materials; co-benefits of green roofs
Ecological Architecture	Scotland	Local, sustainable timber; hempcrete; reclaimed stone; sheepswool; etc	Pioneering and innovative ecological architectural practice established by two (female) experts
Enviroglass	Shetland, Scotland	Processes recycled glass into aggregates and paving materials	Recycles ~99% of Shetland's waste glass, which would otherwise be shipped to the mainland
Ecocel	Ireland	Processes recycled cellulose (newspapers) into blown-fibre insulation	Highly sustainable; non-toxic; suitable for retrofitting into difficult spaces; proven to provide better thermal regulation than conventional insulation
FH Wetland Systems	Ireland	Constructed wetlands; reed beds; zero discharge willow facilities	Natural and sustainable solution to wastewater treatment; reduces infrastructure energy costs
The Hollies Centre for Sustainability	Ireland	Cob; bale cob (strawbale and cob hybrid); timber; stone; clay; sand; lime; locally-sourced earth pigments	Example of a consultancy which also provides training in the use of natural building materials
Inzievar Woodlands	Scotland	Native Scottish hardwood and softwood timber	Mixed woodland managed for co-benefits – recreation, tourism, etc; sawmill is Scotland's main processor of native timber
Locate Architects	Scotland	Local, sustainable timber; hemp insulation; natural paints; Scottish linoleum;	Best practice in combining natural and sustainable materials with modern design approaches – PassivHaus, etc
MAKAR – Design and Build	Scotland	Architectural practice specialising in off-site construction using local, natural and sustainable materials	Use of local, natural and sustainable building materials; dwellings are nearly 100% recyclable or biodegradable; off-site construction using lightweight materials reduces embodied energy costs in rural / island areas
MAKAR - nSIPS	Scotland	Natural structually-insulated panels manufactured from local timber and recycled cellulose	Economically and socially sustainable - contributes to rural regeneration – has grown to ~30 staff and apprentices
Martinsons - Gluelam	Sweden	High strength locally-sourced structural timber product	Use of local timber; economically and socially sustainable in a rural region with a low population density
Martinsons - Xlam	Sweden	High strength locally-sourced structural timber product	Use of local timber; economically and socially sustainable in a rural region with a low population density
Masonite Beams	Sweden	Floor, wall and roof systems using locally-sourced timber	Use of local timber; economically and socially sustainable in a rural region with a low population density
Mud and Wood	Ireland	Cob; lime; reclaimed timber; straw bale	Example of a consultancy which also provides training in the use of natural building materials
SWECO Umeå	Sweden	Sustainable materials sourced from the region	Selected as an example of a larger company using materials certified to the highest standards

Of the smallest Best Practices, Ecocel was notable in having an important benefit (improved thermal regulation over conventional insulation) certified by testing carried out at Delft University, the Netherlands (Ecocel, 2013). Therefore, in order to meet the aim of the NEES project to support the development of small businesses and better understand barriers to growth, the project funded another of the smaller Best Practices, Enviroglass, to be assessed for the Carbon Trust's Product Footprint label, which is the UK's most established certification scheme for low carbon products (Carbon Trust, 2017). Enviroglass, which recycles ~99% of Shetland's waste glass into paving and aggregate products, and which was fending off an attempt by the Scottish Government to require this to be exported to a recycling facility on the Scottish mainland, was seen as an excellent example of a small business which should benefit from certification.

However, although certification was achieved, this proved to be an arduous process which ran significantly over-time and over-budget (the final cost being approximately £13,000 from an estimated budget of approximately £6,000, excluding staff time for Enviroglass). For this, the GCU team contracted a qualified Carbon Trust assessor, paid for the necessary software licence, and managed the contracts and relationships between the three parties. Of the many problems that befell the project the usability of the software, even for an experienced assessor, and difficulties in accessing an electricity meter caused the most significant delays and added costs. The latter was due to Enviroglass's meter being sited in locked premises next door which were rarely used by the tenant, and who proved difficult to contact, and provides a useful example of a practical problem encountered by the smallest businesses working under ad-hoc arrangements (Enviroglass employs two staff who work across the Shetland Isles), and who were typical of the applicants from Scotland and Ireland. For such a small community-based business the staff time required to achieve certification was significant, and as such the main consequence of this experience, rather than to develop a case study to encourage other small businesses to invest in certification, turned out to be exactly the opposite.

A related set of issues was raised by the experience of another Scottish Best Practice, Inzievar Woodlands. Inzievar consists of a sawmill, which processes almost all of the native hardwood and softwood timber grown in Scotland, and a woodland managed for co-benefits including biodiversity, recreation and tourism. As part of engaging the Best Practices with the project, NEES team members visited each of the businesses to interview them about issues including barriers to growing their businesses, and the interview with the staff at Inzievar produced an important observation which was also reflected by other smaller Best Practices – *"we don't want to grow, we just want neighbours"*. This comment reflects a wider critique which emerged from many of the interviews but particularly the smaller companies, that of questioning both the 'growth is good' assumption that is inherent in many political conceptualisations of sustainable development, and within this the role of 'innovation for the sake of innovation' as a driver for growth.

A more nuanced view on growth, articulated particularly by the architects, was about the quality of the jobs created by growth and the benefits of training and retaining skilled employees in rural areas. Measures to promote innovation through competitive funding were also frequently cited as a barrier to growth, in that in order companies were having to add 'something innovative' to their products and services in order to be eligible to apply for support. In some cases this had been overcome by partnering with universities, but was generally seen as an added expense that some felt would be better spent on funding retrofits using existing, proven, energy efficient products and materials.

Conclusions

The title of this paper comes from a quote by Ralph Waldo Emerson, chosen because it articulates the responses of clients of the NEES Best Practices, and of the many policy makers and members of the public who engaged with many activities carried out as part of the project. At no stage did any of the project team encounter any resistance or objections to the benefits (and co-benefits) of promoting locally-sourced, natural and sustainable building products and materials, and these have now been recognised in Scottish policy (Pridmore et al., 2017; Scottish Government, 2017).

Yet in Scotland, and to differing degrees across the European Union, much more needs to be done if we are to re-mainstream the use of sustainable building materials and avoid losing the traditional skills, and skilled tradespeople, needed to sustain these industries. As the Best Practices illustrate, these industries are highly diverse both in terms of the products and services they offer, and of the nature of the companies themselves. This means that whilst some will be receptive to conventional market-led policy responses, the needs of others may be better met through more holistic approaches to promoting energy efficiency and social and economic regeneration in rural and island areas.

Abstract: Hemp-concrete is a green material obtained by mixing hemp hurds, mineral binder including lime, water and additives. Compared to classical building materials, it has a low embodied energy, a high porosity as well as interesting thermal and hydric properties. It also contributes to the reduction of energy consumption and greenhouse gas emissions. Thus, hemp-concrete becomes highly recommended in constructions and finds applications as internal or external thermal insulator in wooden frame walls. At wall scale, studies proved that using hemp-concrete in building envelope seems to improve indoor hygrothermal comfort. In that context, a French building in Champagne-Ardennes region, employing hemp-concrete as external insulation is selected and studied. An apartment is monitored for several months. Indoor temperatures, relative humidities, thermal heat flux as well as external weather conditions are measured using sensors installed inside the apartment and a weather station at the roof of the building. Measurements underline the hemp-concrete ability to dampen external weather conditions by showing satisfactory results for indoor temperature and relative humidity. Experimental approach is then coupled with a numerical validation at the wall scale using SPARK simulation tool. Investigations are conducted on thermal heat flux through the wall. Results show a good agreement between numerical values and experimental measurements.

Keywords: hemp-concrete, experimental measurements, numerical simulation, SPARK

Introduction

Due to the high dependency of human's activities on fossil energy, several environmental issues related to the depletion of natural resources began to threaten the world growth on the beginning of the 21st century. Therefore, turning into renewable resources seems to be a plausible and interesting solution in order to provide a sustainable development. In that context, the building sector is highly concerned, since buildings are known by their high consuming energy rate (43%). Thus, innovative eco-friendly materials, such as Hemp-concrete, have become a new trend in modern constructions.

Hemp cultivation is widespread in many countries of the European Union. France is considered as the major producer, particularly the Grand-Est region, which makes this source affordable in terms of elaboration and transportation fees. The Hemp-concrete technology has appeared in France in 1987 and its composition depends on the application type: internal or external insulator, wall, roof … Several studies in this field proved the interesting properties compared to classical building materials (aerated concrete, hollow brick, …): a low density (between 450 and 700 kg/m^3) making it a light weight material, and high porosity which can reach 70% of its volume (Collet 2004) (Evrard 2008) . The low thermal conductivity and diffusivity allow the Hemp-concrete to dampen external temperature variations. Moreover, Hemp-concrete is classified as excellent hydric regulator due to its high moisture buffering value (MBV >2). However, mechanical properties showed that it is not suitable to be used as load bearing material but could be associated with a wooden frame.

Plentiful works are carried out at the wall scale dealing with Hemp-concrete hygrothermal behavior when subjected to different temperature and relative humidity variations. In this field, several aspects are studied: the influence of the Hemp-concrete hysteresis on the heat and mass transfers within the wall (Lelievre et al. 2014)(Costantine et al. 2016), the effects of sorption isotherms thermal dependency (Le et al. 2015) … However, till now, the literature presents a lack of investigations at the building scale.

In this scope, this work aims to evaluate the thermal performance of a building using the Hemp-concrete as external insulator. For this, an apartment of this building is selected to be studied. Experimental devices are implemented to measure external weather conditions, indoor air temperature and relative humidity, as well as the thermal flux through the south building façade. The indoor comfort is also analyzed. Results show satisfactory conditions in the apartment and highlight the impact of the inhabitants' behavior with respect to their apartment. Moreover, a numerical validation is conducted on thermal flux through the wall via the simulation tool SPARK. Comparison shows a good agreement between the experimental data and the numerical results.

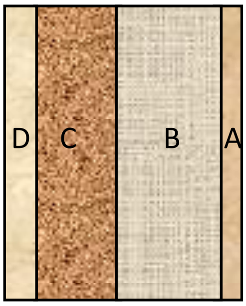
Methodology

Building overview

Figure 1: view of the North façade of the building

A building located in Fleury-La-Rivière, a small town in the Champagne-Ardenne region, is chosen for the study. It consists of three floors with six apartments and is oriented in such a way to maximize the exposure to direct sun rays. The envelope is composed of four layers which are detailed in Table 1 where the Hemp-concrete, sprayed into the walls, is used as external insulator. Materials properties are provided by the constructor. Apartments are equipped with electrical heaters and mechanical ventilation is used for air renewal.

Table 1: Properties of the building envelope layers



2 cm 13 cm 20 cm 1.5 cm
D: outermost surface

Material	Density ($Kg.m^{-3}$)	Thermal Conductivity ($W.m^{-1}K^{-1}$)	Heat Capacity ($J.Kg^{-1}°C^{-1}$)
A : Gypsum	900	0,25	850
B: Optibric	700	Req=1,07	850
C : Hemp-concrete	450	0,095	1000
D : Lime-sand plaster	1650	0,4	830

Experimental approach

Thermographic survey

Building envelope is inspected from the internal and external sides using infrared thermographic technic able to detect the constructions defects and eventual thermal bridges in the structure. For this, an IR FLIR SC620 camera (FLIR system, Wilsonville, OR) with a high resolution pixel detector (640×480 pixels) is used. Emissivity of the walls is set at 0.95 during the thermographic survey. Wall captions were performed in April 2015 early in the morning and, in September 2016 in the evening. These chosen dates guarantee a wide gradient of temperature between inside and outside.

External weather conditions

A weather station shown in Figure 2 is installed at the building roof in order to record external weather conditions. It is equipped with an Integrated Sensor Suit (ISS) to measure external temperature, relative humidity, solar radiations, wind speed and directions as well as rainfall rate. Time step is set to 30 minutes. Data is transmitted via a wireless connection and stored in a console receptor. Measurements were launched in November 27, 2015 until September 28, 2016.

Figure 2: Weather station of type Vantage Pro2 installed outside the building

Apartment monitoring

The study begins with a survey on the internal comfort in the apartment. The encountered problems were related to the high humidity and air leakage in the rooms. A mould development was also observed at the floor level. The selected apartment is a ground floor of 92.30 m^2 composed of four rooms (office, two bedrooms and a living room), a kitchen and a bathroom.A family of three members with two dogs live there.

Four thermohygrometers (TH BeanDevice), installed in the apartment rooms, measure dry temperature (°C) and relative humidity (%) of the indoor air. Three temperature globe sensors (T BeanDevice) also record the wet bulb globe temperature in three rooms except the kid’s room. Moreover, three thermal flowmeters are fixed at the south west office wall: one is placed at the ground level, and the others at a height of 1.20 m (Table 2). Flowmeters measure the thermal losses through the envelope (W/m^2). Data is monitored continuously from November 27, 2015 until September 28, 2016 with a time step of 15 minutes. It should be noticed that slight cracks are identified on this façade near the window.

Table 2: Experimental devices implemented inside the apartment

		
Thermohygrometer	Temperature sensor	Thermal flowmeters
Precision: ± 0.2 °C, ± 1.8 %	Precision: ± 0.1 °C	Precision: ± 5%

Numerical approach

South-west façade hygrothermal performance is simulated with SPARK numerical tool. SPARK is an object-oriented software that is very useful to solve differential systems equations using finite-difference method. Weather data is entered as inputs to the code. The approach proposed by Philipe, De Vries and Mendes to model heat and moisture transfers in hygroscopic materials is used. Moisture transport coefficients are calculated based on Crauss et al. works. Investigations are conducted on heat flux (thermal losses) through the office wall.

Results and discussions

Building envelope inspection

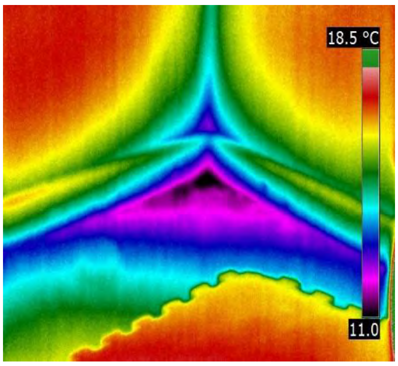


Figure 3 : Thermogram of parents bedroom inside corner

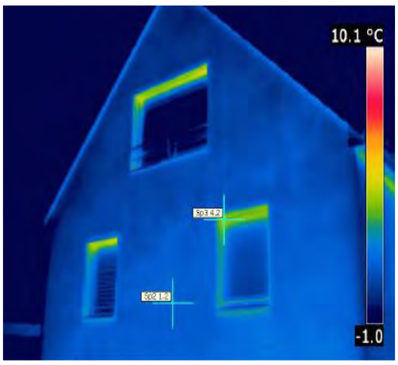

Figure 4 : Thermogram of east building façade

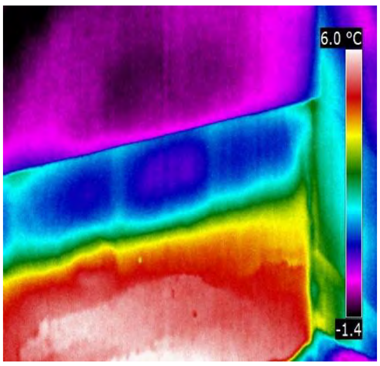

Figure 5 : Thermogram of building south-west façade

Figures 2, 3 and 4 show thermographic images of the internal and external building walls. One can observe that exterior surface temperatures are globally homogeneous. Heat losses appear at windows joints and air vents as well as the slab and floor level. This is an external insulation characteristic where insulator layer is cut at the ground level to avoid capillarity phenomenon. No thermal bridges due to timber framework are observed.

Indoor comfort analysis

The indoor comfort evaluation is performed using psychrometric chart for the different rooms. For this purpose, operative temperature (T_o) is calculated based on dry air temperature (T_a) given by thermohygrometers and the radiant temperature (T_r) deduced from globe temperature measurements (T_g). Calculation method is detailed as follows:

$$T_o = T_a + (1 - A)(T_r - T_a)$$

where *A* is a constant parameter depending on indoor air wind speed (v) :

$$\begin{cases} A = 0.5 \left(v < 0.2\, m.s^{-1} \Rightarrow \text{winter} \Rightarrow \text{closed windows}\right) \\ A = 0.7\ (v > 0.6\, m.s^{-1} \Rightarrow \text{summer} \Rightarrow \text{open windows}) \end{cases}$$

T_r is given by:

$$T_r = \left[\left(T_g + 273\right)^4 + \frac{1.1 \times 10^8 . v^{0.6}}{\varepsilon . D^{0.4}}\left(T_g - T_a\right)\right]^{\frac{1}{4}} - 273$$

$\mathcal{E}$ is the globe sensor emissivity and *D* its diameter in meters.

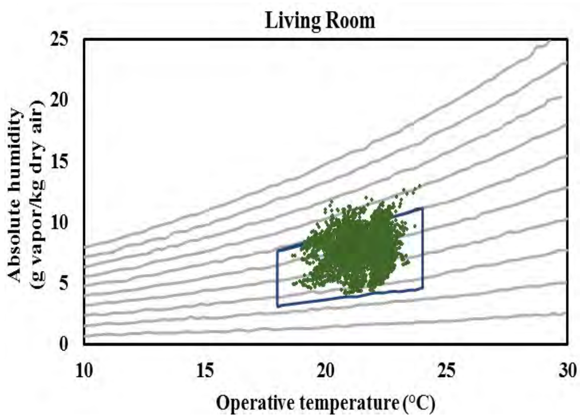

Figure 6: Psychrometric chart for the living room during winter season

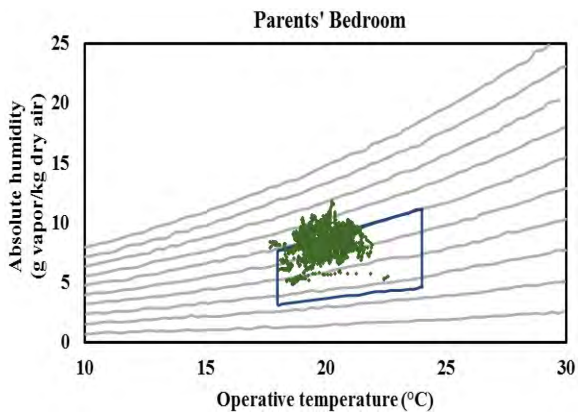

Figure 7: Psychrometric chart for the parents' bedroom during winter season

For simplicity reasons, Figures 6 till 9 present the results during winter and summer periods only for the living room and parents' bedroom. Referring to ASHREA standards, winter comfort zone is located between 18°C and 24°C for temperature and 25% to 60% for relative humidity. Otherwise, for summer period, comfort zone is defined as follows: temperature is allowed to fluctuate between 22°C and 27°C with a relative humidity between 40% and 60%. It can be noted that in terms of humidity, results are satisfactory but relative humidity reaches 70% several times in the living and parents rooms. This can be explained by the fact that kitchen is always opened to the living room and cooking activity usually occurs with a closed air vent. In addition, the laundry is dried inside the living room most of the time.

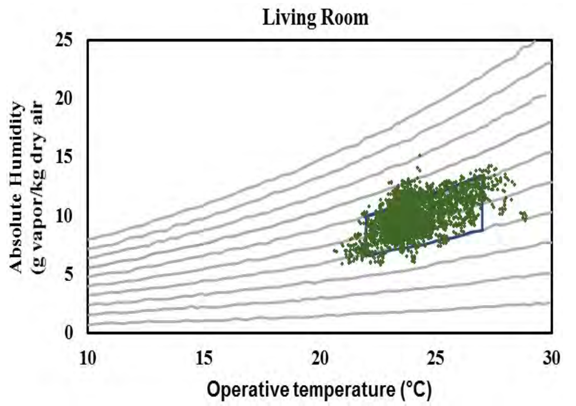

Figure 8 : Psychrometric chart for the living room during summer season

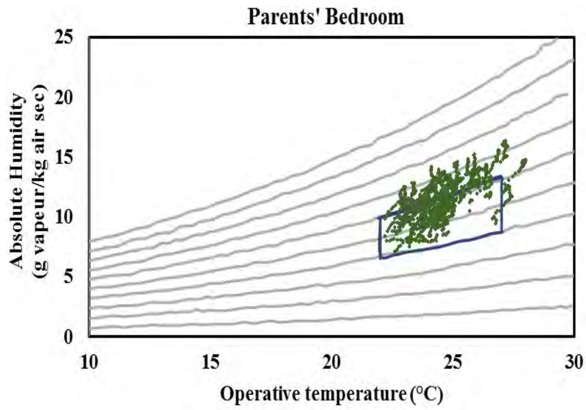

Figure 9 : Psychrometric chart for the parents' bedroom during summer season

For the parents bedroom, occasionally aerated, high humidity rates are observed: dogs are a non-negligible source of air moistening. Therefore, temperature comfort conditions are globally respected. During summer, the temperature exceeds sometimes 27°C: this could be explained by the heat waves period where external temperature reaches 40°C. This result highlights the Hemp-concrete ability to dampen external temperature variations since indoor temperature peaks are delayed about four to five hours in comparison with the outdoor peaks as seen in Figure 10.

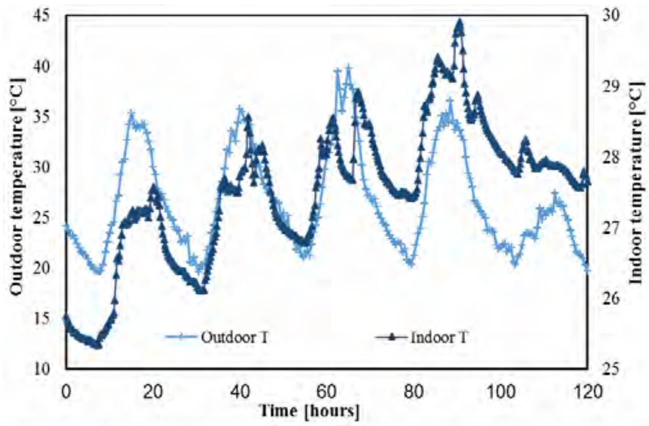

Figure 10 : Comparison between indoor and outdoor temperatures between August 20, 2016 and August 25, 2016

Experimental and numerical investigations on the thermal losses through the office wall

It should be mentioned that, at the beginning of the study, turning on the registration for three connections simultaneously exhausts rapidly the device's battery so that data were recorded for the first and the second flowmeter, then, in the next period, for the flowmeters 1 and 3. For the first period, Figure 11 shows a homogenous thermal flow over the height of the wall, whilst, in the second, thermal losses measured by flowmeter 3 (Figure 12) are greater than the losses measured by flowmeter 1. This is due to the third flowmeter position at the mid of the wall and exposed to wind and heavy rain. The latter can raise the wall thermal conductivity as well as the heat losses within the envelope. However, in both cases, thermal flow respects indoor temperature dynamic variations since it is proportional to the temperature gradient between inside and outside.

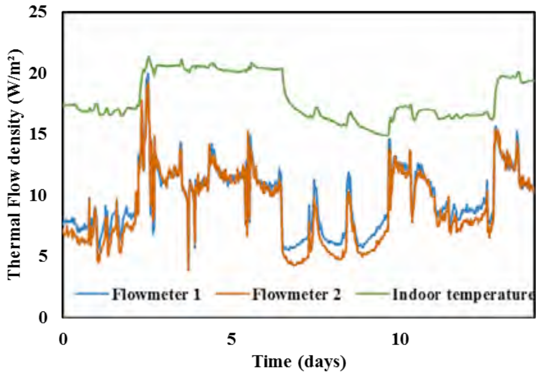

Figure 11: Experimental thermal flows and temperature in the office (Dec. 1st – Dec.15th 2015)

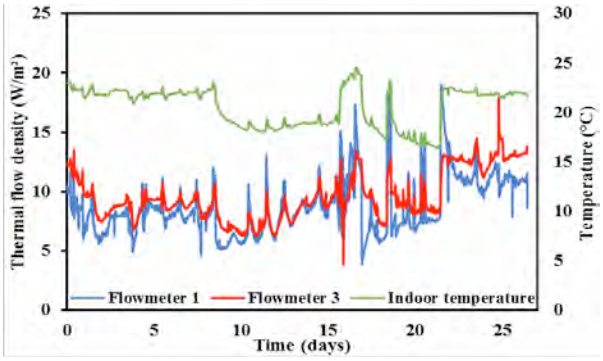

Figure 12: Experimental thermal flows and temperature in the office (Dec. 16th 2015 – Jan.11th 2016)

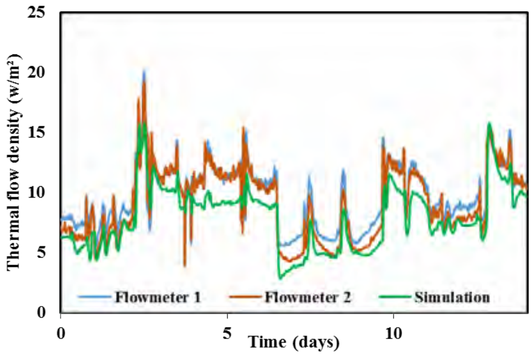

Figure 13 : Comparison between experimental and numerical thermal flows in the office (Dec. 1st – Dec.15th 2015)

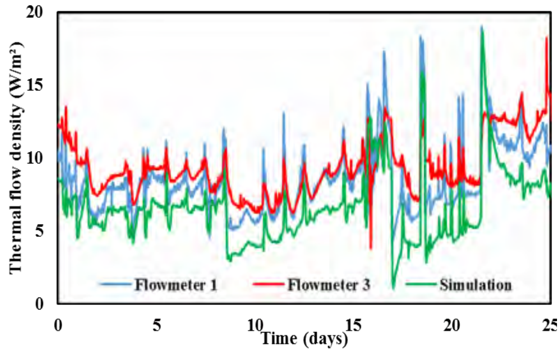

Figure 14 : Comparison between experimental and numerical thermal flows in the office (Dec. 16th 2015– Jan.11th 2016)

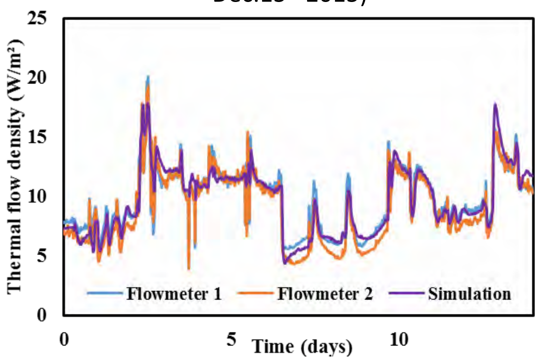

Figure 15 : Comparison between experimental and new numerical thermal flows in the office (Dec. 1st – Dec.15th 2015)

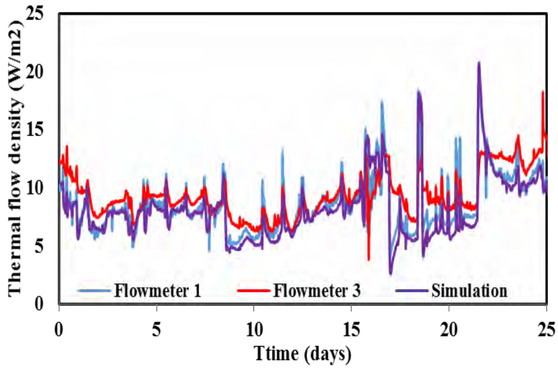

Figure 16 : Comparison between experimental and new numerical thermal flows in the office (Dec. 16th 2015 – Jan.11th 2016

Figure 13 and Figure 14 show a comparison between numerical and experimental heat fluxes through the wall. It can be observed that simulation underestimates globally the experimental measurements. The discrepancies could be explained by the uncertainty on the materials properties given by the constructor: for instance, thermal conductivity of the dry Hemp- concrete is about 0.095-0.1 $W.m^{-1}.K^{-1}$, while literature shows that this value could be much greater when Hemp-concrete is wet and can reach 0.18 $W.m^{-1}.K^{-1}$ (Collet & Pretot 2014). Therefore, taking into account the cracks in the façade, and the exposure of the wall to wind and rain, a thermal conductivity of 0.16 $W.m^{-1}.K^{-1}$ is more suitable. New numerical results show good improvements in comparison with the experiments as shown in Figure 15 and Figure 16.

Conclusion

In this work, a study of a hemp-lime building located in the north-east of France is proposed. The envelope presents a layer of 13 cm Hemp-concrete, used as external insulator. An apartment is selected to be the object of the study. A specific experimental equipment is implemented inside and outside to monitor comfort conditions in the different rooms. A numerical investigation is then conducted on the heat losses through the building south-west façade.

The results show satisfactory thermal comfort in the apartment, and some high relative humidities are detected due to the inhabitants behavior with respect to their apartment. They highlight also the Hemp-concrete ability to dampen outdoor temperature variations. Moreover, simulations present good agreement with the experimental data. However, a particular attention on the materials properties lead to an improvement in the results. No important thermal bridges due to timber framework are identified with the infrared thermography. Further observations are required on the cracks in the South-West façade to identify their effects on the envelope thermal conductivity. Globally, the Hemp-concrete insulation in this building seems to be efficient and the problems encountered are not related to the use of this bio-based material in the structure.

A new printed and spatially transformed ETFE foil provides shading and improves natural light and thermal comfort for membrane structures

Jan Cremers[1], Hannes Marx[1]

[1] Department of Architecture and Design, Hochschule für Technik Stuttgart (HFT), Stuttgart, Germany, jan.cremers@hft-stuttgart.de

Abstract: Standard membrane structures using ETFE foils have a very high solar transmission (a single layer of typical transparent ETFE foil > 93%). Regarding façade and roof applications this can result in serious problems with overheating and also causes a high degree of thermal discomfort. The presented new shading approach is inspired by the widely used architectural idea of the shed roof (saw-tooth roof). By using this geometrical idea with foils on a much smaller scale, the direct sunlight is blocked off, whereas the steeper surface is oriented away from the direct solar radiation and allows for diffuse sunlight in with a high visual transmission of about 92% (transparent ETFE foil) [1, p.114f],[2]. The printing pattern can be adjusted considering the sun´s position and the direct sunlight radiation. This also leads to an improvement with regard to light quality and glare risk inside the room. Samples of the new foil type have been manufactured in lab-scale to investigate different combinations of printing and geometry. Compared to a conventional system (flat foil, fritted/printed), the new spatially transformed ETFE foils with an optimized adaption of the printing patterns and geometry are examined to quantify the maximum cooling energy saving potential by using dynamic thermal simulations. Also, the effect on thermal comfort and the daylight quality is investigated.

Keywords: ETFE, membrane structure, solar shading, thermal comfort, daylight quality

Introduction

Building structures using textile fabrics or foils for the envelope are referred to as membrane structures. Polymer foils such as ethylene-tetra-fluoro-ethylene (ETFE) are implemented for roofs and façade areas but also for less complex applications such as weather- and sun protection. Typical foil thicknesses for this applications range from 100µm to 400µm. Due to the extremely low mass of ETFE foils (approx. 350 g/m² @200µm) and the high transmission in the visible and solar range (one layer ETFE clear > 92% @200µm) ETFE is an alternative to glass. [1, p.114f] [2]

Key design advantages are the aesthetic potential, the large possible span widths, the safe and low-effort application in overhead-situations (cp. to glass) and a short building time. Further benefits of large areas with translucent materials might be increased solar gains in winter with a maximum of visible transmission. However, the risk of overheating and glare effects without an appropriate sun protection in the summer case is very high. This leads to uncomfortable thermal- and visual conditions inside the building [5]. For these reasons, different options exist to minimize overheating and glare due too high luminous intensity. ETFE foils can be printed (fritting) e.g. with colours (silver) which have a high reflection capacity or tinted materials can be used in several colours. Optical properties can be controlled to some extent by the pigmentation grades and printing patterns. This influences the transmittance [τ], reflectance [ρ] and the absorption [α] coefficients. The major common disadvantage of available shading solutions for foils is the fixed transmittance coefficient regardless of the incidence angle of the sun. Another additional solution is an actively switchable sun protection for membrane cushions, where the offset of two top layers with raster graphics can be switch via air pressure changes. Thereby, the solar heat gain coefficient and the natural light situation can be adjusted, however only in a limited range. [1, p.190, 220] A new material (Nowoflon ET 6235 Z-IR) uses a solar-infra-red absorbing effect. Solar infra-red rays which are to a large extent responsible for heating up the building are absorbed by the film (which however leads to an increased secondary heat-transfer in the long-wave IR). [3] Another new material uses the passive daytime radiative cooling with a cooling power of up to 93 W/m² through the atmospheric window in the spectral range to cool down the interior space even during the day. [4] This material however has not been tested under real-live conditions so far (weathering, increasing absorption due to dirt/dust-accumulation or soiling, UV-stability).

The presented new shading approach is inspired by the widely used architectural idea of the shed roof (saw-tooth roof). By using this geometrical idea with foils on a much smaller scale the direct sunlight is blocked off, whereas the steeper surface is oriented away from the direct solar radiation and allows diffuse sunlight in with a high visual transmission of about 92% (transparent ETFE foil). The saw-tooth structure is downsized to a millimetre scale. This requires a geometric modification of the foil. The foil will not only be printed with a pattern, but also additionally spatially transformed, so that the printing pattern can be adjusted considering the sun´s position and the direct sunlight radiation. The spatial transformation with the consideration of the printing patterns is relevant for the reduction of the direct radiation inside the building to a minimum depending on the location. This improves the thermal comfort, saves cooling energy and achieves a largely glare- and shadow- free light situation with sufficient natural light.

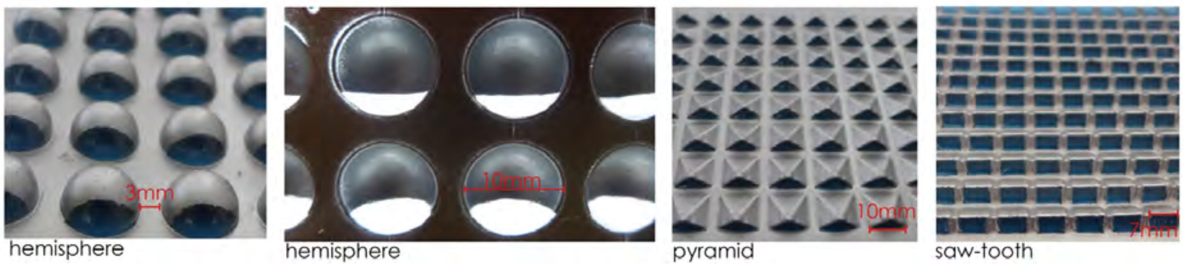

Figure 1. Samples of the new foil type in lab-scale

This allows for new creative- and application-oriented use of space in different climate regions, because natural daylight is extremely important for the visual comfort in covered areas (e.g. shopping malls). A comparable application of the shed roof idea has been followed up before which had involved one of the authors, but on the large scale of membrane cushions: For the roof and façades of the shopping mall "Dolce Vita Tejo" close to Lisbon, membrane cushions with the dimension of 10m x 10m and with partly double printed ETFE foils have been realized on an area of more than 40.000 m^2. They show the idea of a north light shed roof within the geometry of the cushions. In this project, membrane structures (ETFE foils) were mainly used, because allow for a lighter and therefore less expensive substructure compared to a conventional overhead glazing [1, p.256ff].

This study focuses on the summer case (cooling). To calculate the cooling load and to assess the thermal and visual comfort, dynamic simulation software TRNSYS 17.02 and DIVA 3.0 are used. The reduction of the solar gains by the spatial transformation foils in the summer case and the resulting cooling energy saving potential with sufficient natural light will be investigated.

Building integration (architectural qualities)

The new spatially transformed foil can be both applied for roof- and façade areas, thereby the considered printing patterns and the correct orientation of the installation is an important factor. Membrane cushions have at least 2 layers of foils which are stabilized by air at a low overpressure of about 200 - 800 Pascal [2-8 mbar] depending on size, geometry and external loads (wind, snow). Additional internal layers can be installed to get more air cavities. A typical heat transmission coefficient (U-value) for a one layer construction is about 7.3 W/m²K, for a two layer construction about 3.1 W/m²K and for a three layer construction about 2.1 W/m²K, also depending on heat flow direction and orientation (up/down resp. horiz./vert.).[1, p.216]

In a first step, we investigate the new spatially transformed applied as a middle layer of a cushion. The benefits are: flat application, no complex cutting patterns, very low mechanical stresses over the foil by the pressure equalization, no environmental influences (weathering, soiling), more flexibility with regard to orientation towards the sun.

Form optimization

The following simulations and form optimizations are based on the climate data by the German Meteorological Service (DWD) of the climate region of Stuttgart, Germany (latitude: 49°, longitude: 9°). External influences for the form optimization are the position of the sun by the zenith- and azimuth angle, ambient temperature [°C] and the intensity of the direct and diffuse irradiation [kWh/m²a] on the surface. Over the year, a horizontal surface has the highest irradiation, which falls by a steeper angle of the surface. The same applies to diffuse and direct irradiation. This leads to high losses by conventional sun protections regarding solar gains and natural daylight for the winter case and overheating problems in summer. Considering the moderate to hot climate (T_{amb} > 20 °C) with the corresponding high irradiation, results to a period where sun protection is unavoidable in the time from May 19th to Sept. 7th. The optimum solution we found is a geometry with an angle for the south surface of 23° and an angle of 16° for the south-east and south-west surface. The north side has an optimal slope of 65° (highest sun position). Therefore a large amount of diffuse irradiation and natural light enters the building, but no direct irradiation. From an economical point of view, this means that huge manufacturing costs for an optimal location-specific spatially transformed geometry is necessary. Therefore, we investigated the idea of using a fixed geometry which can be combined with adopted printing patterns according to the project's needs. This lead to a hemisphere geometry.

To achieve an optimally coordinated printing pattern, the geometry is investigated on the direct irradiation. Figure 2 shows as an example of a hemisphere geometry the different printing patterns. For a whole year the ideal printed part is found to be about 73% and for the relevant period (May 19th to Sept. 7th) about 57%. These simulations were executed with the software RHINO and the Plugin GRASSHOPPER with the add-on LADYBUG. We considered a gap between the hemispheres to allow for the mechanical stress distribution within the ETFE foil that is needed for the application as a middle layer in a cushion.

Figure 2. Hemisphere geometry a) printing part of one year b) printing part with time limit

Simulation Method

The following describes the method to achieve the desired effect regarding to the direction-selective printing patterns. Variants are defined and compared in the simulation software TRNSYS and DIVA.

Physical properties

The basis of numerous simulation is the exact determination of physical properties for the material characteristics. Therefore, the Bavarian Center for Applied Energy Research (ZAE Bayern) has provided spectral data of the clear ETFE-foil with a thickness of 200 µm measured according to DIN EN 410. The background of the measurement data is the analysis of angle dependent data with Optics 6.0 and Window 7.4. The calculated parameters (Fresnel formula) from the measurement data is written in a DOE-2-report. Table 1 shows some important parameters which were used for the TRNSYS simulations.

For the daylight simulation with DIVA 3.0 (based on the software tool "Radiance") calculated diffuse reflection and diffuse transmission coefficients are used for the input file, see Table 2. Assumptions were made for the calculation of the printed ETFE foil with regard to the reflectance (55%), transmittance (5%) and the absorption coefficient (40%).

Table 1. Simulation parameters for TRNSYS

WinID-Lib (TRNSYS) *Description*	g-Value *[-]*	T-sol *[-]*	Rf-sol *[-]*	T-vis *[-]*	Data generated *[software]*
ETFE - clear	0.933	0.93	0.061	0.923	OPTIC/WINDOW
ETFE - printed	0.201	0.074	0.58	0.057	OPTIC/WINDOW

Table 2. Simulation parameters for Radiance

Window (RADIANCE) *Description*	color *red/green/blue*	specularity *[-]*	roughness *[-]*	transmission *[-]*	transmitted *specularity*
ETFE - clear	0.98	0.08	0.00	0.99	0.98
ETFE - printed	0.44	0.29	0.00	0.16	0.40

Thermal simulation (3D Model for the building simulation)

A fictitious 3D- Building model which was built in SketchUp 8 with the Plugin Trnsys3d that represents an atrium with a 3-layer membrane cushion in the roof area, cp. Figure 3. The dimensions of the abstract building are 20 meters x 20 meters and 10 meters height, with a total volume of 4000m³. It consists of 3 radiation zones and a total of 7 airnodes. Zones I to V are coupled with a defined air mass transfer. Thereby zone I is at the bottom and zone V is directly below the roof. The air mass is transported from one zone to the next zone on top with a fix air change of 2/h to the upper zone. It is assumed that 10% of the air mass of one zone is transported downwards due to convection effects. The roof area is divided into 24 horizontal fields which represent the hemisphere geometry abstractly, because TRNSYS can not directly handle curvature. For the same reason the curvature of the membrane cushion is not depicted as well. The 3 - layer membrane cushion is modelled with a space of 0.50 m between each foil and a total volume of 200 m². The boundary temperature of the atrium´s walls is defined with a constant temperature of 20°C and the boundary ground temperature with constant 15°C. Additionally the atrium is surrounded with a shading group (purple colour) to block solar irradiation.

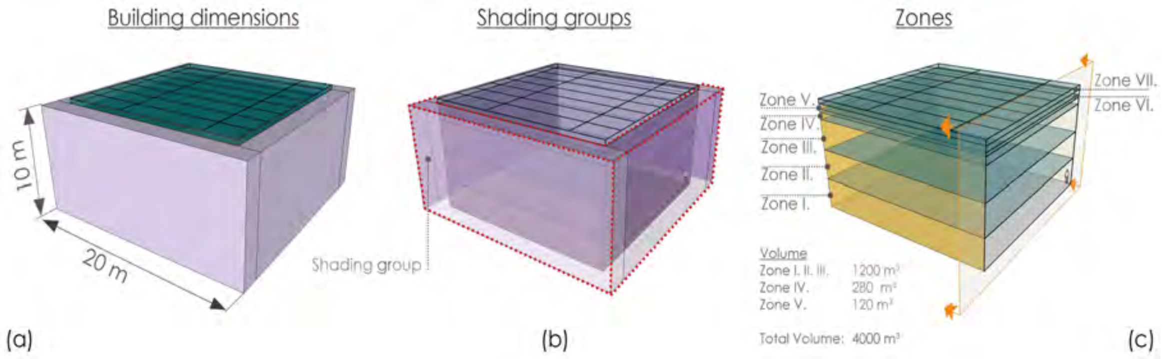

Figure 3. 3D – Model for the building simulation: a) building dimension b) shading groups c) zones

Dummy Zone

A special requirement for the simulations is to represent the small-scale structures. Unfortunately, it is not possible to simulate the geometry in a 1:1 scale with TRNSYS. Therefore, a "dummy zone" with a higher scale factor of 10^3 is created. However, due to the complex form of the hemisphere geometry, the hemisphere is split into 24 single surfaces, cp. Figure 4b. The essential geometry is located in the middle around 8 identical geometries (Figure 4a). This is necessary to get the shading factor for one geometry to each other. The generated *.shm file (Figure 4c = one surface) will then be transferred to the external membrane layer of the multi-zone building.

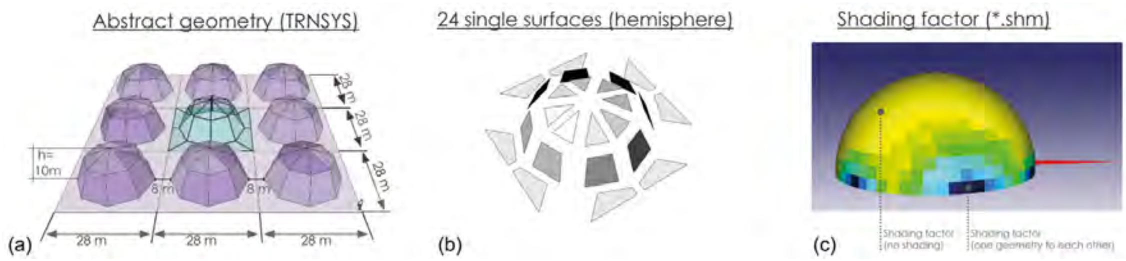

Figure 4. Dummy zone: a) abstract geometry b) single surfaces c) shading factor

The resulting "dummy zone" in TRNSYS shows additional information about the orientation, the shading factors and view factors to the sky for the individual surfaces: (slope: 70 deg. - 0.68, slope: 25 deg. - 0.95, slope: 0 deg. – 1.0). The printed part to block direct radiation is set to 66% and the clear part to get diffuse radiation into the atrium is defined as 44%.

Results and Discussion

Thermal Comfort

The thermal comfort is evaluated by the operative temperature (human thermal comfort), which is a useful parameter to compare simulation results, because the boundary conditions are considered to be the air temperature and the radiance temperatures of the surfaces inside the building. Thereby, for the rating of the variants the number of hours above the operative temperature of 26°C inside the atrium (without a cooling system) is analysed. For the evaluation of the thermal comfort it is assumed that the atrium is used Monday to Friday from 8 am to 7 pm with nobody present at weekends. Figure 5 shows the relative simulation results for the different geometries and zones (I to V) over one year.

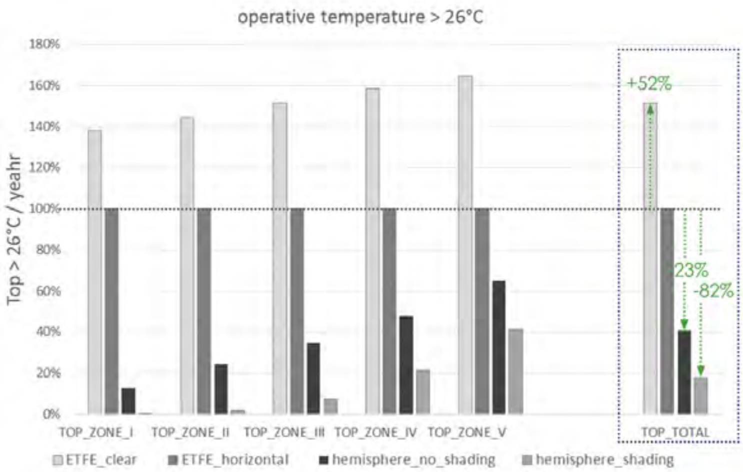

Figure 5. Thermal comfort (operative temperature > 26°C)

Variant "ETFE_clear" is the worst option for the thermal comfort in the summer case, because it consists of a membrane cushion with simple clear ETFE foils in all three layers. The variant "ETFE_horizontal" is defined as the related reference (100%). It has a typical printing ratio of 66% without any spatial transformations. The improvement of the thermal comfort by the spatially transformed foil reaches up to 82 %. Two explicit variants of the spatially transformed foils were calculated. One is calculated without the own shading factor and the other one with the own shading factor (*.shm) to show this important effect. With the own shading factor in variant "hemisphere_shading" the improvement compared to variant "hemisphere_no_shading" reaches up to 22 % for the summer case.

Cooling and heating loads

The cooling time period for the summer case is from May 19th to Sept. 7th. It is necessary to cool down the atrium to 26°C within this period. The energy demand for heating up to 22°C during the day and 16,5°C during the night is calculated for the winter case (Sept. 8th to May 18th). We considered no more internal gains inside the atrium, because this has no significant influence on the rating. All results are based on simulation time steps of 0.25 hour.

The relative results for the energy loads are showed in Figure 6 for the heating and cooling case. Again, the conventional variant "ETFE_horizontal" is the reference variant to compare the energy loads (100%). By changing the upper layer with the spatially transformed foil compared it is possible to reduce the cooling load by about 69% compared to the horizontal printed ETFE foil. Without the consideration of the own shading factor "hemisphere_no_shading" the cooling load is reduced by about 52% compared to the reference variant. The heating energy demand in the winter case increases, when the spatially transformed foil is used. In variant "hemisphere_shading" the increase of the heating energy demand is about 11% and in variant "hemisphere_no_shading" about 5%.

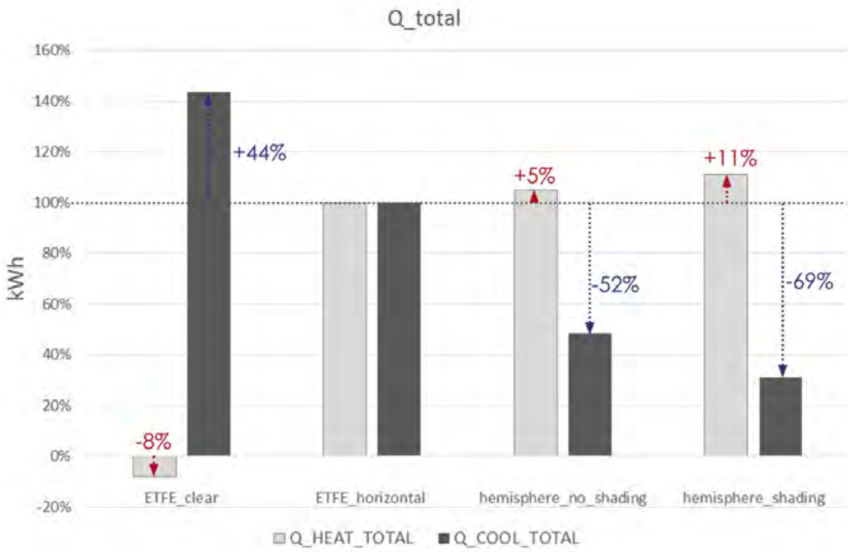

Figure 6. Heating loads (light grey) and cooling loads (dark grey) [kWh]

Daylight simulation

The visual comfort is as important as the thermal comfort, especially for lounge areas or the previous example for atriums. Due to the high transparency of the ETFE foils (τ_{vis} 92% @ 200µm) the risk of glare effects by too high luminance inside the building is extremely high [5]. Moreover unpleasant shadow effects could arise.

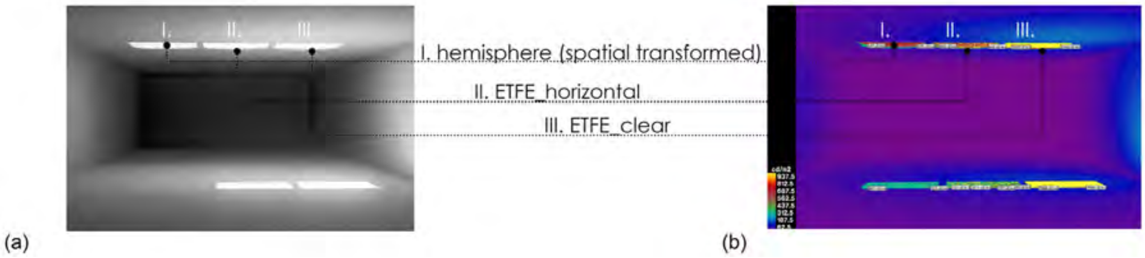

Figure 7. Daylight simulation a) shadowing b) false colour

Figure 7 shows an example of a daylight simulation for June 21st at 12:00 o´clock at noon (highest sun position) with a clear sky and direct irradiation. Illustrated is a 3 –layer membrane cushion. The dimensions are 0.5 meters x 1.0 meters. Three different variants are investigated of the glare- and shadow free situation. The printing part in variant I. (spatially transformed, hemisphere r=10mm) and variant II. (horizontal printing without spatial transformation) amounts to 66%, variant III is not printed (clear ETFE foil).

Figure 7 shows, that with variant I (≈ 300 cd/m²) a pleasant luminance inside the building plus a sufficient reduction of direct sunlight for a pleasant workplace (DIN EN 12464) could be achieved. Variant II (≈ 1000 cd/m²) and variant III (≈ 8000 cd/m²) indicate a too high luminance on the workplace.

Further daylight simulations (daylight utilization) will be investigated in another currently unpublished paper.

Conclusion and Outlook

The main aim of the present study was to describe the potential of the new spatially transformed ETFE foil with regard to the improvement of thermal comfort, energy consumption and daylight quality. It was difficult to model and simulate the extremely small scale of the structure with consideration of the orientation, own shading factor and the optimally coordinated printing pattern. Compared to a conventional ETFE foil (flat printing), the thermal comfort of a spatially transformed foil was found to improve by about 82%. However, the results have to be validated by measurements (transmission, reflection, g-values for different angles) as soon as we have larger material samples. The informative value of the simulations results alone is limited as a lot of factors can lead to different findings. The high improvement comes from the blocking of direct sunlight. It is expected to save up to 69% cooling energy compared to a horizontal printed foil. In the winter case, as a consequence of the reduction of solar gains, the heating energy demand increases about 11%. In order to make a more precise estimation, a site-specific simulation should be carried out. The natural daylight results shows that a pleasant workplace with about 300 cd/m² could be achieved in the summer case.

The simulation results can be validated with these measurement data. At the end and if the new spatially transformed ETFE foil can also be put to production on a larger scale, it might allow for significantly improved solar protection of membrane cushion applications.

Abstract: There is no fixed method to analyse the carbon impact of a building. The most comprehensive guidance given in BS:EN 15978 (BSi, 2011) but provides a poor understanding for designers on how building components make up the Green House Gas impact of buildings. This study quantifies different construction materials within a building showing their significance at differing Life Cycle stages in relation to the design lifespan. The study is conducted through 3 and 6 storey timber, steel, concrete buildings covering differing foundation typologies. An existing software package ATHENA and an elemental bottom up approach is used to compare relative impacts. Apartment floor areas used in UK regulations create large variations in the assessment of Life Cycle impacts which do not include communal areas which requires a whole building approach. There are not large variances in the overall Life Cycle between differing construction types with concrete reducing replacement factors, steel with high recyclability potential in later Life Cycle stages and timber sequestering carbon in early stages of the building Life Cycle. Elementally foundations, upper floors and facade materials have the most influence and should be considered carefully at an early design stage.

Keywords: LCA, Apartment buildings, Building Lifespan, Future Carbon Use

Introduction

When considering the life span of a building it is important to promote the architect's understanding of various design implications and their impact on lifetime Green House Gas (GHG). As buildings are made up of hundreds of products whose interaction is not straight forward, it is unpractical for designers to understand their design choices, to conduct an extensive assessment of materials early in the design process. Full Life Cycle (LC) quantification in previous studies are often inconsistent on the LC stages and measurement parameters used, despite many using BS:EN 15978 (BSi, 2011a), a modular framework which is also adopted in this study. Additional problems include the lack of a standardised methodology in quantifying the impact of apartments units within larger structures. Currently in UK regulatory standards as operational carbon is determined by internal floor space only (Building Regulations, 2013). Measurements do not accurately quantify materials for a building in a LC study and exclude common areas.

The use of building materials needs to be considered across a range of LC stages otherwise an incorrect assumption may be made, for instance where an unrobust material must be replaced several times over the building's life. Considering the full LC impacts the operational carbon is important to determine when overheating is likely to occur. This is conducted using CIBSE TM52 (CIBSE, 2013) methodology in naturally ventilated buildings, detailed in a previous study (Din and Brotas, 2016) that used weather files from Eames et al (2012) to produce a dynamic model using future climate data to account for different constructions. The study presented the likely date for active cooling to be adopted and determined the subsequent GHG impact.

Aim

This study assesses typical apartment buildings using ATHENA (2017) software against a bottom up methodology utilising comprehensive Life Cycle stages, where practical, to determine the LC stages of importance in a GHG calculation of a building. The GHG of differing constructions types demonstrates the main features that influence the whole Life Carbon solution, for a given building life span.

Background

Menzies et al (2013) identified a range of LC free tools, the one that was most closely aligned to the construction process was ATHENA (2017) Impact Estimator for Buildings, a US based software which covers a range of LC stages of a building life span.

Within previous academic literature a range of life spans for dwellings were adopted (Chastas et al, 2016) but 60 years is most commonly used by the industry. This is the basis of BRE certification (Anderson et al, 2009), and 100 years is used in PAS 2050:2011 (BSi,2011b) for products. The apartment buildings in this study use these life spans with associated replacement factors along with the influences on operational GHG.

Previous studies have quantified the Embodied Carbon of foundations (Sandanayake et al 2016) in isolation but do not deal with the superstructure or other systems that impact LC values. An holistic picture is required so that design dependencies can be understood. Most foundation types require concrete (which has a high GHG impact) with pad, strip and pile foundation typologies used in this study dependant on the height and construction weight of the apartment building considered. These archetypes are based on a good ground bearing conditions rather than real life solutions where physical surveys and investigations can influence the final structural design.

Environmental Product Declarations (EPD) (BSi, 2012) are used as the GHG dataset for construction materials directly from manufacturers. In particular EPDs account for sequestration (Wood for Good, 2014) which highly influences timber construction calculations. As a result, this paper investigates the influence of sequestration over differing LC stages. In contrast, heavyweight materials (CIBSE, 2016) have the advantage of storing heat which delays the installation of air conditioning thus minimising operational GHG.

Some LC stages are practical to quantify whilst others are not, due to lack of information available and their impact on the overall LC value is discussed in the paper.

Product stage			Construction		Use stage							End of life			
A1	A2	A3	A4	A5	B1	B2	B3	B4	B5	B6	B7	C1	C2	C3	C4
raw material suppy	Transport	Manufacturing	Transport	Construction Installation Process	Use	Maintenance	Repair	Replacement	Refurbishment	Operational Energy	Operational Water	Deconstruction Demolition	Transport	Waste processing	Disposal

Figure 1. Stages within BS:EN 15978 (BSi, 2011) by author.

Three and 6 storey apartment buildings are evaluated with a core serving two apartments per floor, a typical arrangement for many multi occupancy buildings. In the case of the 6 storey solution a lift is added to show its influence the on LC calculation. These solutions comply with the UK building regulations although the 6 storey timber building would not due to a lack of redundancy required in disproportionate collapse in the current regulations, it is presented in this study for comparison purposes. A number of duplications in measurements occur and are discussed as part of the results.

Methodology

Each individual apartment has a floor plan layout is similar to those dynamically modelled in a previous study (Din and Brotas, 2016). The Gross Internal Floor Area (GIFA) remains constant but the Gross External Floor Area (GEFA) changes according to the construction used. The U values of the dwelling envelope is similar in each case by compensating the thickness of the insulation layers. The dwellings are organised in a 3 and 6 storey blocks and individually named to assess the importance of their position within the block. A floor to ceiling height of 2.5m is used, in line with PassivHaus Planning Package (PHPP) default calculations.

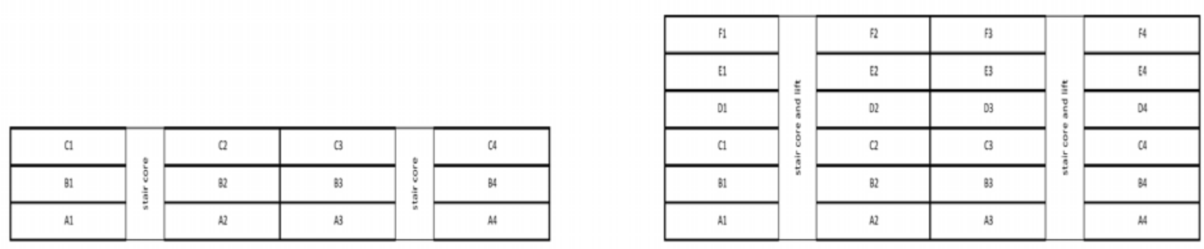

Figure 2. Dwelling nomenclature used to identify apartments within the blocks modelled

The 3 structural types used reflect the majority of the UK apartment market. Each typology influences the construction of other elements used within the building and are summarised in Table 1.

Table 1. Construction specification of each model.

Structure	Timber	Steel	Concrete
stairs	wood	sheet steel	precast concrete
lift core	cement board	cement board	concrete block
foundation			
3st	450 concrete strip	concrete pad	600 concrete strip
6st	600 concrete strip	precast pile	precast pile
ground floor	concrete slab	concrete slab	concrete slab
party floor	timber I joists	steel tray with screed infill	hollowcore
ext wall	timber, insulation, sw boards	met sec, insulation, cement board	block, insulation, block
internal wall	timber	met sec	timber
windows	double glazed timber	double glazed timber	double glazed timber

It should be noted that all timber is Forest Stewardship Council (FSC) certified and the concrete used is 50% cement replacement in line with current industry norms (with reinforcement added according to current structural regulations) and metals with a 70% recycled content. The ATHENA software is used for the 3 storey buildings of differing structures over 60 years. All the input values quantified in both the software and the bottom up analysis are identical to ensure consistency. The basis of the elemental calculation is as follows:

LC Stages A1-A3 the GHG is quantified using EPDs from manufacturers. Taking the weight of elements stage A4 is established by using 30km road transport in 10 tonne truck loads. In addition, timber is sourced from Poland (with associated road transport) and steel from China (a combination of container ship and road transport) these parameters avoid the investigation of individual supply chains resulting in a unique LC analysis rather than an archetypal one.

Stage A5 is approximated as 6 months of a digger on site for foundations or a piling rig for 3 months. Other equipment used includes 6 months for a forklift and 6 months of 10 power tools with an additional 6 months of power tools for a concrete structure with a cement mixer for 6 months. Construction timescales and equipment used are doubled for 6 storey structures apart from the piling rig. These approximations are based on observations, experience and construction site records.

Stages B1 to B3 are not included in this study as these would require observed facility management records and site assessments. Stage B4 is used instead with replacement rates based on Williams et al (2012). Within this stage buildability (replacing dependant elements), disposal, recyclability and deconstruction of the replaced material is considered based on a smaller LC study within this module. Stage B6 is based on a Din and Brotas (2016) energy use under future climates, by assessing the reduction in heating and the increase in overheating periods to estimate the date of adoption of active cooling systems and the associated GHG usage. Hot water and appliance loads have been accounted for from a PHPP calculation for an individual flat. In addition, an annual reduction of 2% in grid carbon is calculated as an extrapolation of the last 10 years UK electrical grid figures (DEFRA, 2017) to account for future grid decarbonisation through the adoption of low carbon generation sources. Stage B7 is ignored as this has little GHG impact but has a greater weighting within other LC indicators.

Stage C1 deconstruction, is established as 3 months for a concrete/steel building and 2 months for a timber building. The basis of the calculation of stage C2 is by mass in a 30km radius to a recycling plant or landfill in the UK. C3 recycling rates are taken from WRAP Net Waste Tool figures (Burton and Freidrich, 2008) by assigning a proportion of the original GHG value dependant on the recyclability of the material. This stage is not calculated from EPDs figures, which give an optimistic end of use scenarios such as waste to energy. C4 is the residual calculated amount land filled with materials classified either as inert or degradable with the associated GHG outcome. D stage of the LC dealing with reuse is ignored as this is beyond the scope of the study boundaries.

Given the detailed data classification outcomes can be presented in various formats. The ranking of the design importance of the findings is discussed.

Results

As ATHENA is an US based software some input parameters available may not be appropriate for other locations. This requires compromises to be made on the location and the associated GHG values for grid carbon (for its internal calculations). In addition operational carbon B6 is not considered by the software. The results are broken down by stage and by material classification in Figure 3. These are for the 3 storey block of the differing construction types over 60 years covering stages A-C of the building LC.

The clear distinction can be made between the different constructions with a penalty for using a timber construction with an increased number of replacement cycles within the building lifetime. Stages A1-A3 predominate the results and may encourage designers to adopt a timber building design for the archetypes explored.

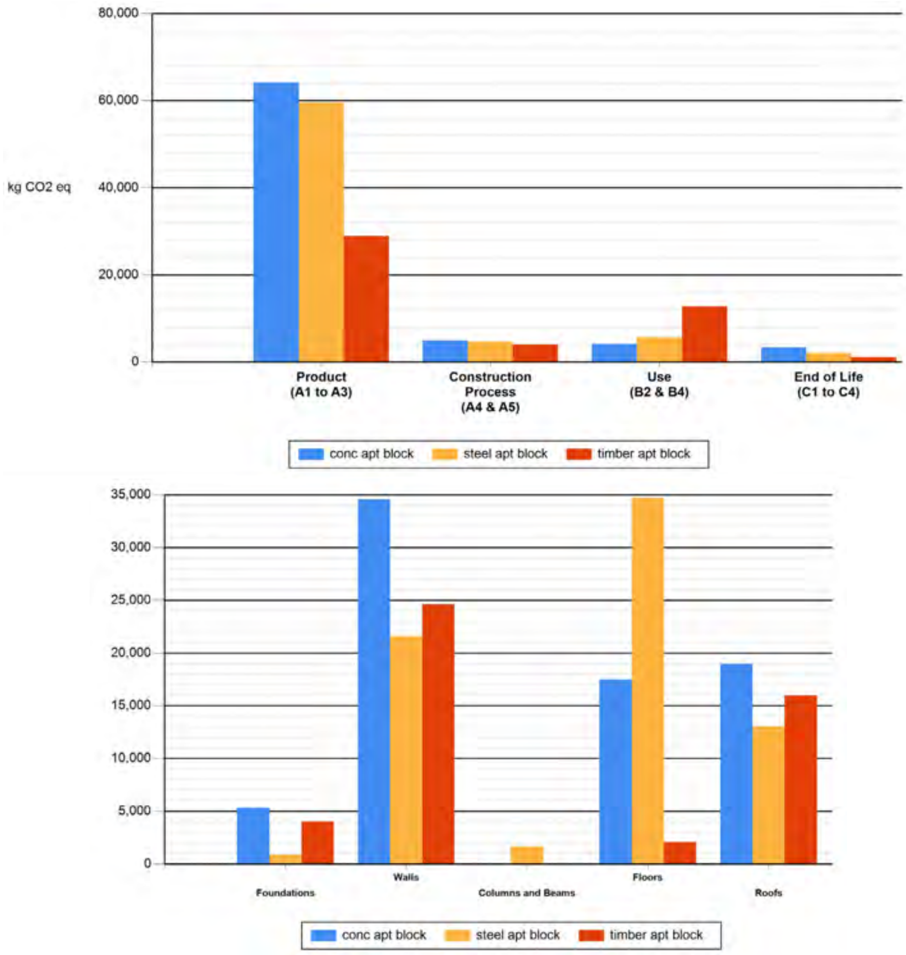

Figure 3. GHG ATHENA breakdown by building component

Foundations play a minor role in the component breakdown in ATHENA with the external walls and floors being the most critical elements within the concept design for the overall building. These distinctions would be proportionally larger for the 6 storey building with unchanging areas of the roof and foundations spread across more of the overall GEFA of the apartments.

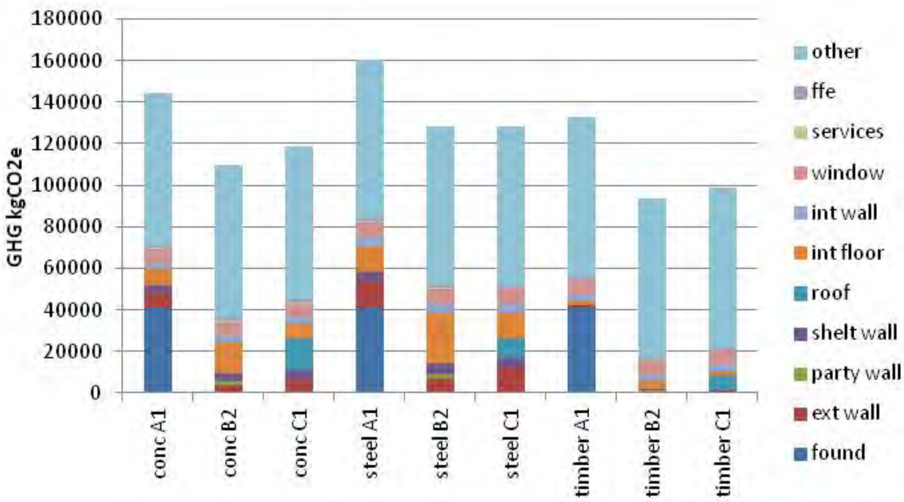

Figure 4. component breakdown by unit location

In Figure 4, the 'other' section includes transportation of materials and the operational carbon of the dwelling which is largely consistent in all units regardless its location in the building due to high insulation levels. Where a dwelling is placed on the ground floor (A1) the foundation causes a significant increase but is replaced by wall and floor influences in upper dwellings following the trend in the ATHENA results. The values given in ATHENA are low in comparison to the building overall when the number in Fig 4 is multiplied for the whole building. 9% of values measured are consistent across all cases which cover elements such as kitchens, bathrooms and services. The dwellings GHG values (excluding other) range from lowest to highest by a factor of 10 between a mid timber B2 apartment and steel A1 ground floor unit.

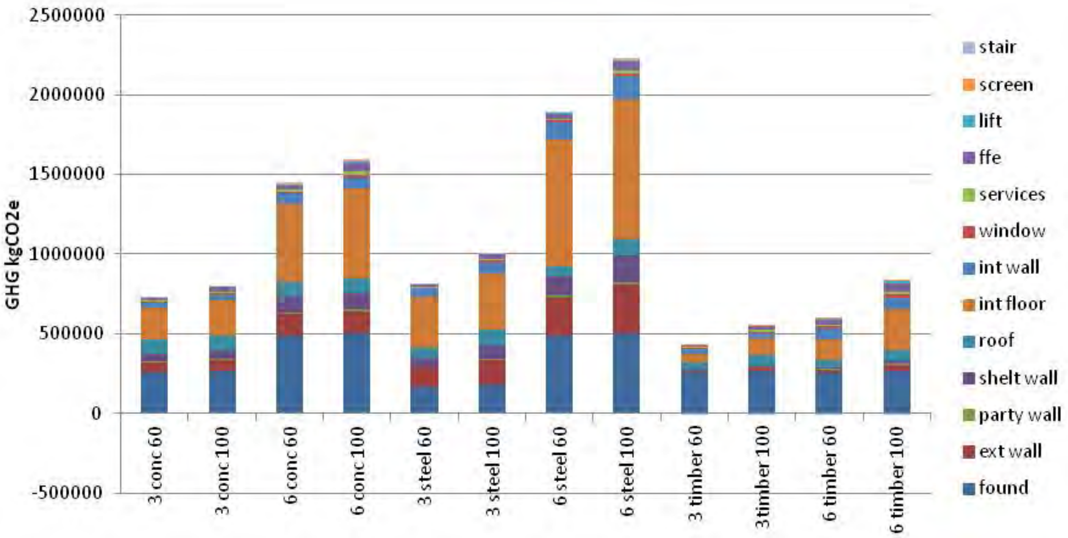

Figure 5. Building type by construction, height and lifespan

Figure 5 shows that the taller the building is, the higher is its proportional LC impact however, this is more than compensated by the amount of dwellings the block contains and its overall GEFA. Foundations (13% in the case of a pad foundation) are a major component second to internal floors (21%), in multi-storey buildings. Roof types vary little between construction typologies and foundations have a single influence on the overall result. The operational B6 and construction A4, A5, C1, C2 values are excluded from the graph due their largely consistent value, which makes up over half of the LC quantification.

The variation in facade materials using timber as a base case, is that a load bearing concrete facade has a factor of 4 times more GHG and a steel lightweight metal section (met sec) wall 6 times higher GHG value across all the LC stages.

Figure 6 shows the impact of all LC stages on each construction typology. The operational B6 stage contributes to 60% of the buildings overall GHG expenditure and shows an area where the designer's decisions can have an important impact. About 30% is in the A1-A3 stage which has the most impact on the environment as this stage typically lasting 1-2 years rather than the longer timeframe of the operational GHG used within stage B of a LC study. Replacement accounts for around 12% of the overall value showing that buildings should be built for longevity rather than demolition (C1) and expending the GHG of stage A of the LC again.

Currently only a small proportion is recovered from buildings at around 5% of the GHG (concrete piling excluded due to difficulty of extraction). Although this is larger for a steel building, due to the full extent of the subsequent supply and international transport chain to a new building product and its proportional mixing with virgin material, has not been assessed in this study, which leads to a lower steel recycling advantage.

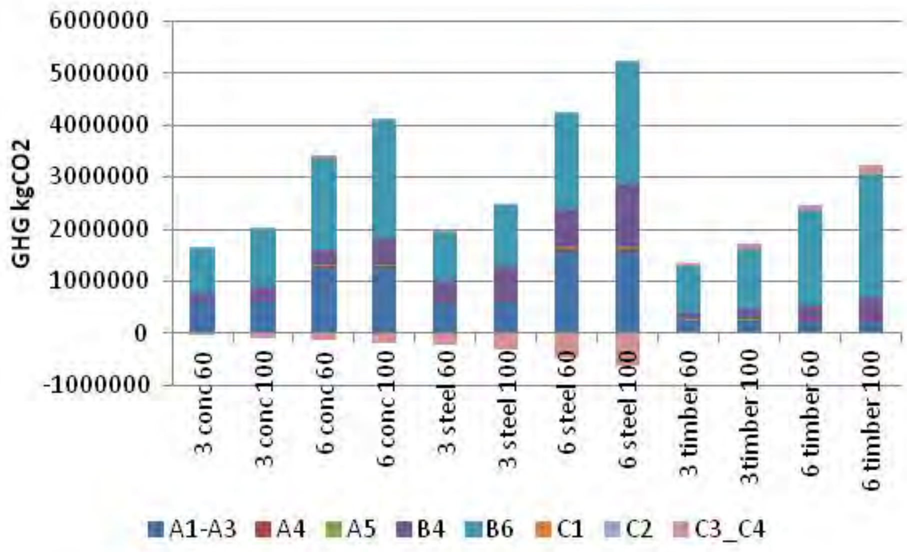

Figure 6. Building breakdown by LC stage

Future Implementation

The transportation in supply chains has been approximated in this study along with the omission of the maintenance and repair of buildings which has the potential to make heavier weight buildings lower in overall GHG impact and compete with the GHG of a timber building. The variation in site carbon is interesting and a further level of detail from site measurements, with indirect carbon through workmen transportation values, may create a better quantification of this stage.

The implementations of stage D and its accounting methodology for the transferable reuse of materials is critical in properly assessing the impact of stage C in a project LC along with the practicality of the proportion of recycling needs. This study shows guidelines can be established when stages outside of traditional 'Cradle to Gate' analysis.

Conclusion

ATHENA has the correct order of magnitude of results for the superstructure of a building but not to its substructure especially when piling is used. There is an overestimate of stage B of the LC compared to in depth studies conducted.

Results show GHG of differing structural materials are inconclusive with other LC stages influencing results significantly. A piled foundation does cause considerable GHG expenditure leading to arguments for taller buildings to expend the GHG of piling across more dwellings. Other aspects such as internal floor construction may be resolved by using a hybrid design approach, differing structural materials and other building construction elements.

The analysis of dwellings within the blocks show a large variation depending on the construction and location but does not lead to useful results when shared services are accounted for. A steel building has the worst GHG impact , as a result of the international transportation distances covered but does gain credits from its recyclability. Timber buildings have the lowest GHG impact but the sequestered carbon is largely released back into the environment at its disposal stage. Buildings should be built for longevity as demonstrated by concrete structures with the proportional increase in GHG being insignificant compared to the life time of building service.

Given the incremental decrease of grid carbon more needs to be done in terms of reducing the amount of operational carbon in buildings. Particular areas of interest are appliance and hot water loads which are not adequately addressed by current regulations or PassivHaus standards. The results do show a framework for a toolkit to show the significance of factors to consider at the design stage even if the results given do not show a distinct construction preference. Results both by life cycle stage and material need to be considered in parallel within the design process.

Abstract: Sun-shading plant-inspired skins can use plant actuation principles to develop reversible motions. This paper describe the intersection between plant actuation principles, their morphology and low energy strategies, to propose potential mechanisms in responsive dynamic shading skins. This paper will investigate non-autonomous reversible plant movements to develop elastic kinetic solar screens. New approaches to soft mechanics have found inspiration in plant movements applied to pliable structures in architecture. Interestingly, global flexibility is often achieved through the adaptive behaviour of plants that change their morphological features by acting as living hinges and allowing for elastic deformations. These motion patterns are found in nastic structures which are very promising as natural actuators. By studying how plant species take advantage of mechanical, compositional and structural gradients to perform mobility with minimal energy use, it is possible to learn how to integrate these properties into the design of kinetic shading solar screens. The focus of this review is to understand soft mechanics approaches and their applications for responsive shading skins. A critical review of the current progress in mechanical properties and actuation principles of nastic plant movements is illustrated.

Keywords: Responsive skins, Plant movements, Biomimetics, Deployable structures, Actuation

Introduction

The urgent demand for more energy-efficient and sustainable architecture is leading to a growing interest in kinetic skins that can adapt to changing environmental conditions (Fiorito *et al.*, 2016). The term 'Kinetic skins' has come to be used to refer to building envelopes capable of configuration changes due to their geometrical, material and mechanical properties (Adrover, 2015). Recent literature shows that most environmental kinetic facades are based on mechanically operated systems. A mechanical system, such as Al Bahr Towers in Abu Dhabi, has the disadvantage that it is complex to build, difficult to maintain and require high energy consumption (Reichert et al., 2015). Lately, more recent attention has focused on two approaches that have the potential to simplify the mechanical designs utilized in kinetic skins, Biomimicry and Smart materials.

Plant tissues have the capability to adapt to constantly changing environmental conditions even when their cells are dead. This is achieved through iterative feedback loops, which sense, record, inform and instruct the fibre composite to alter their current configuration towards an optimized one (Mingallon and Ramaswamy, 2012). By studying how plant species take advantage of mechanical, compositional and structural gradients to perform mobility with minimal energy use, it is possible to learn how to integrate these properties into the design of kinetic shading solar screens.

Moreover, the investigation of new responsive smart materials could simplify mechanical actuation (Reichert et al., 2015). Materials with embedded actuation can alter their morphology under external stimulation and adapt autonomously to their respective environmental conditions (Schaeffer and Vogt, 2010; Reichert et al., 2015). Smart materials have permanently reversible properties which can be triggered by external stimulus such as temperature (Schaeffer and Vogt, 2010). For example, Shape memory alloys have the potential to act as a servo-actuators to design low-tech responsive skins. The activation temperatures of Embedded Shape Memory Alloys can be achieved in hot arid climates through direct solar contact and can be applied for responsive solar shading skin. This paper concentrates on the mechanical, compositional and structural constraints which enable plants to actuate their organs, summarizing current knowledge in how plants generate movement. It focuses on reversible plant movements with a view to the development of elastic kinetic solar screen.

Biomimetic Approach for efficient movement

Biomimicry is imitation of nature to design objects and systems help in solve human problems. Some designers and researchers argues that nature is the best, most influencial and the guaranteed source of innovation. Plants can be a promising inspiration source to learn soft mechanics (Schleicher et al., 2015). Suitable analogues can be developed into responsive motions production that could meet design as well as sustainability demands. Plants have evolved the capability to respond to a wide range of signals and efficiently adapt to changing environmental conditions. They perform mobility with minimal energy use, due to the fibre elasticity composition and integration of sensing and actuating capabilities into their system (Fiorito et al., 2016). In particular, the leaves and pedals bending and folding mechanisms demonstrate how the number of mechanical parts can be reduced by making use of flexible and elastic material properties and allow reversible deformations (Poppinga *et al.*, 2010; Schleicher *et al.*, 2015).

For biologists, the classification of plant movements is an important aspect to understand how plants develop morphogenesis (Boudaoud, 2010), and specially how they respond to environmental stimuli. Plant biologists distinguish between nastic and tropic movements. The movement in nastic responses is independent of the spatial direction of a stimulus, whereas tropic movements are influenced by its direction (Burgert and Fratzl, 2009; Schleicher, 2016)**.** Generally, Nastic movements occur due to the swelling and shrinking of motor cells and result in reversible movements that could be of high interest in responsive skin applications (Ueda and Nakamura, 2006; Poppinga *et al.*, 2010). In order to understand how plants' movements develop in general, they will be analysed through different applications in mechanical, compositional and structural systems.

Actuation mechanisms in Plant Movements

Numerous studies have attempted to classify plant movements. Poppinga et al. (2010) developed wide-ranged matrix focused on actuation systems found in active or passive nastic plant movements in response of environmental stimuli. The study distinguished between autonomous and non-autonomous movements as well as the active and passive. Non-autonomous movements are mostly reversible deformations caused by a release of stored elastic energy in pre-stressed structures or are initiated by external mechanical forces.

Similarly, (Schleicher, 2016) distinguished between frequently encountered drivers like external loads, growth processes, hydraulic mechanisms, and elastic instabilities.

Accordingly, a more detailed structure of nastic non-autonomous reversible movements is given as shown in figure 1. Reversible Plant movements can be actuated either hydraulically in active way by turgor changes, or in passive way by hygroscopic swelling and shrinking. Other mechanisms use the release of stored elastic energy after an external trigger or by direct application of mechanical forces. The next section will discuss the actuation mechanisms derived by external loads, hydraulic mechanisms, and elastic instabilities.

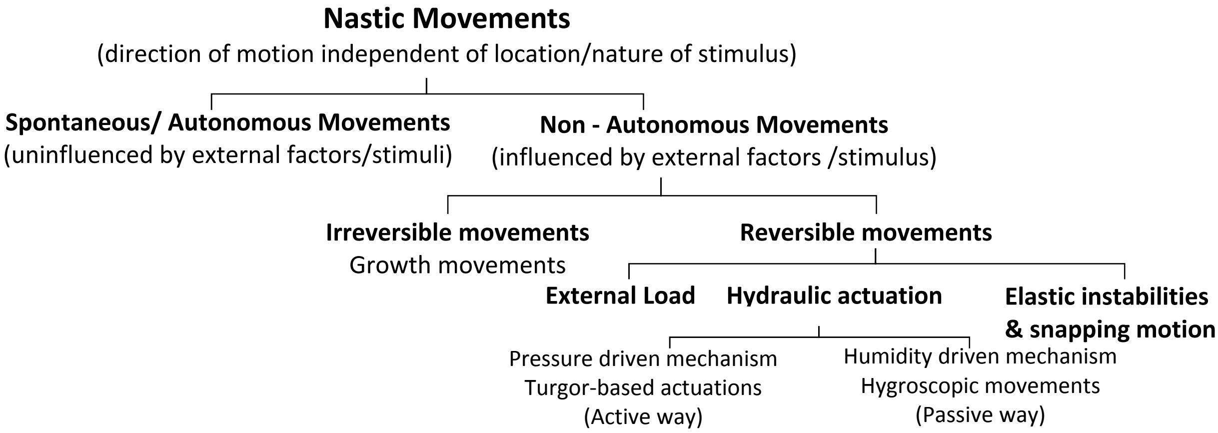

Figure 1. Classification of nastic plant movements.

External loads

The motion of plants can be a response to direct application of mechanical forces. This movement follows an external influencing factor passively rather than being driven by the plant itself. Different loads can act on a plant, such as flowing water, wind gusts, contact with pollinating insects, or attacks of natural predators. According to the plant's composition, an outer drive can either cause an immediate deformation or be diverted to trigger secondary transformation processes (Schleicher, 2016). For example, the movement of the Bird-of-paradise due to the pollination mechanism is triggered by a locally applied load at a specific point as shown in figure 2 (c).

Hydraulic mechanisms

Hydraulic mechanisms in plant movements can be actuated either actively by turgor changes that lead to reversible movement or passively by hygroscopic swelling and shrinking. *Osmotic actuation:* Osmotic actuation is a ubiquitous plant-inspired actuation strategy that has a very low power consumption but is capable of generating effective movements in a wide variety of environmental conditions (Sinibaldi *et al.*, 2014). Living plant cell can generate an internal hydrostatic pressure (turgor pressure) by maintaining an osmotic gradient between its cytoplasm and ambient environment (Li and Wang, 2016). Variations in turgor pressure enable plants to perform volumetric changes and rapid movements (Burgert and Fratzl, 2009; Schleicher, 2016).The pressure driven, water based actuation mechanism in plants is closely related to the hydraulic and pneumatic actuators that are attractive for morphing applications in adaptive structures (Li and Wang, 2016). For example, Mimosa pudica exhibits a rapid, defensive response to external stimuli, closing its leaves and bending its pulvinus. Motor cells, divided into flexor and extensor cells on the ventral and dorsal side of the leaf as shown in figure 2 (a), respectively, regulate the volume and shape according to their relative turgor pressure (Guo *et al.*, 2015).

Hygroscopic shrinking or swelling mechanism: Other than the pressure driven mechanism, plants also exploit a humidity driven mechanism to achieve shape change and actuation. Plant cell walls are composed of a hydrophilic material, so will shrink in volume due to evaporation when they are exposed to dry atmosphere. This process can occur in both living cells and dead cells in the sclerenchyma tissues (Li and Wang, 2016). For example, a change in relative humidity causes a closed, tightly packed Pine cone to open gradually. The mechanism relies on the bilayered structure, the active outer layer of tissue, closely packed long parallel thick-walled cells respond by expanding longitudinally when exposed to humidity and shrinking when dried, while the inner passive layer does not respond as strongly as shown in figure 2 (b) (Reyssat and Mahadevan, 2009). But to be consistent with the scope of this review, this mechanism is only applicable in humid climates.

Elastic instabilities and snapping motion

Elastic instabilities and snap-buckling effects are methods for translating small stimuli into large and amplified movements. Snap-buckling effects speed up movements beyond the limits imposed by simple hydraulic mechanisms. These elastic instabilities are special mechanical failure modes characterized by a sudden deformation of a structural element withdrawing from high tensile or compressive stresses by deflecting into a less strained but geometrically deformed state. In particular carnivorous plants like the Venus Flytrap seem to have mastered that technique (Schleicher, 2016). Interestingly, a kind of "memory" appears to be involved in the leaf closure (Ueda and Nakamura, 2006). The main source of the fast closure is the bistable, doubly curved structure of the leaves, which snap-buckle to reverse their Gaussian curvature upon closing as shown in figure 2 (d) (Guo *et al.*, 2015).

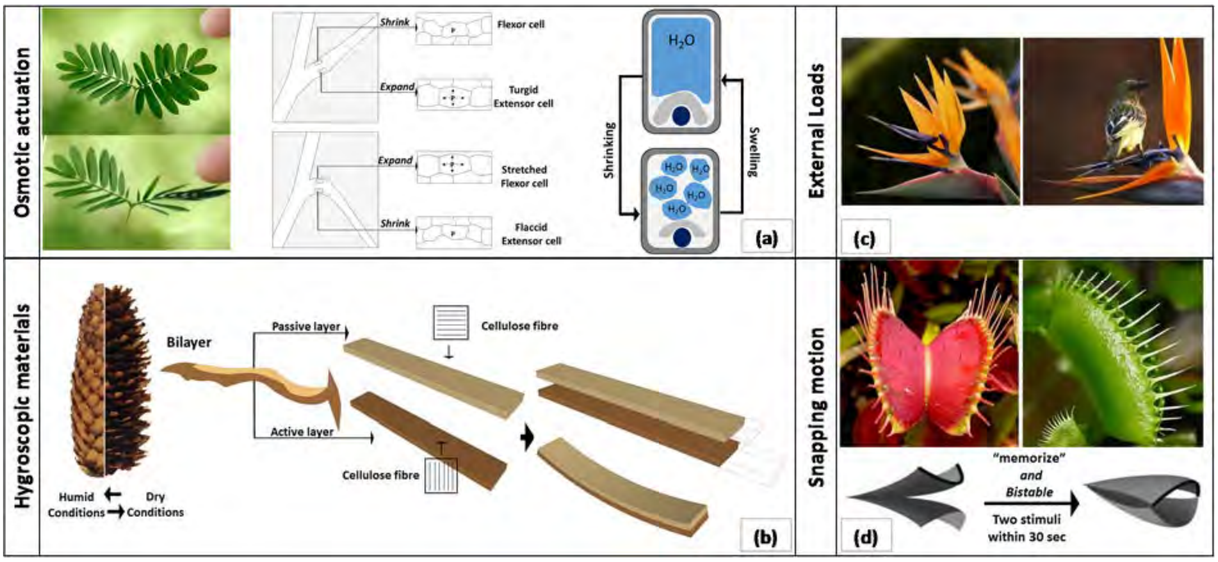

Figure 2. Reversible movements in the plant kingdom.

Compositional features

Plants have also evolved to strategically combine various physiological features with different actuation mechanisms to achieve sophisticated movements (Li and Wang, 2016). Material self-organization is a processes present in the formation and adaptation of biological tissues. They are responsible of the resultant high performance, found in natural fibre composites, to deal with unprecedented environmental conditions (Mingallon and Ramaswamy, 2012). They have the ability to create gradients of tissue, cell or cell wall properties to create actuator-type "smart" materials. The organ deformation is controlled at various levels of tissue hierarchy as shown in Figure 3, which are: Geometrical tissue organization at the micro-level, and Cell size, density and Cell wall polymer composition at the macro-level as shown in Figure 4 (Burgert and Fratzl, 2009). The composition and the geometry of cellular patterns influence the complexity of the actuation system, the folding directions and the reversibility of the system.

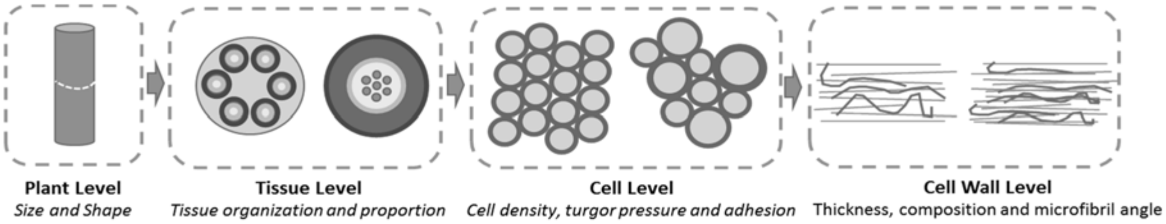

Figure 3. Hierarchy of mechanical parameters influencing plant movements.

Cellular organization (micro-level)

Plant materials are made up of plant tissues, either simple tissues, or complex tissues, each with their own structure (Gibson, 2012). Plant tissues are essentially close-walled cellular solids, which are well known for providing better stiffness and strength to density ratios as compared to their constituent solid materials. Cellular organization could also facilitate movements (Li and Wang, 2016). The cellular structure of plants varies, from the largely honeycomb-like cells of wood to closed-cell, liquid-filled foam-like thin-walled parenchyma cells and to composites of these two cellular structures, as in arborescent palm stems. Honeycombs have prismatic cells which can be periodic (often hexagonal, but sometimes rectangular or triangular) or random (as in Voronoi honeycombs. Foams have polyhedral cells, typically without a repeating unit cell. Open-cell foams are solid at the edges only, while closed-cell foams have solid faces (Gibson, 2012). Integrating the cellular feature and osmotic pressurization mechanism can provide the ability to achieve differential pressurization for more complicated deformations (Li and Wang, 2016).

Fibrous cell wall materials (macro-level)

Plant cell walls are fibrous in nature, non-homogenous membrane, consisting layers of four basic building blocks: cellulose (the main structural fibre of the plant kingdom) hemicellulose, lignin and pectin. Each fiber has a complex, layered structure consisting of a thin primary wall encircling a secondary wall. The secondary wall is made up of three layers and the thick middle layer determines the mechanical properties of the fiber (Kalia *et al.*, 2011). Although the microstructure of plant cell walls varies in different types of plants (Gibson, 2012), all cell walls are composites of cellulose fibrils and a partially cellulosic matrix material. They are assembled into three major architectures: parallel fibrillar, sheet-like, and bulk. Microfibrillar angle is defined as the angle between fiber axis and microfibrils, and it was found to be a crucial factor in determining the mechanical properties of plant organs (Kalia *et al.*, 2011). For example, in bilayers, differential swelling of neighbouring tissues with dissimilar microfibril angle and/or degree of matrix swelling leads to reversible shape changes (Brule *et al.*, 2016). In summary, Cellulose orientation in plant cells direct organ actuation.

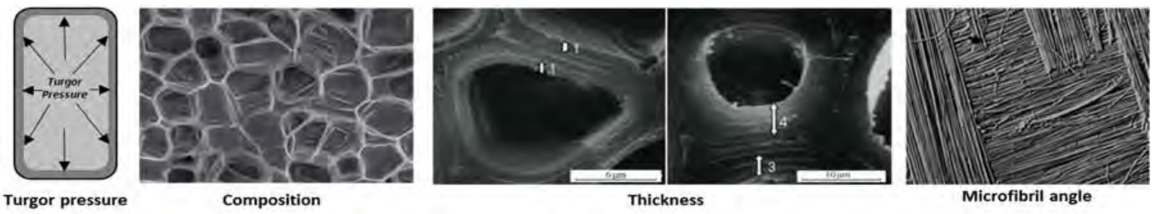

Figure 4. Cell and cell wall level.

Structural systems in engineering

The employment of elasticity within a structure facilitates not only the generation of complex geometries, but also creates elastic kinetic structures. Plant flexibility, represent a compliant mechanism that reduces the number of mechanical parts through integrating mechanical actuation into the materials themselves. (Schleicher, 2016). Howell (2001) defined Compliant Mechanisms as mechanisms that gain their motion from the deflection of elastic members and transforms the kinetic energy to strain energy in the members and then transforms it back to the kinetic energy (Howell, 2001). Compliant mechanisms combine strength with elasticity and gain some of their mobility from flexible members deflection rather than only from movable joints (Howell, 2001; Schleicher, 2016). In pliable systems the deformation behaviour of individual elements is constrained by their neighbouring elements. The linking of these elements allows the transmission of forces and torque (Schleicher *et al.*, 2011). Thus the deformation of one element will result in the deformation of the adjacent element. This relationship can be used to build up a cascading deformation movement. Pliable structures are based on elastic deformation as well as on the fact that it can convert between different stable configurations (Vergauwen *et al.*, 2017).

Bending-active structures are pliable constructions, which generate their geometrical form and their system rigidity by elastically deforming their members (Schleicher *et al.*, 2011). Bending-active structures, defined by Lienhard as structural systems that include curved beam or shell elements which base their geometry on the elastic deformation initially planar configuration. Yet, most bending-active structures are designed to bear loads and to be stiff only in their final configuration (Lienhard, 2014). Some researchers combine folding (plastic deformation) and bending (elastic deformation) using Curved-line folding to design efficient kinetic system. Curved-line folding is the act of folding paper along a curved crease pattern in order to create a 3D shape. (Vergauwen *et al.*, 2014) demonstrates how the choice of the composition of the crease pattern, the curvature of the creases and the Length–Thickness Ratio affect the resulting kinetic. In addition, Vergauwen *et al.* (2017) introduced the secondary layer principle (Bilayering) to perfectly control the folding motion by changing the distance between the two layers, which drive the layers to tension and pull into the desired position. On the whole, the selection of the composition, the structural behaviour and material have a great responsibility on the actuation system.

Applications of kinetic solar shadings

Some projects link kinetic design with biomimicry; from the selection and investigation of plant movements to the abstraction methods which were developed to translate plant movements into hinge-less elastic kinetics for deployable structures.

(Project A) The Flectofin® façade was developed by a team; from Plant Biomechanics Group (PBG) and the Institute of Building Structures and Structural Design (ITKE). A sun-shading system for complex building facades was inspired by the elastic deformation behaviour of the Bird-Of-Paradise flower. It is based on the valvular pollination mechanism of the Bird-Of Paradise flower. The logic of curved line folding was discovered accidentally from manufacturing tolerances but is understood as a key to the function of the mechanism. The curved-line folding kinematics was informed by the rapid trap closure mechanism of the carnivorous waterwheel plant (Lienhard *et al.*, 2010; Lienhard *et al.*, 2011; Lienhard, 2014).

(Project B) The Thematic Pavilion at the EXPO 2012 trade-fair in Yeosu, Korea was inspired by Flectofin® concept. It was proven that up-scaling of the basic principle is possible.

It is magnified to the large scale of 108 individual GFRP lamellas with varying heights that are deformed by controlled buckling. The skin can adapt to light and physical building conditions.

(Project C) was inspired by Aldrovanda vesiculosa. This aquatic carnivorous plant has a quick and reversible snapping motion. The movement is hydraulically driven by a central surface with a midrib, which cause a bidirectional change (Schleicher et al., 2015).

(Project D) The Lily mechanism was inspired by the compliant mechanism in the flower of Lilium casablanca (Liliaceae). The movement of the plant organ is based on unidirectional changes at the periphery caused by differential edge growth. Since the movement driver is based on internal changes of the material state, a temperature-controlled actuator that enforces edge expansion was simulated (Schleicher et al., 2015).

(Project E) Hygroskin project is developed by another team from the Institute for Computational Design (ICD), Achim menges in collaboration with Oliver david krieg and Steffen Reichert, presented a comprehensive development of smart skins based on the biomimetic transfer of hygroscopic actuation of plant cones. The shape change of wood was utilized to develop humidity responsive, integrated technical system (Reichert et al., 2015).

(Project F) studied the same mechanism of hygromorphic (moisture-sensitive) materials by (Holstov *et al.*, 2015) to produce low-tech low-cost adaptive systems by deploying materials with embedded responsive properties. A prototype of a responsive umbrella canopy consists of triangular panels with 7 different types of active layers.

Table 1. Summary of Bio-inspired skin systems.

	Project name	Project	Plant-Inspired	Biomimetic Methodological Approaches	Actuation mechanism
Project A	Flectofin		Bird-Of-Paradise (Strelitzia reginae, Strelitziaceae)	'Bottom-up-approach'	Valvular pollination mechanism
Project B	Thematic Pavilion				Elastic mechanism based on structural failure (buckling).
Project C	Lily Mechanism		Lilium casablanca	'Bottom-up-approach'	Differential edge growth in the tepals
Project D	Aldrovanda vesiculosa		Aldrovanda vesiculosa (Droseraceae)	'Bottom-up-approach'	Hydraulically driven by a central surface with a midrib
Project E	Hygroskin		Pine cone	'Bottom-up-approach'	Hygroscopic actuation (shrinkage and swelling wood)
Project F	Hygromorphic responsive umbrella		Conifer cones (e.g. spruce and pine cones)	'Top-down-approach'	Hygroscopic actuation (shrinkage and swelling wood)

Conclusion

The inability of contemporary adaptive skin systems to meet performance and cost efficiency requirements is a result of their excessive dependence on mechanical components which is associated with increased complexity and cost. In contrast, plant-inspired skins present an alternative approach of soft mechanics which provide opportunities for design of low-cost low-tech adaptive skins achieving dynamic behaviour by means of passive response. The current study has provided an understanding for the response mechanism of plants and principles for selection of their configuration. A number of morphological and compositional parameters affecting plant movements have been discussed across multiple scales ranging from tissues to cells and cell walls. The core principles of bi-layering have been extracted and discussed to develop Plant-inspired hinge-less kinetic skins. Future research could focus on development of efficient strategies; such as Bi-stability for practical application.

PLEA 2017 EDINBURGH
Design to Thrive

An inquiry on residential furniture market in terms of innovative technologies and materials

Elnaz Farjami[1], Ozlem Olgaç Türker[2]

[1.] Res. Assist. Elnaz Farjami, Department of Architecture, Eastern Mediterranean University, Famagusta, north Cyprus. elnaz.farjami@cc.emu.edu.tr
[2.] Assoc. Prof. Dr. Özlem Olgaç Türker, Department of Interior Architecture, Eastern Mediterranean University, Famagusta, north Cyprus. ozlem.olgac@emu.edu.tr

Abstract: Innovative technologies in residential furniture design are important for improving the quality of future life. Material characteristics changed their old role of being less important in design, to a new functional performance after the Industrial Revolution. Innovative materials (smart / green) are believed to affect various aspects of contemporary design industry deeply, at all scales such as furniture, interior design, architecture and urban design. Nano technology serving smart materials is expected to change our environment, so it is necessary to take advantage of it and produce healthier, comfortable and humane materials, by considering all aspects of sustainable design and manufacturing. The aim of this study is an investigation on the usage frequency of innovative materials in residential furniture which is less than the expectations due to high cost or lack of knowledge etc. and extracts the positive features for residential furniture. The residential furniture in professional market is scanned through a selected international furniture fair, which collects a high number of companies from all around the world. Through this way, the study is expected to inspire the development, as well as the spread of usage of innovative materials in residential furniture.

Keywords: innovative materials, technology, residential furniture, green materials, smart materials

Introduction

Based on the definition of sustainability including energy efficiency, which is applicable in all scales of design, innovative technology is upgrading rapidly. Innovative technology provides various solutions and opportunities for human lives, environment and future lifestyle. By making innovations, there is a number of concerns such as maintaining environmental quality and extending the life-time; adapting and adjusting with the least disruption for other activities; low energy and material consumption, and low cost (Nakib, F. 2010).

This embodied energy, which is used during the material production processes, has different approaches in various types of materials, e.g. plastics, concrete and steel have higher amount of embodied energy in material construction as opposed to natural materials as timber and stone. Additionally, one of the most significant criteria to achieve sustainability is the volume of emission of toxic gases, which is used during the material usage period and production processes. Moreover, the right choice of sustainable materials is a vital point in human health issues (Onaran, B., 2009; Aktas, G. G., 2012).

Furniture as one of the main elements in interior design issues, has two main concerns in sustainability context, which are the long term usage and the materials used in production process. Accordingly, the selected materials for both building and furniture can be selected from the ones which are manufactured efficiently by concerning the energy and material consumption from renewable sources to make long-lasting, recycled materials and not to give out the indoor contaminants. Local, natural and green material can be designed in order to improve the material and energy efficiency in interior elements, comfort, aesthetics, economical issues and ecology (Onaran, B. 2009; Aktaş, G. G., 2012).

The frequency of using innovative technology and materials in residential furniture is less than the expectations due to reasons as high cost or lack of knowledge. The questions to discuss are: How do the innovative materials, including both smart and green materials, affect the contemporary residential furniture? Is the rising amount of research on innovations in materials, reflected to residential furniture market?

The aim of this study is an investigation on the usage frequency of innovative materials such as smart and green materials, in residential furniture market. In order to achieve this aim, a wide range of the aspects of innovative materials and the direct relationships with the residential furniture is explored. Moreover, a number of suggestions and recommendations about increasing the functionality of applying smart and green materials on residential furniture is discussed in conclusion.

Due to the lack of enough case studies to find out the exact types of innovative materials that the companies are applying, researchers are rely on commercial websites to collect the required data. The residential furniture in professional market has been scanned through a selected international furniture fair, which collects a high number of companies from all around the world. Keywords which are related to the features of innovative technology and materials are extracted from literature surveys such as books, articles, papers on innovative furniture materials.

Innovations in Residential Furniture:

Furniture design is an interdisciplinary science since it is related to humanities, applied art and good knowledge of working with material and manufacturing method that leads to have broad range of designing rules (Postell, 2012). The periods until industrial revolution made a simple connection between materials and architecture. The way that different materials used was for their practicality, availability, decorative characteristics and forms (Addington & Schodek, 2005). Within improvement processes, 18th century holds an important step, where designers started to think about flexibility and adaptability in furniture as a concept of sustainability. Furniture design depends on various factors such as insight, judgment, designing proficiency, engineering rules and good information of rules for problem solving. Different requirements for furniture design are vision, idea and obligation to satisfy the user. However, by using contemporary technologies in furniture production to make them sustainable and easy to use, clean, move, and change, user satisfaction increases (Broekhuizen, 2012; Ritter, 2007).

The environment has the capability of surviving from some of the human action without leading any harm (Field III, 2001). The contemporary developments based on new technology introduces innovative furniture. These new systems improve the quality of life, and ecologic character Hence, in order to accomplish the aim of the study, the categories related to innovative furniture are classified below to be searched on web sites of companies:

Smart:

- Nano-materials: Inorganic, Fullerenes, Graphene, Nano-crystals, …
- Nano-coating materials: Polypropylene, Polyethylene, sustainable coating, …

Green materials:

- Natural eco-friendly materials: Bamboo, Original wood, Health impacts
- Recycled materials: Salvage, Reusable, Rebuilt, Eco-friendly
- Nature-friendly design, packaging.

Smart Materials in Residential Furniture

There are widespread types of Nano-technology for different activities in furniture industry. Recently, the Nano-materials in furniture are considered by many contemporary furniture companies and factories (Broekhuizen, 2012). Nano-technology is used for product and material development. Applying Nano-materials is a core level for each part of furniture (Berger, 2013). Nano-materials or nano-enhanced materials have essential roles to create smart furniture for various purposes (Broekhuizen, 2012).

Nano-materials used in residential furniture

Nano-technology is believed to change our environment deeply at all scales, as object, interior space, building, and urban design, so it is necessary to take advantage of it and produce healthier, comfortable, and humane materials. Nowadays, Nano-technology has provided a lot of capabilities such as manipulation, changing and even designing around objects and their materials in the scale of Nano (0.0000001-0.000000001 m) since different behaviours of materials can be controlled accurately in Nano-scale (Niroumand et al, 2013). When Nano-materials are made professionally, they may end up with high costs.

Some features expected to be obtained from Nano-materials are listed as: easy to clean; to prevent bacteria to enter; focus on the scratches on glass or wooden furniture; protect materials from UV-protective coating; lower consumption; easy to change; easy to take form (they are plastic and can be coloured so easy); safety (private or public spaces); novel flame retarding methods (fire resistance); more durable (long life); stronger (stiffness behaviour); and self-healing (having a good characteristic of reconstructing their mechanical properties when damaged); sustainable characteristic and processes of production; lighter materials; and various transparency levels (Gilman, 2009; Broekhuizen, 2012; B. A¨ıssa et al, 2012; Karana et al, 2013).

Composites

There are some steps of activities for both plastic and wood composites. Wood composites like Nano wood fibres need to improve and optimize the benefits of using composite materials, though it is not achieved in markets, indeed hereof costly and not effective enough. The effectiveness level to attach Nano composites on fibres to achieve the best surface product is at the constructive level. Nano-cellulose fibres are applied to the wood composites and make them a renewable material; hence, it will be used as finding composite layer material for reaching more sustainable level (Broekhuizen, 2012). Society of Plastic Engineers (2012) list some features as: Improving the strength and the structure of materials (durability), coating preservation (durability), wear resistance (durability), safety, flare determent (fire resistance).

Concrete

One of the self-cleaning factor in concrete would be reliable with UHPC (Ultra High Performance Concrete) that is made by silica fame and 24nano- TIO^2. On the whole, the concrete that is used for furniture in kitchen should have enough density UHPC to prevent spots and water. On the contrary, UHPC will be used in new lighter furniture products or with slim size (Broekhuizen, 2012)

Metal

Nano-metal amelioration accrued when the modification is in the structure level instead of surface edit level, through this proses, metal will be sustainable and durable (Broekhuizen, 2012). Surface cladding metals are not stable since they can easily be damaged during usage. But their advantage is that they can be recycled by melting, however they have the hazard of emitting dioxins since they are coated by polyvinyl chloride (Berger, 2013).

Nano-Coating in Residential Furniture

By regarding Nano material technology as an expensive but new science, Nano-coating technique has been concerned and applied on current developments. Basically, Nano-coatings are using nano-materials in particular application. Meanwhile they have the ability to gain scratch resistance, anti-graffiti, easy to clean and water repellent, UV/ light stability, self-cleaning, anti-microbial / bactericidal, fire-resistance properties (Broekhuizen, 2012).

Glass

The function of new technology is applying a coating on each kind of normal glass which has 98% effect. There are different types of Nano-glass such as non-reflectivity, privacy-glass, thermal isolation and biocide glass, which can be implemented for various applications, i.e. glass-cabinets, lamps, tables, office furniture or medical furniture. To achieve a privacy glass, there is a liquid crystal between the glass sandwich layers, which creates a high opacity. A thin layer of metal oxides makes one kind of glass that can collect infrared radiation. Furniture surface should be controlled in interior space about preventing slow heat up around heat-sources (Broekhuizen, 2012).

Wood

Nano-technology is applied to the forestry wood production to achieve more sustainable wood and protect them from fungi, pest and biocides. These processes can be like co-biocides to protect the deep inside of the wood in a system named Nano-cannier. Besides, wood can be protected by Nano-metals, such as cooper-zinc and Nano-silver that release biotical caused by oxide in the long-term. An important matter about long life of wood and wood composite is their surface swelling when they are exposed to water, even by cleaning. In addition, pesticides that are used during wood growth may still be remaining in usage stage. Nano-technology is appropriate to increase sustainability in some wood products like MDT or OBS (Mantanis, Papadopoulos, 2010; Broekhuizen, 2012).

Textiles

One of the flexible and comfortable materials in designing and changing furniture is textiles (Addington & Schodek, 2005). Anti-stain furniture textile can be produced by coating the material with liquid-glass, i.e. coating by Nano-titanium dioxide or by Teflon. The textile fibres can be individually impregnated. To achieve another biotical textile, 'Nano-silver coating' which can be chemically connected to the textile is used. Besides, durability and quality of textiles are affected from three types of Nano-silver that are 'loose coating'. Nano-clay is a class of Nano-material which is known to have fire resistant characteristic. These different types of textile treatments do largely affect the quality and the durability of the textile's performance. (Broekhuizen, 2012).

Adhesives

Generally, adhesives in furniture production have been used in spite of insufficient information about their optimization that will be possible with Nano-materials. In addition, one of the effective factors in furniture durability is about the interplay between strand surface conduction and glue constitution to preserve the base from the erosion and decrease glue usage, the dispensation coating has been effective to keep Nano-roughening (Broekhuizen, 2012).

Green Materials in residential furniture

Green materials used in residential furniture are categorized under three sub-titles as natural eco-friendly materials, recycled materials and environmentally-friendly design / production / packaging / transportation.

Natural Eco-friendly Materials

Since ancient times, Chinese cabinetmaker took advantage of solid bamboos as a sustainable material to avoid using any screws and nails. Another eco-friendly material which gives furniture shine and aesthetic appearance is mango wood. One of the bamboo properties, which make it to be convenient and useful in bath and kitchen components is its anti-bacterial characteristic (Crateandbarrel, 2014) in addition to concrete reinforcement (Adams, 1998). Characteristically, bamboo is a kind of fast-growing natural grass that can be grown in different climates, both hot and cold in all over the world, Latin America, Africa and Asia with economical cost (Milani.B, 2005; Architecture in development, 2012).

Mango wood is very popular because of its natural hardwood and spectacular sustainability in comparison with oak and teak. It belongs to the sumac family of trees and it is evergreen. Distributed from India, now it is cultivated in South-East Asia, Australia and South Pacific Islands (Melange Decoration, 2013).

Recycled materials

The history of the salvaging material goes back to a long time before Romans. Nowadays science is used in order to investigate salvage materials. If the materials are unusable, recycling can be an option in order to optimize them. Materials such as clean timber, metals, gypsum board, and cardboard or paper can be mentioned among recyclable materials. A pre-recycling procedure, which is necessary in some cases, is to divide waste hauling at site which also decreases pollution. Advantages of salvage and recycled materials are listed as (Seattle public utilities associate, 2013): ‘Give usable items another life’; ‘save money’; ‘support the local material reuse and recycling industry’; ‘reduce natural resource use’; ‘cut greenhouse gas emissions’; ‘earn green building rating system (e.g., Built Green™, LEED™) points’; ‘send less waste to the landfill’.

Environmental friendly design / production / packaging

By using environmentally-friendly approaches in design, production, packaging and transformation of furniture in companies, contribute to sustainability. They are extending the life of furniture to reduce waste by reducing consumption. Besides, energy efficiency is used in production of furniture. Furthermore, the companies are also taking care of forests and planting more trees in place of the used timbers and by having fewer pieces of furniture for various functions / ages to reduce waste materials through a smaller number of furniture. As for transformation, using small packaging to take little space in transport and storage will be part of environment friendly transportation.

Exploration of ICFF 2015

In order to investigate the reflections of the recent developments in residential furniture industry, one of the international furniture fairs which include the highest number of companies attended from all around the world, is selected as ICFF 2015 in USA with 723 companies. Accordingly, the related keywords for innovative materials such as smart and green materials, have been scanned through companies to distinguish the variety of features among them. For the investigation, the categories of residential furniture are classified as: seating, including single seat (chair), multiple seats (sofa, bench), dining (dining table, buffet), Storage (bookcase, closet, drawers, and shelves, cabinet), sleeping or lying (bed, bunk bed, and sofa bed), study (desk, chair), entertainment (billiard table, TV table).

Through this analysis, the study is expected to reveal the usage frequency of innovative materials and hence, inspire the new developments as well as the spread of usage of innovative technology and materials in residential furniture. As it is analysed in Table 6 below, each keyword has been searched among selected companies according to their residential furniture products. In the search of innovative furniture material keywords within furniture category, two companies were found, whereas innovative furniture material keyword within seating category was 15, Table 1.

Table 1. Distinguish the number of companies which produce residential furniture by using Innovative technology and Innovative material technology

Company	**Innovative Furniture Materials**				
	Smart material		**Green material**		
	Nano-Material	Nano-coating	Natural Eco-friendly Materials	Recycled Materials	Eco-Friendly Design / Production / Packaging
Furniture	1	1	0	0	0
Seating	0	0	10	4	1
Total	1	1	10	4	1
	17				

By considering the features among seventeen companies with either smart and / or green innovative materials, ten of them are selected by random sampling to investigate the distribution of sub-categories in innovative residential furniture in ICFF 2015, Table 2, 3. The related keywords are searched within WEB pages of selected companies to find out the distribution of features.

Table 2. Various keywords of innovative materials characteristics which are searched in selected companies Web sites

Innovative Residential Furniture Materials			
	category	**Sub-category**	**Related keywords**
Innovative Furniture material	Smart	Nano Material:	Energy efficient, sustainable, smart, transforming to sustainable material, durable, easy-cleaning, safety, composite, property-changing, phase-changing materials (PCM), colour-changing materials, electro generating, light emitting, multipurpose materials,
		Nano- enhanced:	Reclaimed polypropylene, polyurethane, sustainable coating, UV-protection, durable, child safety, easy-cleaning, anti-microbial, safety
	Green	Eco-friendly material (natural or artificial)	Natural, earth friendly, timber absorbs carbon dioxide, natural materials, green natural finishes, sustainable timber, bamboo, mango, environmentally-friendly, long-lasting, last for generations, caring for the environment, protect environment, environmentally responsible, environmentally responsive, eco-friendly, sustain environment, sustainable materials, environment friendly finish, water-based finishes, reduce environmental impact, heavy metal free
		Recycled:	Recycled ground, re-adored, recycled cosmopolitan glass, salvage tiles, salvage wood, recycled aluminium, recycled plants, recycled obsolete, salvage specialist, wood waste, re-usable, re-built, eco-friendly
		Eco-friendly production / packaging:	Energy efficient factory, energy efficient production, sustained yield forestry practice, innovative production, eco-friendly packaging

Table 3. A comparative analysis of selected innovative residential furniture companies from ICFF-2015.

Innovative Residential Furniture

Company 5			√	√	
Company 6	√	√	√	√	√
Company 7			√		
Company 8			√		
Company 9			√		√
Company 10			√	√	

Although contemporary researches focus on sustainability issues on contemporary residential furniture design, it has been observed through the analysis, that only a limited number of companies have all sub-categories of innovative materials. In other words, the frequency of using innovative materials in residential furniture is less than expectations. Moreover, it has been observed that the use of smart materials such as Nano-materials or Nano-enhanced materials in residential furniture is limited with only one company in ICFF 2015, whereas the majority of using green materials as a sub-category of innovative materials mainly gather around natural eco-friendly materials.

Conclusion

Generally, environmental sensitivity and quality for future furniture have main indications, anti-bacterial, water pellet, high resistance to scratch and UV protection, which are beneficial points of innovative materials and covering layers. Another concern of contemporary furniture design is being sustainable, which addresses the environmental impacts of furniture products on the ecology of the planet by considering all aspects of design and manufacturing. Nano-technology serving to smart materials is expected to change our environment, so it is necessary to take advantage of it and produce healthier, comfortable and humane materials. Nano-materials and furniture work together in order to complete each other into a new system.

Table 4. Smart and green material features that are mentioned in WEB sites of case studies

Smart and Green material Features
▪ Organic shapes and ease-of-use to enhance the spontaneous
▪ Use eco-friendly materials that will sustain families and the environment for many years to come.
▪ use of more environmentally-friendly water based finishes
▪ Natural products are made with natural earth friendly materials
▪ focuses on applying a uniquely artistic and environmentally responsible approach to interior surface design
▪ easy to clean and can be customized using embossing
▪ energy efficient, environmentally-friendly, protect environment, environmentally responsible
▪ Natural finishes, Caring for the environment, natural materials, natural earth friendly
▪ Smart materials, polypropylene, sustainability, woven metallic polyurethane

For enlightening future studies and involving innovative technology and materials in the production processes of residential furniture, a deeper analysis of some companies which include the majority of sub-categories is accomplished in Table 4. There are some beneficial features explored from selected companies which are producing residential furniture by using innovative materials (smart and green materials).

The beneficial features explored above need to be included in future production processes of innovative residential furniture by using innovative materials (smart and green materials). It has been investigated that the frequency of using green materials is higher than using smart materials in recent residential furniture production worldwide. The higher usage of green materials needs to shift towards togetherness of both smart materials (Nano / Nano-enhanced) and green materials (Recycled / Natural / Eco-friendly production and packaging) in order to achieve more durable and sustainable production quality.

An investigation into the inclusion of polymers to low carbon clay-based external renders and the effect on waterproofing and vapor permeability

Androniki Giannatou[1,2] Tom Robinson[1]

[1]Graduate School of Environment, Centre for Alternative Technology, Wales, UK
[2]School of Architecture, National Technical University of Athens, Athens, Greece

Abstract: External renders work as a safeguard to ensure not only water proofing but energy efficiency of buildings. BRE, NIHE or IEA have conducted research to estimate energy savings from wide scale retroffitings. Energy efficiency was reduced by up to 50%, due to insulation failures in external walls, caused by rain penetration and other reasons. An external render combining very low Water Absorption for rain penetration, high Vapor Permeability for breathability, and low embodied energy, is lacking in current UK market. Therefore, report explores a potential alternative to lime render, based on an innovative composite of nanoclay and waterproofing polymeric additives. 15 different clay-based specimens with 4 waterproofing polymeric agents and 2 breathable organic aggregates were tested for their physical (density, porosity) and hygric properties (Water absorption, Vapour permeability) using gravimetric and British Standards laboratory tests. 3 out of 15 specimens achieved the desired criteria of notably low absorption rates and high VP, outperforming those of known lime renders of UK market and relevant clay renders of existing academic research. The results indicate that they have a potential application as low carbon, highly waterproofing, breathable and compostable render solution, either in traditional porous buildings or in new structures.

Keywords: Clay-based render, nanoclay bio-polymeric composites, water absorption, vapour permeability

Introduction

External renders work as a safeguard to ensure water proofing and in many cases energy efficiency of buildings. Due to UK wide scale energy retrofitting in the last decade, organisations such as BRE (Stirling, 2001), NIHE (2014, p.18) or IEA (2007) have conducted research to estimate energy savings as a result of interventions. They concluded that buildings energy efficiency was reduced by up to 50%, due to insulation failures in external walls, caused by rain penetration. Mould and fungus were also present.

Current market renders exhibit similar limitations as traditional ones. Specifically, although cement renders display low Water Absorption (Wa), their low vapour permeability (VP) hinders moisture evaporation. Furthermore crystallization of soluble sulphate salts enhances cracking (Kopacz et al, 2013; Wilk et al, 2013). Although Lime renders display higher VP, they exhibit higher Wa than cement renders (Straube, no date), leading to cement mortar cracks (Izaguirre et al, 2009 ; Nezerka et al, 2014). New nanotechnology and silicon-based renders provide high waterproofing, but low VP (Manoudis, 2009). In UK with high precipitation and porous structures an external render, which combines very low Wa properties to prevent rain penetration, with a high VP, to ensure breathability of the building and low embodied energy to reduce emissions, is lacking in current market and building practice.

On the other hand clay renders and structures have stood the test of time (NCCHS, 2014). Examples in UK is the ''wattle and daub'' construction system based on clay, sand, animal dung and straw applied on wooden lattice (Bowyer 1973, p.48-51 ; Graham 2003) or a plaster finish with clay, chopped straw, hay and dung added to daub (Davey 1961, p.40-41). In addition, In a Life Cycle Assessment clay render exhibits a holistic ecological profile providing savings in Energy (2 times), CO2 emissions (7 times) and in environmental contamination of air, water and soil (2.5 times) (Melia et al, 2014)(Table 1).

Table 1. Earth, lime and cement renders ecological profile (Melia et al 2014).

Renders	Cumulated Energy demand (MJ)	Carbon Emissions (kg CO2eq)	Environmental footprint (mPt)	Ecological footprint (m2 yr)
	(Cradle to Gate Embodied Energy)	(Cradle to Gate emissions)	(Environmental impact on 19 indicators in air, water, and soil)	(land occupation for the material extraction, production, cultivation,etc)
earth renders	29.1	1.22	182	4.2
lime renders	63.2	7.64	501	19.4
cement renders	54.6	7.03	454	18.2

Acknowledging all the above, this research tested a potential alternative to external lime render, based on a clay binder of one synthesis, hoping to cover a gap in current market or in literature. The innovative ecological nanoclay composite was enhanced with four polymers (one synthetic and three organic) for waterproofing and two aggregates for breathability. The physical and hygric properties were compared to air-lime render and to a limited number of well known UK commercial lime products. The contribution of polymers and aggregates was also identified. The research may share important data, since published data is extremely limited on a) clay waterproofing agents (Minke 2006 ; Straube no date) b) renewable ''green'' organic polymers (bio-plastics) in construction industry, as opposed to petrol-based plastics c) nanoclay bio-composites in renders. However, bibliography for bio-polymers is mostly associated with biodegradable films in food packaging industry, (Henriette de Azeredo, 2009) where casein polymer displays waterproofing (Cheema,2015) and vapor permeable performance (Bonnaillie et al 2014)while cornstarch polymer displays low porosity (Srikaeo et al,2005) plasticising properties but high water absorption. The research exploited the nanoscale (1nm) electric structure of clay as negative charged platelets in order to bond it with positive charged polymers, thus block water molecules (0,3-1mm) while allow vapor(1nm) to pass.

Methodology

15 types of clay-based specimens (45 replicates) enhanced with 4 waterproofing polymers (based on siloxane, casein, cornstarch, bioplastic) and 2 breathable additives (perlite, straw) (Table2) and one air-lime render (1:3) as control render (3 replicates), are tested for their Physical (Density, %Open Porosity) and Hygric properties (Wa, Vp, water penetration depth) are compared. The above tests are small part of a larger Thesis research, testing crucial properties in market industry (Giannatou, 2016). The research is linked with current literature. Specifically, the soil type used, its constituents, the ratios of its basic Category (Category A) and its control render(A0) (Table 2) align with those that G.Minke used in an educational workshop conducted in Greece (2008) in collaboration with Anelixi, an ecological research association. The research continues above work testing A0, while differentiates using different composition in the same waterproofing agents (casein mix, cornstarch mix) and adds 2 aggregates. All specimens have the same synthesis which is A0 composition. So new polymers and aggregates effect on Wa and Vp, which was the research target, is measured by comparing relevant specimens of different categories. As for constituents, sand mixture incorporated three distinctly different particle sizes.

Hydrophobic, siloxane-based, synthetic polymer emulsion (400ml/m²) is applied in two layers, after the specimen dries. Organic polymer agents or bio-plastics (casein, cornstarch, bioplastic mixes) are produced under heat with the addition of positive ions (H,Na,Ca) in each solution with volume strictly not exceeding the 5%. Melt intercalation enhanced with manual shearing and compressing (Theng, 2012) is then used for the clay nano-composite production, intercalating positive charged polymers into clay negative sheets.

Table 2. Constituents and Ratios of specimens tested.

Specimen synthesis	**Code**				
Clay renders _A Category		**Clay renders _B Category**		**Clay renders _Γ Category**	
Basic(B) : 0 aggregate		**Basic(B) : 1 perlite**		**Basic(B) : 1 straw**	
Basic (B)	**A0**	B/perlite	**B0**	B/straw	**Γ0**
B/ siloxane coating	**A1**	B/perlite/ siloxane coating	**B1**	B/straw/ siloxane coating	**Γ1**
B/ corn starch mix	**A2**	B/perlite/ corn starch mix	**B2**	B/straw/ corn starch mix	**Γ2**
B/bioplastic mix	**A3**	B/perlite/bioplastic mix	**B3**	B/straw/bioplastic mix	**Γ3**
B/casein mix	**A4**	B/perlite/casein mix	**B4**	B/straw/casein mix	**Γ4**
Air-lime Render Control	**L**	**1 lime : 3 sand**			

The %Open Porosity (OP) (%ratio between the difference of saturated and dry mass of the specimen to its dry volume) examines all additives effect on the porous structure and the OP relation to Wa examines the value connection to waterproofing. Water absorption was tested in accordance with British Standard BS EN ISO 15148 (2002) guidelines. The test measures the rate of water absorption of a specimen by capillary action during 24hrs, and defines the water absorption coefficient (Aw=kg/m² sec ½). Specimens were sealed on sides (aluminium foil, 100% virgin beeswax) and stored at 28°c and 50%RH in the climate chamber to stabilize their total mass to 0.1%. They were submerged by 5mm in water cups and stored in a climate chamber(28°C, 50%RH) for 24hrs. 17 weightings during the 24hrs were recorded, instead of the 8 required by British Standards, to minimize error from 4% to 1.5% and form the Wa diagram in high precision.

VP testing (dry cup) measures the resistance (μ-value) in the vapor flow through a specimen in a steady state in accordance with BS EN ISO 12572(2001) and accuracy methods required. Specimens whose sides were primarily sealed with foil tape and wax, were sealed on a cup of similar diameter incorporating desiccant (CaCL2, size<3mm) and a USB data logger(°C, %RH) to measure the VP of stagnant air. All specimens were located in a climatic chamber (TAS,ECO 900) (23°C±5,50%±5RH) for 6 days. An electronic scale (±0.005gr) was used for specimens periodic weighting. The μ-value was measured as the ratio between the VP of stagnant air (inside a cup) and the VP of the specimen under23 ±5°C and 50±5%RH.

Results and Discussion

Physical properties

Density and Porosity

In 10 of 12 specimens the addition of polymers decreased their Density, except in the basics A1,Γ1 (Figure1). This suggests that they work as both light fillers and binders. In addition, casein polymer was found lighter as a filler compared to aggregates, such as perlite or straw. Specifically, comparing A0 density, to B0 and Γ0 which were aggregate-based, they reduced the A0 density less than the casein-based A4. Both aggregates did decrease Density of 11 of the 12 specimens, except the A1, performing as light fillers, aligning with relevant literature data (Straube, no date; Ashour et al, 2010 ; Minke, 2006, p. 49). All specimens displayed lower density from 4% to 26% compared to the research control lime render (1780kg/m3). Significant cause for lower density of the clay-based renders is that both polymers and aggregates (30–150 kg/m³) work as lighter fillers than sand (1300-2000 kg/m³).

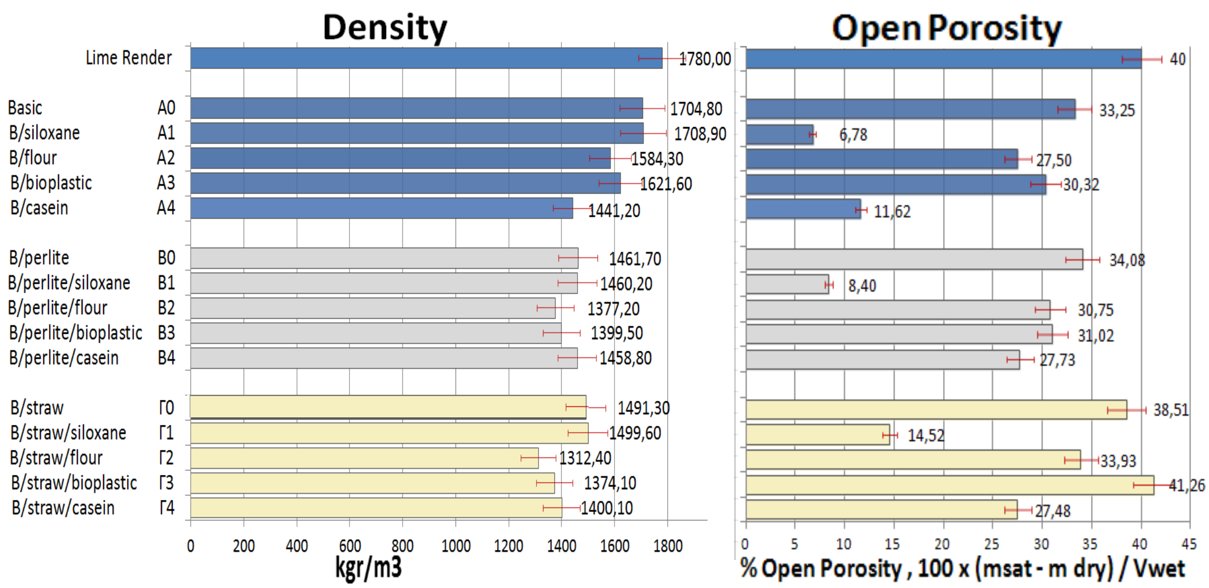

Figure 1. Density (kg/m³) and Open Porosity (%) values of specimens tested (Mean value, ±95Cl).

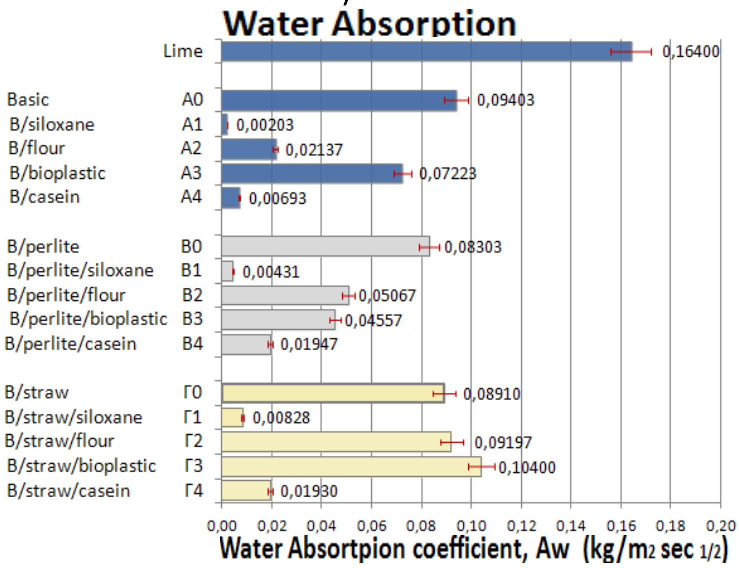
Polymers decreased the % Open Porosity of 11 out of 12 specimens except Γ3(Figure1). The highest %OP decrease was achieved by siloxane coating (A1,B1,Γ1)(62%-79%) and by the organic casein (A4,B4,Γ4) (28%-65%).This implies that polymers nano-structure turn them into high porosity reducers but not pore blockers (%OP>7%). Aggregates (perlite and straw) increased the porosity of all 10 poymer-based specimens, with straw exhibiting the higher increase in all categories (Γ1,Γ2,Γ3,Γ4) (15-136%) and perlite (B1,B2,B3,B4) the lower (2-138%). All of the above indicate that aggregates work detrimentally for the external renders porosity and potentially for their Wa. This is against existing orthodoxy, practice and market trend, where straw and hemp is frequently used in external renders. 13 out of 14 specimens displayed 45% to 255% lower porosity than lime, except Γ3. Siloxane and casein when mixed with Category A specimens, A1 and A4 skyrocketed their porosity reduction to 255.54% and 218.08% respectively (Figure1). Minke (2006) and Straube(no date) also tested siloxane to be a high porosity reducer on clay and cement respectively.

Hygric properties

Water Absorption

Polymers significantly decreased Wa for 10 out of 12 specimens by 23-96% compared to their non-glued Category Basic (Figure 2) displaying a significant waterproofing ability. Best sealers proved all siloxane mixes (A1,B1,Γ1)(90-96%) and all casein mixes (A4,B4,Γ4)(76-92%). Aggregates significantly increased Wa for 7 from 10 specimens by 26-178% compared to the relevant specimen of Category A incorporating the same polymer. This implies that perlite and straw combined with polymers work as water absorbers but alone in clay specimens (B0,Γ0) work as water reducers (5,25-11,70%) complying with current practice. In the literature, aggregates usually work as absorbers (Ashour, 2010; Minke, 2006). 13 to 14 specimens displayed lower Wa than A0 and 14 to 14 than lime render. Earth-based specimens proved to be better sealers by 36-97% compared to air lime render control. In fact the siloxane-based A1(0,00203 kg/m² sec½), and the casein-based A4 (0.00689 kg/m² sec½) exceeded most commercial renders performance (Table 3). Furthermore A1 met and A4 exceeded the performance of relevant specimens of Gernot Minke (2006) which displayed Wa 0.0 017 and 0.0117kg/m² sec½) respectively (Table 3).This aligns with current literature and goes against existing orthodoxy and market practice that associates clay renders with inner use only.



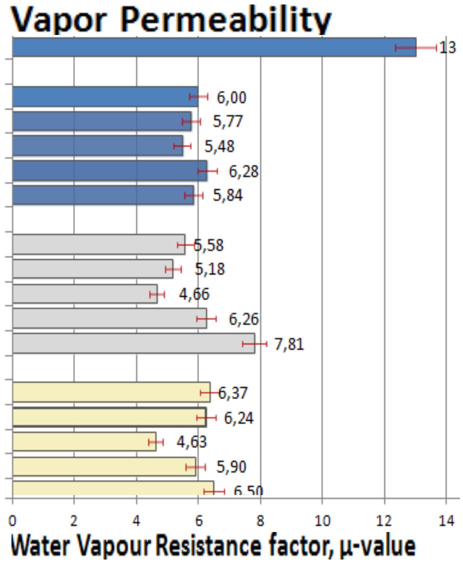


Figure 2.Water Absorption coefficient values, Aw (kg/m²sec½) of specimens tested (Mean value, ±95Cl).
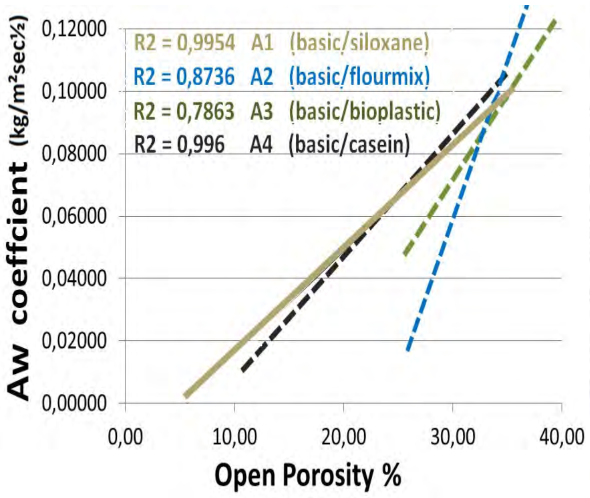
Figure 3. Vapor Resistance factor values, μ (unitless) of specimens tested (Mean value, ±95Cl).



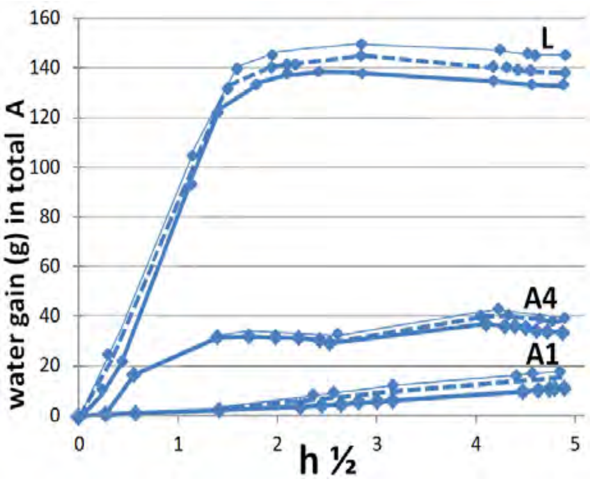


Figure 4. Relation of Water Absorption coefficient, Aw (kg/m²sec½) to %Open Porosity (Category A).
Figure 5. Water Absorption gain (g) per time, during the 24hrs Wa test.

Polymers inclusion did result in a strong positive Porosity/Wa correlation for 9 out of total 12 specimens, except for B2,Γ2,Γ3 (Giannatou, 2016)(Figure 4). This implied that polymers not only reduced the number and water size pores of the specimens, but this maybe among the reasons that turned them into waterproofing agents. Siloxane (A1,B1,Γ1) (R^2=0.95-0.99) and casein (A4,B4,Γ4)(R^2=0.92-0.99) had the strongest correlations in all 3 categories(Figure 4), experiencing the highest porosity reduction which implied that their polymers final porous system was the finest of all, closing specimens pores in a higher level. Category A specimens (A1,A2,A3,A4) displayed the strongest correlations of all categories (R=0.78-0.99) (Figure 4), and a higher waterproofing capacity implying that all polymers are more waterproofing, when specimens acquire no aggregates.

Specimens Wa performance was further examined by; a) measuring the water penetration depth of specimens after the Wa test by cross-sectioning b) assessing the Wa diagrams. In water penetration depth test air-Lime render was completely saturated (25mm) after 24hrs, while A1,B1 displayed no water penetration after 24hrs or 42hrs, and A4 which displayed 5,7mm(24hrs) and 10mm(42hrs) respectively (Figure 6). The siloxane based specimens (A1,B1) were light in color and weight, showing little signs of moisture. The casein based A4 displayed water ingress that has been blocked up to a distinct horizontal level (Figure 6). The Wa diagrams is concurrent with the above. Samples A1 and B1 displayed a very low but steady Wa rate since its siloxane hydrophobic coating repelled water, while the casein polymer performance in A4 seemed to have blocked water intrusion twice. The above relates to the known ‘’clay tortuous path’’ mechanism (Figure 7) (Henriette de Azeredo, 2009) where successful intercalation (insertion) of polymer into the clay stratification of horizontally bonded layers blocks water intrusion.

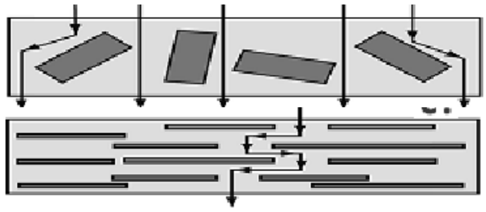

Figure 6. Depth of water penetration (mm) in the relevant test for A11,A21,A41.
Figure 7. Clay platelets versus polymer-clay platelets dispersion after compressing(Tortuous path).

Vapour Permeability

Paradoxically 11 out of 15 polymers did increase, instead of decrease the Vapor Permeability of their Basic specimen (2%-27%) working as vapor enhancers (Figure 3). In addition, some polymers and especially cornstarch mix when added to A0 increased VP more than even perlite(B0) or straw(Γ0). This implies that some glues could replace equally or even better perlite and especially straw to increase specimens VP property. Potential cause could be that most polymers reduce the pores sizes, and since they are hydrophilic they enhance attached vapor molecules velocity (0.2nm) according to Bernoulli law (Portella, 2009). From the 2 aggregates tested, perlite (μ- value=2) did increase the VP of all specimens (0.3%-15%) except the B4, but paradoxically straw decreased the VP of all (-11% --6%), except Γ2 and Γ3. This is logical and revealed that the clay-based specimen is highly Vapour Permeable by itself (μ- value<6) and straw is simply less (μ- value>6). No academic data has found straw (μ- value>6) to reduce specimens VP, given that most specimens in literature displayed (μ- value>6) (Minke, 2006; Ashour, 2010; Straube, no date). Also this is against existing orthodoxy and practice, since straw is always considered a VP enhancer for plaster and renders, which maybe not always be the case, in low μ-value specimens.

8 out of 14 specimens outperformed A0, and 15 out of 15 outperformed air-lime render, displaying higher VP between 39% to 64 % (Figure 3).Thus, they are considered highly VP agents. It was the polymers that primarily enhanced specimens VP, but furthermore the clay-based specimens synthesis was further reason, since A0 (the basic specimen of all categories) was 53.80% more vapor permeable than air-lime render control. In comparison to academic data, a notable finding is that the 3 best specimens tested by Gernot Minke(2006), the casein-based, the flour based and the siloxane based specimens (Table 3) displayed lower VP (μ=13) than the research relevant specimens (μ=5.18-6.27).

Furthermore, the research specimens displayed superior performance to widely used renders (Table 3).

Conclusions

Polymers decreased Density(10/12),%Open Porosity(11/12) and Wa (10/12) while increased VP (11/15) (Table 3). This implies that they worked beneficially as light fillers and binders, porosity reducers, strong waterproofers and VP enhancers at the same time. Furthermore, some proved better VP enhancers, than perlite and straw, meaning that they could replace them. The polymers contribution to porosity reduction, waterproofing and breathability increase implies that they decrease pore size, so as to block free water (0.3-1mm) but allow vapor (1nm) entrance. The synthetic polymer of siloxane and the degradable bio-polymer (bio-plastic) as caseinmix displayed the best performance. Although aggregates decreased density (11/ 12) they increased porosity (10/10) and Wa (7/10). As for VP perlite increased it (4/5) while straw decreased it (3/5). Since they proved to be porosity enhancers, water absorbers with mixed performance in VP, their performance proved detrimental in the end. As for clay-based specimens, they proved to be lighter (15/15), less porous (13/14), more waterproofing(14/14) and more vapour Permeable(15/15) than air-lime render (1:3) control.

Table 3. Wa and Vp performance of research renders compared to literature and market products.

A4 (CASEIN-CLAY RENDER)		1441 (dry)	0,00698	5,84
Γ1 (SILOXANE-CLAY RENDER)		1499 (dry)	0,00803	6,24
A2 (FLOUR-CLAY RENDER)		1584 (dry)	0,021	5,48

A notable research finding is that research specimens (A1,B1,A4) outperformed both in Wa and Vp a) similar specimens in literature and, b) current commercial lime renders in UK Market (Table3). Regarding the first, A1 siloxane-based specimen displayed almost equal Wa (0.002 kg/m² sec½) to G. Minke(2006) relevant specimen (0.0017 kg/m² sec½) and the A4 casein-based specimen(0.0069 kg/m² sec½) displayed half Wa (0.0117 kg/m² sec½). Furthermore, both were twice as vapour Permeable (μ=5.77) as their relevant referenced specimens (μ=12-14). Regarding the second, further research in specimens performance in adhesion, durability, thermal conductivity, reaction to fire following the BS EN 15824:2009 guidelines for renders based on organic binder, will be conducted to prove the product market applicability. Also their exposure in real weather conditions could further verify the above. Assessing Wa and Vp results, clay-based specimens with polymers show potential as alternatives to external lime render. They combine notably higher water proofing capacity, breathability and minimum carbon footprint. These properties are primarily needed to protect energy efficiency of buildings, either a) in Historic energy restoration of porous structures, b) in existing stock renovations, or offer high sealing and VP in flood-prone areas.

Effects of Weather Exposure on Solar Reflectance of External Paintings

Lucila Chebel Labaki[1], Edna Figueiredo[1], Adriana Petito de Almeida Silva Castro[1], Rosana Maria Caram[2]

Abstract: Nowadays, there is a great variety of paintings' colours, available in the construction market, which greatly influence architectural projects. One may observe that, in a large number of buildings, the external painting is one of the most exposed elements to solar radiation, being responsible for a great deal of heat flow, which is transferred to and around the building. The influence of the external colour in the thermal performance of buildings has been extensively researched in many countries, as well as in Brazil, by using spectrophotometer analysis in recently painted tile samples, but there are few studies about the effect of weather exposure on these paintings. The analysis presented in this paper was carried with 2X2 cm samples of tiles painted with different painting colours, which were exposed to weather conditions for two years, by using a spectrophotometer with integrated sphere. in The analyses were carried out for several intervals of sun exposure in order to check the discolouring that each one went through along the period of two years, every two months. The superficial temperatures on a masonry surface painted with the same colours used in the samples and in the same intervals of time were simultaneously measured using an infrared thermometer. The results allowed a comparison of the two different methods of analyses showing the differences in behaviour among the different painting colours, not only in the visible range, but also for the near infrared, which gives an insight on important parameters which can contribute to improve studies about thermoenergetic performance and thermal comfort in buildings.

Keywords: colour reflectance, spectrophotometric analysis, environmental comfort

Introduction

Solar radiation directly influences indoor climate, human comfort and energy demand in buildings. When radiation reaches a building, the energy is partly absorbed and partly reflected. The heat gains through opaque surfaces due to solar radiation exert a great influence on the thermal comfort conditions of the internal environment (SEKER; TAVIL, 1996). In most of the buildings, the exterior painting is one of the elements most exposed to solar radiation, being responsible for part of the heat flow transferred to the building and its surroundings.

Solar heat gain is mainly defined by the reflectance of external surfaces as determined by their colours. Hence the importance of knowledge of the reflectance of painting colours most used in external paint.

Several researches have highlighted the exterior colour as a determining element that influences the amount of radiation absorbed or reflected by the construction materials, especially in hot and dry climates, making the choice of the colour extremely important in the construction process.

Light surfaces are not always indicative of high reflectance, since the reflectance of the materials depends not only on their reflection in the visible region, but also on their reflectance in the infrared region. Exposure to weather tends to decrease the reflectance of light materials and increase the reflectance of darker materials. Studies that monitored the effects of aging on ten roofs in California found that the reflectance of materials decreased by approximately 15% in the first year of use (Bretz, Akbari, 1997).

The use of high reflectance coatings can contribute to the reduction of surface temperatures. Prior to the application of a coating at a specific site, a complete study should be carried out to estimate the impact of such reflective surfaces on the microclimate, avoiding heat gains (Synnefa et al, 2005).

Alchapar et al (2013) studied solutions for urban spaces in order to mitigate the impact of Urban Heat Islands. It was considered that solar reflectance of the building envelope tends to change with time due to outdoors conditions and dirt accumulation. For a period of two years they measured thermo-physical behaviour of 80 textured coatings for facades on two compositions: acrylic and cement, with colours, textures and finishes spread locally to the vertical resolution of the urban envelopes. The results showed that 35% of acrylic coatings decrease their ability to mitigate the effects of heat island, while 98% of the cementitious ones maintained or increased their mitigation capacity. Coelho et al (2017) verified that the natural aging processes of asbestos cement tiles aged between 28 days and 36 months considerably alter the absorption and thermal performance over the lifetime of a building.

In this work the effect of solar radiation on external painted surfaces with several colours exposed to climatic conditions was studied, in order to verify the influence of the aging of the paints on the values of reflectance to solar radiation.

Methods

In this work, the adopted methods are separated in two stages: laboratory and field work, for a 2 years period. The results in laboratories express reflectance values by wavelength, in the range of 300 to 2000 nm, while the field measurements express the surface temperature of the wall.

For laboratory measurements, 25mm x 25mm cement pellets were prepared. After drying they were coated with spackling, to obtain samples with smooth surfaces, in order to reduce the maximum possible the roughness effect in the results of reflectance measurements. The samples were then coated with 3 coats of acrylic latex paintings in 10 different colours. This shape of the tablets suits well to the spectrophotometer support, allowing better fixation and ensuring stability when handling the device. The samples were fixed to the wall vertically, in order to obtain results closer to the real surface.

When using the spectrophotometric technique, the samples were analysed in several stages of Sun exposure, in order to verify the influence of the colour fading over time in relation to the reflectance, in the different regions of the solar spectrum. Samples were taken for analysis for 2 years at intervals of 6 months.

The reflectance values were obtained by the area integration method, by using the graphs obtained in the measurement. Initially the area relative to the measurement of a reference sample was calculated with an approximate reflection of 100%. Then the integrated area below the specular reflection curve of each sample was calculated. The results for each sample were obtained for the desired intervals: Ultraviolet (290 to 380nm), Visible (382 to 780nm), Infrared (782 to 2000) as well as to the whole solar spectrum.

Simultaneously, in order to verify the behaviour of the paintings in real weather conditions, a panel with ten spaces in the size of 40x40cm was also prepared on a masonry surface north oriented. Each space was painted in one colour, the same colour as the painting used in the laboratory samples. In this panel, the colours behaviour was accompanied by measurements of the surface temperature performed at various times of the day and also at different stages of exposure to time. For this stage of the work an infrared thermometer was used.

Colour surface temperature measurements were also taken at six-month intervals, however, to obtain a more accurate result, the temperature was measured at various times of the day (9h, 12h, 16h; 7:00 p.m.), for three consecutive days and always on sunny days. By means of the measurements realized in the three days an average of the temperature values was obtained for each hour. The measurements were performed in five steps: freshly applied paints and after 6, 12, 18 and 24 months, considering exposure to time.

Results

Results for the laboratory measured reflectances

Figures 1 to 5 show the obtained graphs for each colour, showing the spectral reflectance differences that occurred during the various periods in which the samples were exposed to the climatic conditions.

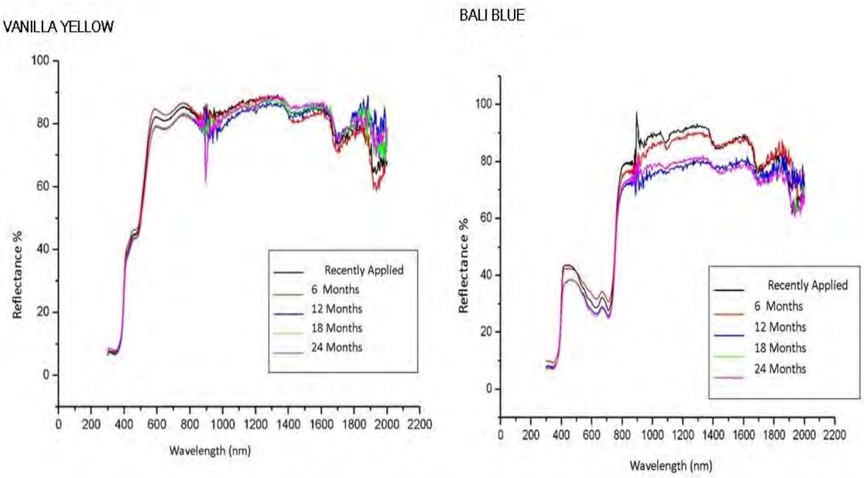

Figure 1. Reflectance curve yellow vanilla color and blue bali

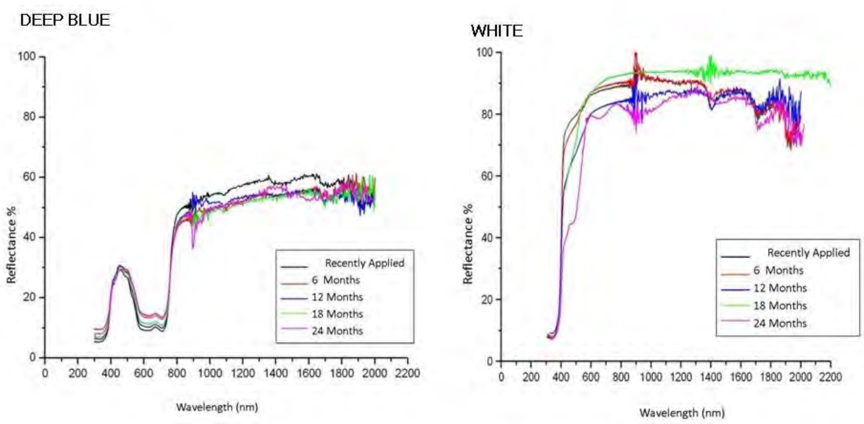

Figure 2. Reflectance curve yellow deep blue and white

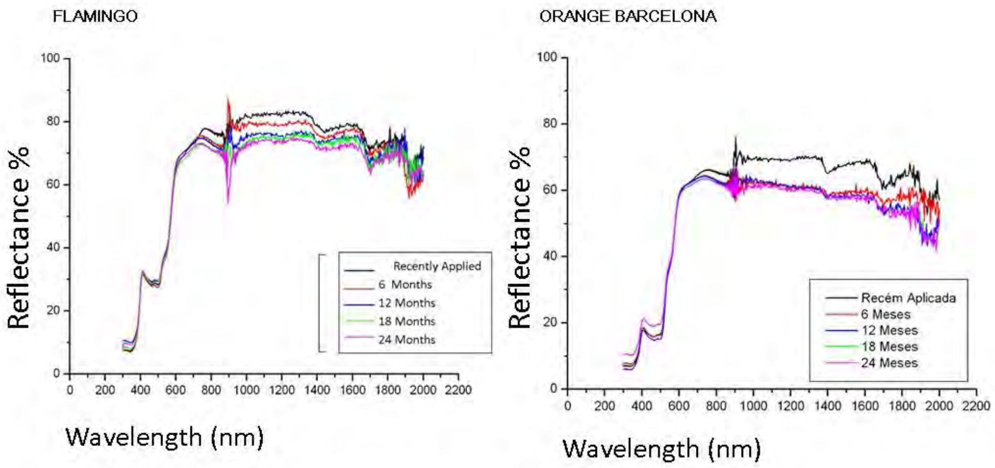

Figure 3. Reflectance curve flamingo color and orange barcelona

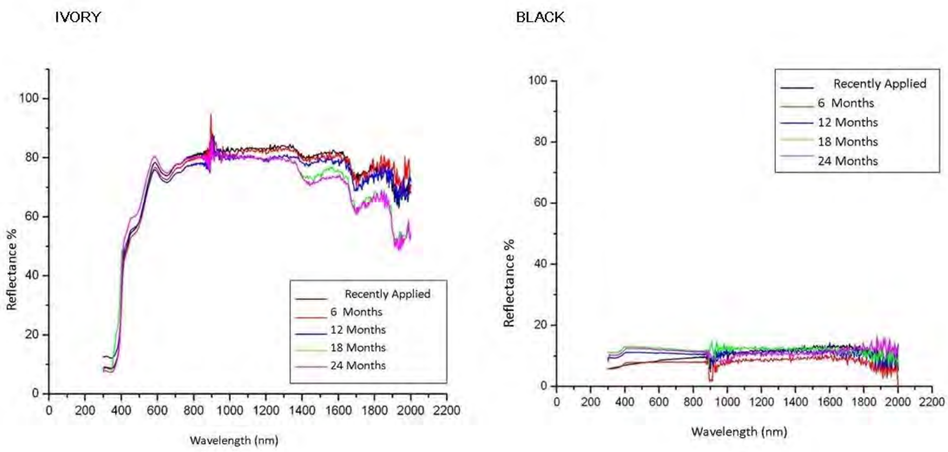

Figure 4. Reflectance curve ivory color and black

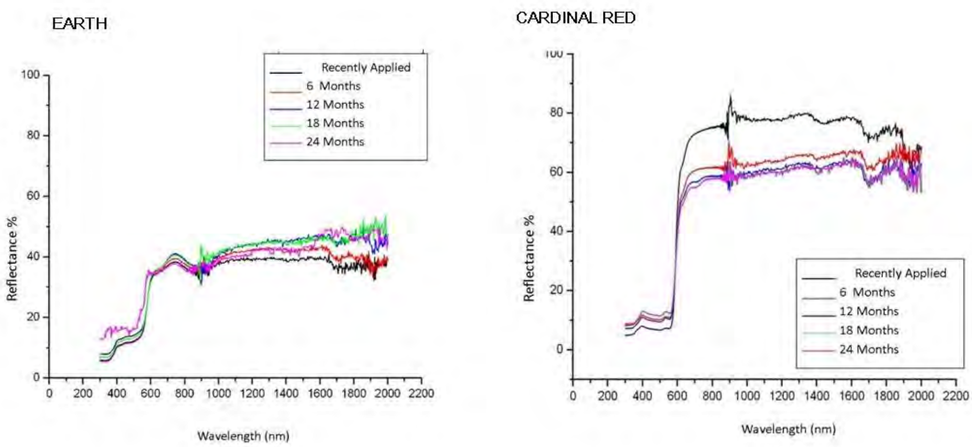

Figure 5. Reflectance earth color and cardinal red

By means of the results obtained, a comparison was made between the reflectance of the samples and the values obtained in the verification of the behaviour of the paints under real conditions through the surface temperature, aiming to obtain parameters that can identify how much the fading of the paints can influence in the values of solar reflectance.

Table 1. Reflectance of paints recently applied

COLOR	REFLECTANCE% (PAINTS RECENTLY APPLIED)

Earth	29,2	44,2	46,7	34,7	40,0

Conclusion

Results for the total reflectance show that the majority of the colours considered as light and medium, in the course of 24 months exposed to weather, had their reflectance values decreased, when compared to the initial values. For the white colour, a great difference in the values of total reflectance is observed (81% for the newly applied paint and 74% after 24 months exposed to weather). Dark colours such as Black and Earth over time had their values increased.

The Red Cardinal and Orange Barcelona, considered as medium colours, showed the biggest differences in relation to the initial values and after 24 months exposure to weather. As for the Red Cardinal, its initial reflectance was 63% and after 24 months exposed to the sun reached 50%, with the biggest difference occurring in the first 12 months. For Orange Barcelona, its initial reflectance was 58% and after 24 months, it diminished to 51%, with the biggest difference occurring in the first 6 months exposure.

The results showed that the light colours presented higher reflections in all regions of the spectrum.

During the 24 months period, it was confirmed that the colours that reflect more in the visible are the same ones that reflect more in the infrared and in the UV, being, therefore, those that present greater total reflections.

In the visible region, the light colours showed higher reflections and, over time, these were decreasing. It is valid to assume that the effect of accumulation of the deposited dirt over time is quite significant for the light colours, to the point of significantly decreasing the reflectance.

In relation to dark colours, over time their reflections increased, because even with the dirt accumulation the surface temperature values diminished due to colour fading, showing behaviour similar to the tablets: the effect of dark colour fading exceeded the cumulative effect of impurities and dirt.

Use of a whole building heat and moisture transfer building simulation tool to evaluate moisture buffering capacity of clay plasters in hot-humid climates

Shaghayegh Mohammad[1], Stephen Lo[1]

Department of Architecture & Civil Engineering, University of Bath, U.K., s.mohammad@bath.ac.uk

Abstract: Studies on hygrothermal properties of materials to passively moderate indoor humidity levels has in cold-moderate climates conclude that it helps improve Indoor Air Quality and reduce auxiliary energy loads. This research uses a validated whole building **H**eat **A**nd **M**oisture transfer energy simulation tool (WUFI Plus) to study the effect of a selected hygroscopic clay plaster on indoor environment in hot-humid climatic condition. A reference scenario was defined with use of gypsum plaster as the common wall finishing. Results indicate that clay can help buffer indoor RH especially when high indoor RHs happen. However, the effect on indoor temperatures is negligible. Results also indicate the importance of taking moisture into account in building energy calculations.

Keywords: humidity, mass transfer, modelling, indoor air quality, hygroscopic materials.

Introduction

The study of the moisture buffering capacity of materials has been the subject of renewed interest in the last decade (Rode et al., 2008). This capacity, known as the hygroscopic behaviour of a material, is defined as the change in a material's physical properties as a result of the simultaneous absorption, storage and release of both heat and moisture (Hall & Casey, 2012). When additional moisture is generated in indoor spaces, hygroscopic materials act as a buffer, absorbing and storing it; when the humidity source is removed, they release this moisture back into the environment. This capacity can be used as a passive way of controlling the diurnal amplitude of indoor relative humidity (RH) and keep it within the range for thermal comfort. Passive control does not require energy input or human intervention, so it represents a more resilient and sustainable option in many situations (Woloszyn et al., 2009). Removal of humidity also removes latent heat, thus reducing cooling loads.

It should be noted that adsorption/desorption of moisture by materials also affects their heat transfer properties because the basic properties of materials, such as thermal conductivity and density change with moisture content (Hall & Casey, 2012). This adds complexity to building energy modelling when attempting to simulate moisture transfer because a more dynamic approach is needed to take into account the mutual influences of heat and moisture on one another.

Existing studies describe the hygroscopic behaviour of materials and their effect on indoor climate, heat transfer, energy consumption and the durability of construction assemblies mostly in the context of cold and temperate climates of north European countries specifically Scandinavian countries as well as north Americans (Simonson et al., 2004, Woloszyn et al., 2009, Yang et al., 2012, Kalamees et al., 2009, Lengsfeld et al., 2005). The research described in this paper adopts the same level of robustness for a more challenging climate to support building practitioners in those areas to apply this concept when designing buildings. The study takes place in a hot-humid climate with small amount of precipitation and high rate of cooling load during summer which is known to be difficult to provide thermal comfort for occupants. Controlling indoor RH is more important in these climates as combination of high temperature and RH limits boundaries of comfort.

WUFI Plus has been selected to study effects of applying a hygrothermal material (clay plaster) on the diurnal indoor fluctuation of RH and the impact on comfort and well-being of occupants. This software is a whole building Heat And Moisture (HAM) transfer energy simulation based on the hygrothermal simulation model for building envelopes developed by Künzel (Künzel, 1995) and has been used and validated against experimental data in different studies (Lengsfeld et al., 2007, Antretter et al., 2011).

Indoor humidity and comfort

Indoor Air Quality (IAQ) is closely linked to indoor RH levels (Arundel et al., 1986). Low indoor RH levels result in dryness of the skin, mucous membranes, sensory irritation of the eyes and upper airways. High RH levels may result in material deterioration and mould growth (Padfield, 1998, Kwiatkowski et al. 2011, Woloszyn et al. 2009). Moreover, in most indoor environments inhalation of air will cause a cooling of the mucous membranes in the upper respiratory tract, which contributes both to the perception of thermal environment and to the perceived air quality (Toftum et al.,1997). At high air temperatures and humidities, respiratory cooling is reduced resulting in air being perceived as stuffy and uncomfortable. In addition, at high RH levels the rate of transpiration from the skin is decreased, hence reducing the evaporative cooling effect caused by sweating of the human body. Therefore, different parameters need to be accounted for when defining the optimum range for indoor RH (Figure 1). As illustrated the indoor humidity should be kept below 60% RH to avoid the growth of fungi and mites and above 40% RH to reduce respiratory infections (Arundel et al., 1986). In terms of thermal comfort, ASHRAE standard 55-2010 defines the upper limits of RH between 55 and 80% depending on the temperature. However, no limit has been defined for lower limit of indoor RH (ASHRAE, 2010).

Simonson et al. (2004) investigated the effect of hygroscopic wooden panelling on indoor humidity conditions in three Canadian cities using a numerical model. Their result indicated the importance of hygroscopic materials specifically during the humid and cool seasons.

Hall and Casey (2012) studied HVAC energy consumption in a room located in Leicestershire, UK, constructed with stabilised rammed earth and compared the results with non-hygroscopic and less-hygroscopic cases. The results indicated that when used in conjunction with the HVAC system, there was a significant reduction in humidification and dehumidification energy demand when compared to the conventional wall materials. However, energy saving was less when HVAC unit was used intermittently due to the extra load imposed on the HVAC unit to remove the moisture being absorbed by the SRE walls when the system had been turned off.

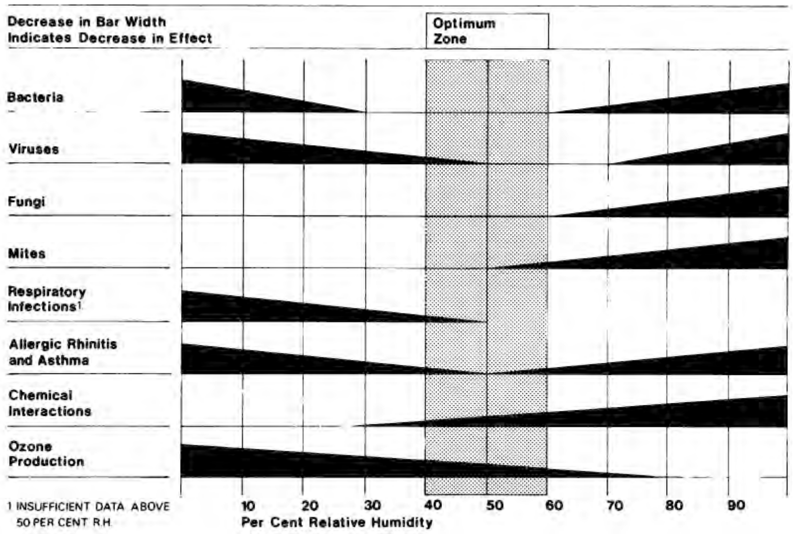

Figure 1: Health and IAQ parameters are affected by indoor RH (Arundel et al., 1986)

Kunzel et al. (2005) studied the hygrothermal performance of a plastered room against a room covered with aluminium sheets in hot and humid climate of Bangkok and Miami using WUFI Plus. Their result indicates that indoor RH in plastered room stays well below 80% hence reducing the risk of mould growth.

Qin et al. (2011) investigated the effect of hygrothermal transfer through building envelopes on indoor air humidity and energy consumption in moderate, hot-humid and hot-dry climates. They concluded that taking moisture into account has a more distinct effect on indoor humidity in hot-humid and moderate climate than the hot-dry one. The use of suitable hygroscopic materials reduces energy consumption with the most promising results coming from buildings located in hot-humid climates. The peak cooling demand is 12% and 33% lower in moderate and hot-humid climate respectfully.

Clay Plasters as an alternative construction material

For several years, earth construction was abandoned in favour of concrete in developed economies. In recent years, following the global awareness towards more sustainable use of natural resources and the negative environmental impacts of conventional construction materials (Wang et al., 2014), earth-based products, plasters being one of them, are becoming popular again (Faria et al., 2016). Besides its low embodied energy and recyclability, earth is known to be a natural humidity regulator helping in improving IAQ and comfort inside buildings (Laborel et al., 2016); a capability that is related to the hygrothermal properties of this material.

It should be noted that although the soil used for earth construction cannot be regarded as a renewable resource, its extraction is much less energy-intensive than the extraction of raw materials for conventional masonry products, as the soil used for earth construction is located immediately below the organic layer of the soil (Torgal & Jalali, 2011).

Building energy simulation tools

When building energy simulation tools started to be used in 1960s, they were mostly concerned with modelling the thermal performance of the building and interaction of moisture was mostly neglected (Hong et al., 2000). IEA Annex 41 project, launched in 2004, was the first attempt for simulation tools to take into account moisture in handling the whole building performance (Woloszyn and Rode, 2008). Today there are different numerical models that evaluate moisture balance in an enclosed space or predict indoor humidity levels. They differ in the way that they deal with the moisture storage process within the material and can be categorised under two general classifications (Janssens & de Paepe, 2005).

For the first group the main focus is on predicting temperature profiles and energy demands of each space, so two types of simplified approach are taken to account for water vapour exchange with surrounding materials; firstly, the effective capacitance, assumes that room and material humidity are always the same, therefore one single room moisture capacity is considered to include both parameters. Secondly the Effective Moisture Penetration Depth model, differentiates between the room humidity and a representative material humidity, so a single equivalent volume representation of the average moisture transfer and storage in the material is considered to represent the material. The second group of indoor humidity models has been produced by combining thermal building simulation with models for Heat And Moisture transfer in building components (Janssens & de Paepe, 2005). A HAM model takes moisture sources and sinks inside a component, capillary action, diffusion and vapour adsorption and desorption as well as the well-known thermal parameters into count (Antretter et al., 2011). It is also capable of defining the exchange of water vapour (transfer and storage) between the room air and the surrounding enclosure (Janssens & de Paepe, 2005). Therefore, interactions between the heat transfer in the walls and the moisture balance in the enclosure are accurately described in HAM models. HAM models also incorporate the dependency of thermal material properties on moisture content.

Figure 2: BESTEST building

Methodology

The IEA BESTEST building (Figure 2), also referenced in ASHRAE Standard 140, was used in this study allowing simple comparison between results of different simulations. This model was devised in the WufiPlus software and different scenarios were defined to study the potential benefit of applying clay plaster to moderate indoor RH (hygrothermal case). The reference simulation was defined by applying gypsum plaster on internal surfaces (non-hygrothermal case). The weather data used for all simulations is for a port called Lengeh in south of Iran which features hot and humid climate. The southern coastal region of iran has the highest rate of energy consumption in the country.

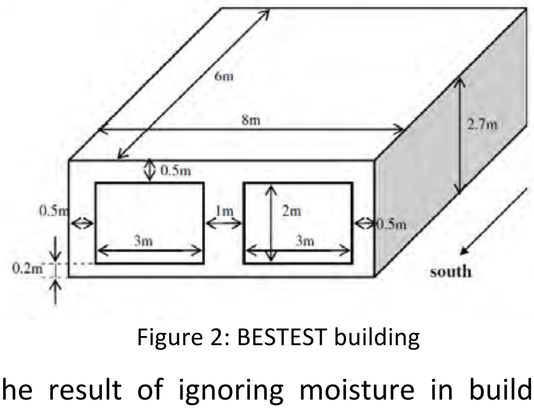

Figure 2: BESTEST building

In first scenario, the result of ignoring moisture in building simulation models is discussed by running an only heat transfer simulation as well as a heat and moisture transfer simulation in Wufi Plus. In this software there is an option which allows the user to include or exclude moisture in calculations. A gypsum plastered solid brick construction was modelled as well as a construction plastered with clay to compare their effect on indoor RH. Air infiltration rate was 0.5 air change per hour, no internal gains were added to the simulation and windows were closed i.e. no natural ventilation.

In a second scenario, two types of construction blocks i.e. Autoclaved Aerated Concrete and solid clay brick were modelled in Wufi to study the role of substrate in hygric and thermal calculations and indoor RH. These blocks are commonly used in Iran. In this scenario it was decided to remove all glazed surfaces i.e. all surfaces were opaque to eliminate the effect of solar gains and have a pure evaluation of thermal and hygric behaviour of materials themselves. A third scenario was also defined with night time ventilation applied during 6 months of the year from May to the end of October from 23.00 pm to 7.00 am to see if natural ventilation reduces the potential benefit of hygroscopic materials in moderating indoor environment. In all simulations all surfaces of the building including floor and roof were made of the same construction assembly and were in contact with the same environment being outdoor air (even for the floor slab) to facilitate interpreting the result. Simulation scenarios have been summarized in table 1.

Table 1: Simulation scenarios

Scenario	Construction		Infiltration
1	- Solid clay brick + Gypsum plaster - Solid clay brick + Clay plaster	-No NV - No internal gains	0.5 [ac/h]
2	- Solid clay brick + Gypsum plaster - Solid clay brick + Clay plaster - AAC block + Gypsum plaster - AAC block + Clay plaster	-No NV - No internal gains - No windows	0.5 [ac/h]
3	- Solid clay brick + Gypsum plaster - Solid clay brick + Clay plaster	-Night time NV 8 lit/s From 23:00-7:00 May to November - No internal gains	0.5 [ac/h]

Results and discussion

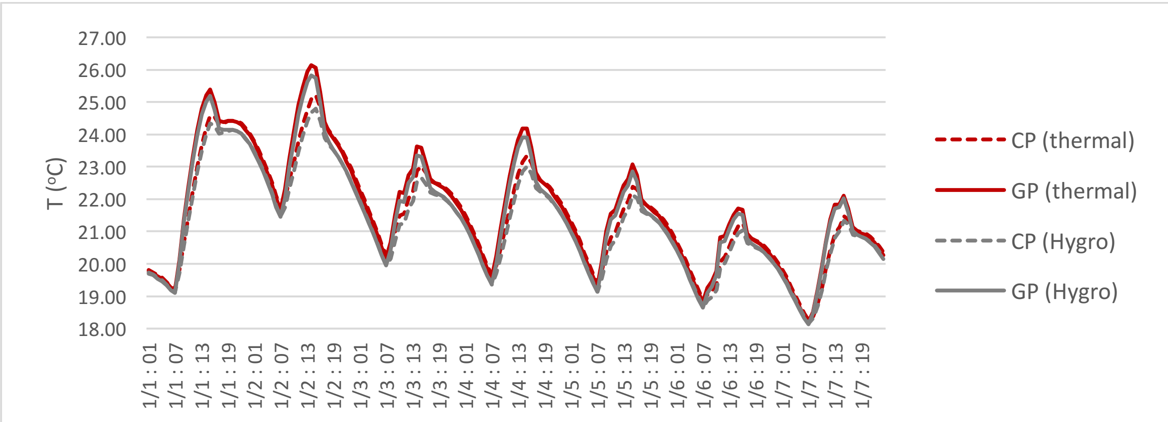

Figure 3: Indoor temperature derived from thermal & hygrothermal simulations, 1-8 January
GP: Gypsum Plaster CP: Clay Plaster

Scenario 1**:** In order to illustrate the importance of taking moisture into account in energy simulations, a simulation was run with only thermal simulation applied and the result was plotted against the result of a whole HAM transfer simulation during one week in winter. As can be seen on figure 3, there is not much difference in indoor temperature when moisture is ignored. However, the variation in indoor RH is distinct (figure 4 & 5). The difference in result of hygrothermal and thermal simulation is even more distinct when applying a hygrothermal material i.e. clay plaster as even the pattern of fluctuations is different. This difference in calculation results leads to a wrong estimation of heating, cooling, de/humidifying demands of the building and a poor design which does not meet the requirements of the building occupants.

This result also indicates that indoor RH is more stable when Clay Plaster (CP) is applied especially in winter when higher indoor RH (above 60%) is prevalent. However when moderate RH is observed in indoor environment (45-50%), the effect is not distinct. In terms of indoor temperature the performance of both constructions is quite similar despite Brick + GP having lower U-value. Construction covered with clay plaster experience slightly less fluctuation in indoor temperature in winter and in summer a time lag is observed in indoor temperature peak due to higher heat capacity of clay compared to gypsum.

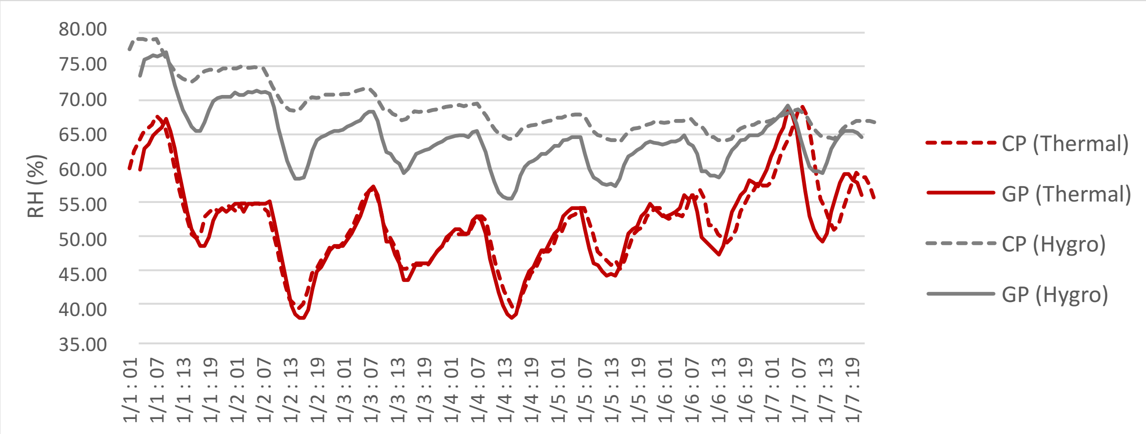

Figure 4: Indoor RH derived from thermal & hygrothermal simulations, 1-8 January
GP: Gypsum Plaster CP: Clay Plaster

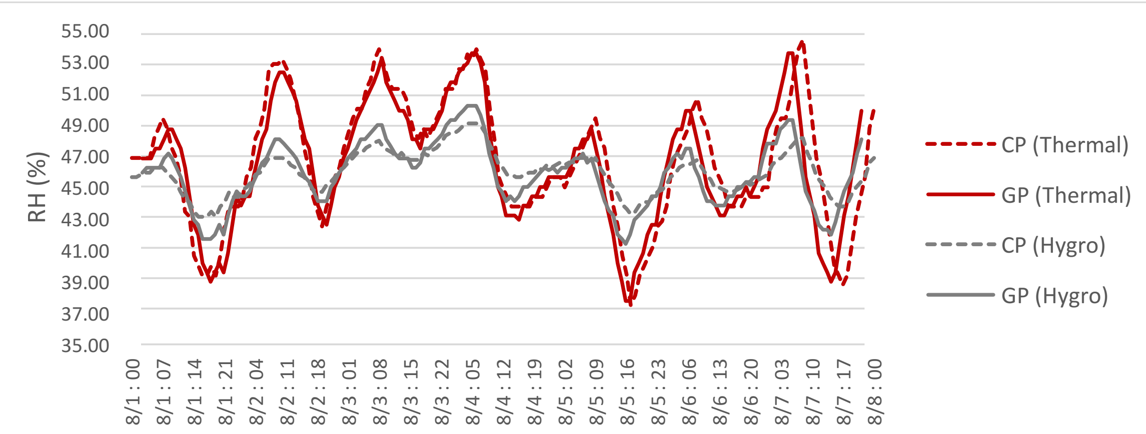

Figure 5: Indoor RH derived from thermal & hygrothermal simulations, 1-8 August
GP: Gypsum Plaster CP: Clay Plaster

Scenario 2: In order to have a clear evaluation on hygrothermal performance of building fabric, it was decided to remove all glazing in one simulation. This eliminates the effect of solar gains and makes it possible to interpret the result solely based on materials performance. As can be seen on figure 6, constructions with same block type result in similar indoor temperature. However when it comes to indoor RH, internal finishing becomes the influential factor and constructions with same plaster type show more similar performances in dealing with moisture and resulting indoor RH. Therefore, the role of substrate in governing indoor RH is negligible. An appropriate combination of the construction block (substrate) along with the finishing material (plaster) can improve building fabric performance.

Scenario 3: In final scenario night time ventilation was applied to study materials performance in a more realistic situation. Night time ventilation reduces indoor temperature resulting in indoor RH peaks. Same as in the first scenario clay plaster helps in humidity buffering and especially in avoiding low RH levels. This strategy needs to be combined with a HVAC unit to give some actual data on energy use and potential energy saving.

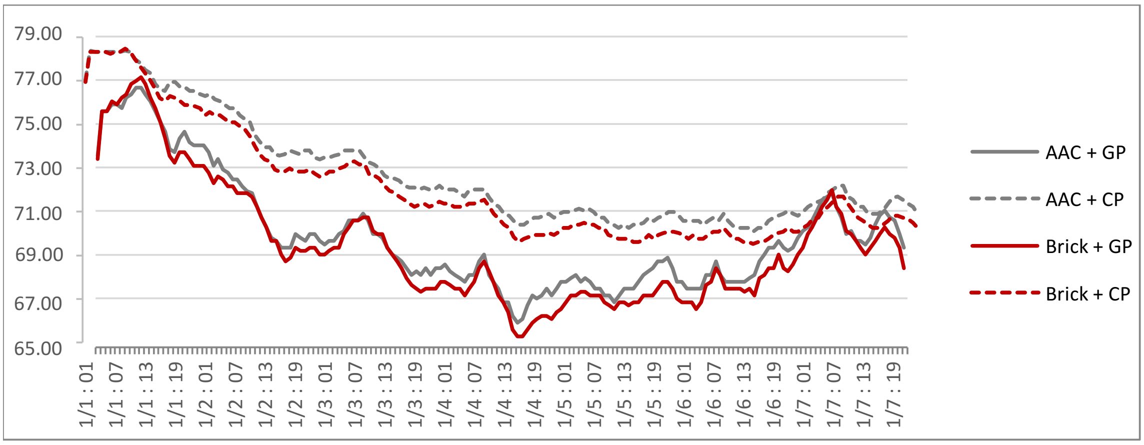

Figure 7: Indoor RH in non-glazed construction, 1-8 January
GP: Gypsum Plaster CP: Clay Plaster

Conclusion

The importance of taking moisture into account in energy simulation models and the potential benefit of the use of hygroscopic materials in moderating indoor environment in a hot and humid climate were studied in this research. A whole building HAM tool, WUFI Plus, was used to model a simple geometry comparing performance of clay plaster as a hygroscopic material with gypsum plaster. Results show that ignoring moisture in building performance modelling has a distinct effect on predicted indoor RH levels especially when a hygroscopic material such as clay plaster is applied.
Results also indicate that in a free running building clay plaster buffers indoor RH fluctuations to some extent, however it has a more distinct effect in higher indoor RHs (above 60%) which happens mostly during winter. Adding plant-based aggregates to clay plaster can help increasing moisture adsorption in lower RH levels. A more sophisticated simulation scenario involving mechanical systems can help studying the potential benefits of hygroscopic materials when mechanical system are in use.

Abstract: Recently, the use of agromaterials in buildings is of great interest in order to improve energy efficiency and renewable energy in a sustainable development context. Some studies are conducted on tropical agro-resources such as Typha which grows abundantly in African west coast countries. In this work, an agromaterial composed of clay and Typha Australis aggregates is characterized in terms of mechanical, hygrothermal and acoustic properties. The Typha aggregates morphology and the binder amount are evaluated in order to determine their impact on the material behavior. For this, different formulations are tested. The first two formulations are of the same binder quantity (clay and tap water) but differ by the Typha aggregates cutting mode: one from longitudinal plant cut and the other from a transverse cut. However, the third formulation comprises an aggregate produced by cross-cutting with a greater binder amount. In the fourth formulation, designed for coating applications, the residues of two different aggregates are used. Mechanical tests are performed such as bending at four points and acoustic measurements including sound absorption. In addition, hygrothermal behavior is characterized by measuring the moisture buffering value. Results show a real impact of the Typha aggregates morphology and the binder amount on the material behavior.

Keywords: Typha Australis, clay, experimental characterization, mechanical properties, hygrothermal properties, acoustical properties.

Introduction

Construction and building industries are the two sectors responsible for 40% of energy consumption (Yan and Chouw 2013). The energy production, mostly of fossil origin, has increased the greenhouse gases emission which consequences are disastrous (climate change, deforestation, migration for economic reason). Building is one of the sectors responsible for excessive energy consumption leading to a high level of greenhouse gases emission (ADEME 2005). Therefore, there is a crucial need to minimize the environmental impact by reviewing the buildings design using the existing methods as for instance, HQE (Haute Qualité Environnementale) in France, LEED (Leadership in Energy and Environmental Design) in USA, and BREEAM (BRE Environmental Assessment Method) in UK. Architects(Niang 1986) and researchers(Gaye,S 2001) carried out studies to integrate bioclimatic architectural design and improve the thermal comfort of buildings using appropriate materials. Among the recommendations, these methods propose the use of biosourced materials as wood, hemp, and straw due their technical (Cerezo 2005), (Samri 2008),(Glé 2013), their environmental performance, and their permanent renewal as Typha Autralis. Typha Autralis is a plant which grows in hot climate especially in Senegal. However, it threatens the local ecosystem and constitutes a socio-economic danger for the invaded area (PNUD 2013). Thus, this plant must be valorized as a bio-based building material in association with an eco-friendly binder as clay. The review on mechanical, hygric, and acoustic properties of building materials derived from biomass (Cerezo 2005) (Millogo et al. 2014) (Dieye et al. 2017) (Diaw,A.S. et al 2016) (Diatta, M 2011) shows a good hygrothermal and acoustic performances but a low mechanical strength.

The present contribution presents an agromaterial based on Typha and clay. The material behavior dependency is analyzed with respect to the morphology and Typha aggregates amount. The first part presents the material and its physical characteristics. Then, the experimental methods are detailed followed by the results and the impact of the type and aggregates amount on the material behavior.

Materials

Typha

Typha australis is an herbaceous, monocotyledonous plant grown in hot climate countries especially in Senegal. Its height can reach 3.50 meters. It is composed of rhizomes, a stem surrounded by leaves, and a cob-fed blade that can contain between 20,000 and 700,000 seeds (Theuerkorn 2002) explaining its high reproductive capacity. In our study, Typha plants (figure 1) were harvested and transported from Senegal according to (ASN 2014). For this study, samples are prepared using two types of Typha aggregates: one from longitudinal cut and the second from transversal cut of the plant. Figure 2 illustrates the two aforementioned types of cut (L: longitudinal; T: transversal).

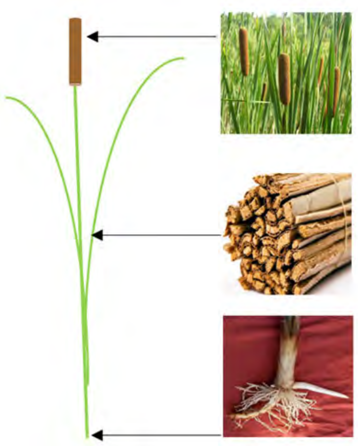

Figure 1 : Typha Australis plant

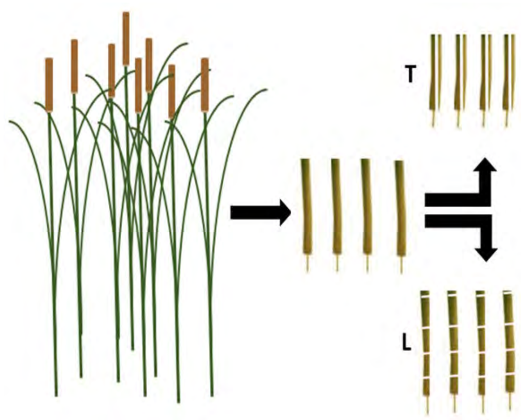

Figure 2 : Cutting strategy of Typha plants

Physical characteristics can be resumed as follows:

- Aggregates resulting from transversal cut (figure 3): this cutting mode maintains the internal structure of the plant characterized by a high porosity. The outer surface of the fiber is rough. The bulk density of the aggregates is about 55 kg/m^3;

- Aggregates resulting from longitudinal cut (figure 4): In this case, the aggregates are similar to chips with a low intra-particle porous structure and a smooth external wall. The bulk density is of 60 kg/m^3.

Figure 3 : Morphology of the transverse fraction of Typha

Figure 4 : Morphology of the longitudinal fraction of Typha

Clay

In this work, clay soil provided by "Thicky" in Thiès region in Senegal is used. Several tests such as granularity and plasticity were carried out to characterize this soil in order to examine if it is suitable as a building material. Figure 5 (Riveros Olmos 2016) shows the granulometric result and it appears that the clay is almost composed of 62% fine particles.

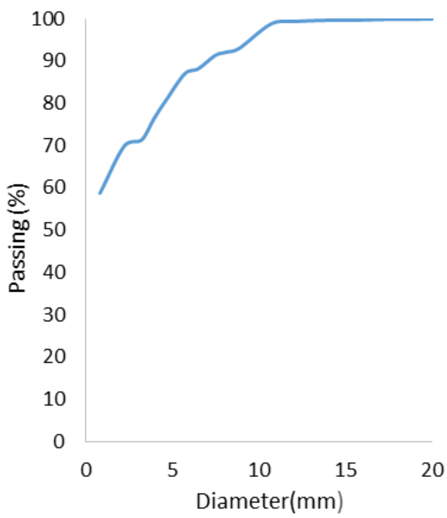

Figure 5: Thicky soil granulometric analysis

Materials formulation

Different formulations are prepared (tab 1) (Samin 2016) in order to estimate the influence of Typha aggregates morphology and the mass fraction on the behavior of this eco-material. The 1A and 2A present approximately the same amount of Typha aggregates but differ in the cutting mode. However, the 2B results from a transversal cut with a high proportion of water and clay.

Table 1 : Material characteristics

Formulation	Cutting type	Fraction content (%)	Density ($kg.m^{-3}$)	Standard deviation ($kg.m^{-3}$)
1A	Longitudinal	32	322,990	9,710
2A	Transversal	28	304,281	1,271
2B	Transversal	17	585,499	3,814

It can be seen that aggregates produced by longitudinal cut (1A) present the highest standard deviation value. Indeed, it should be noticed that they broke up quickly after the drying phase. This is due to the morphology of these particles. In fact, because of their low roughness, they adhere less to the binder.

Experimental characterisation

Four-point bending

Four-point bending tests are carried out using an Instron 8800 traction machine (Grove City, USA) (figure6) with a speed of 0.05 $mm.s^{-1}$. The maximum flexural strength is given as follows:

$$\sigma_{max} = \frac{3.F}{b.h} \quad (1),$$

with F is the applied stress(N), b the thickness (mm), and h the height (mm).

The samples (400 x 100 x $100mm^3$) are subjected to a bending force applied by an electromechanical press and perpendicular to the direction of aggregates orientation. The resulting displacement is then calculated by the measuring device.

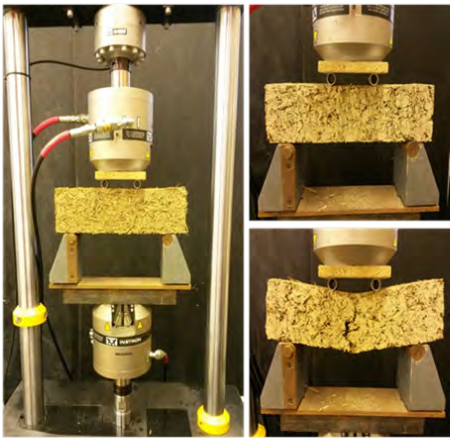

Figure 6 : Experimental device for bending test

Moisture buffering capacity

Moisture buffering value characterizes the ability of a material to dampen relative humidity variations. Based on a specific protocol (Rode 2005), it is defined as :

$$MBV = \frac{\Delta \mathrm{m}}{\mathrm{A.(HRhigh - HRlow)}} \ (2) \ ,$$

where Δm is the mass variation during the absorption or desorption phase (g), A is the exchange surface (m^2), HRHigh and HRLow are the high and low relative humidity during the cycle. It is expressed in g/m^2%RH. Samples of dimensions (100 x 100 x 50mm^3) (figure 7) are subjected to several dynamic sorption and desorption cycles during which the relative humidity is successively set at 75% for 8 hours then at 33% for 16 hours. Test is stopped when the mass variation during adsorption phase is less than 5%, on 3 consecutive days. A preliminary phase of mass stabilization is necessary where the samples are placed in a climatic chamber maintained at 23 ° C and 50% relative humidity.

Figure 7 : Sample for MBV test

Sound absorption coefficient

To evaluate acoustic performance of the studied agromaterial, sound absorption coefficient and transmission loss TL in the frequency ranged between 100 and 2000 Hz are measured. Sound absorption corresponds to the material ability to absorb the energy of a sound wave. The highest level of absorption is that of a material whose coefficient is close to 1(ISO 10534-2 1998). These tests are carried out with the Kundt AcoustiTube (Akustikforschung AFD1000 / AFD1200) (figure 8) which is a measurement method using samples of 10 cm diameter. The used measuring method is based on the use of three microphones (two upstream the sample, and a third downstream).

Figure 8 : Kundt's tube

Results

Flexural strength

Figure 9 shows the load versus displacement obtained for the flexural tests for each formulation 1A, 1B and 2B. The 2B formulations have an important ultimate load (near 900N) and a brittle failure to compare with 1A and 2A formulation. For 1A and 2A formulation the ultimate load is low (between 150 to 200 N) and the flexural test does not lead the failure of the agrocomposite, and induces a continuous increase of the displacement. This results show the influence of the binder ratio in the agrocomposite. Formula (1), make possible to plot the curve of the tensile stress for each formulation as a function of the density.

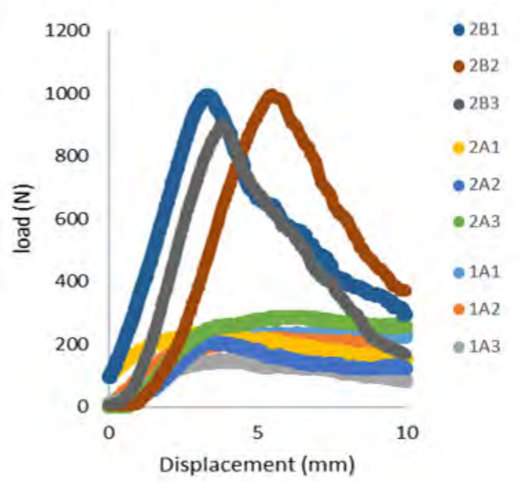

Figure 9 : Load versus displacement for each formulation

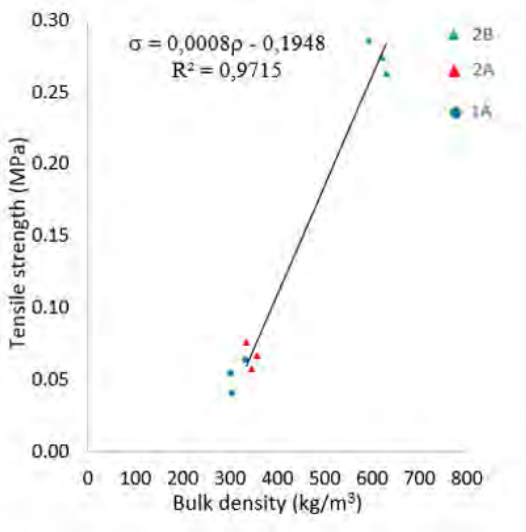

Figure 10: Tensile strength versus density of each formulation

Figure 10 shows that the formulation 2A has a better flexural strength (0.066 MPa) than the formulation 1A (0.054 MPa). Indeed, the section "Typha" in this paper show that transversal fraction of typha are more porous. The cohesion between the typha and clay allows a better transfer of the stresses on the matrix. Moreover, an increase in the binder amount significantly improves the tensile strength thanks to its greater stiffness (0.280MPa). Formula (2) shows the evolution of the maximum tensile stress as a function of the density for each formulations where aggregates are only derived from the transverse cutting of Typha:

$$\sigma = 0.0008\rho - 0.1948 \ (2)$$

Moisture buffering value

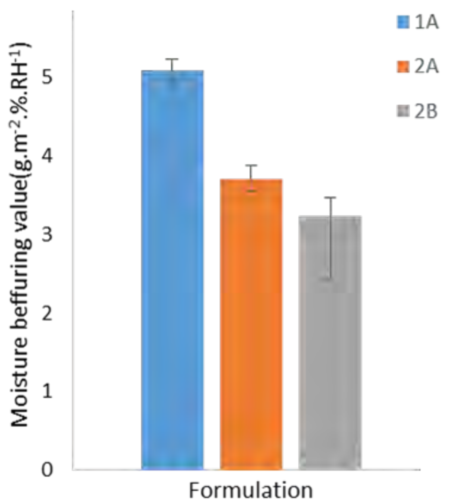

Figure 11 : Moisture buffering value

Figure 11 shows the moisture buffering values for the tested formulation. Values are ranged from 3.24 to 5.08 g.m^{-2} %.RH^{-1}. According to Rode classification, Typha-clay agromaterial can be classified as an excellent moisture regulator (MBV > 2). Measurements show that, at equivalent binder dosage, samples having aggregates from a transverse cut present a lower moisture buffering value (3.75 g.m^{-2} %.RH^{-1}) compared to those made by aggregates from a longitudinal cut (5.08 g.m^{-2}.% RH^{-1}). This could be explained by the porous structure of the longitudinal aggregates mainly composed of macropores which are able to adsorb and desorb water more than micropores presented in transversal fraction. It should also be noted that for the same type of aggregate, an amount of additional binder decreases the capacity of the moisture regulator material from 3.75 to 3. 24 g m^{-2}% RH^{-1}.

Sound absorption coefficient

Figure 12 shows the sound absorption coefficient as a function of frequency for the three formulations. It is found that the sound absorption coefficients for the two first formulations (1A and 2A) are low at low frequencies (60 to 500 Hz) then, they increase sharply with a maximum absorption level at frequencies between 1000 and 1250 Hz. For the 2B formulation, the absorption level is high compared to the first two formulations at low frequencies with a maximum level of 0.91. The acoustic absorption value increases to 0.91 for a frequency ranged between 500 and 900 Hz then decreases to 0.46. The 2A and 2B are more porous than the 1A formulation resulting in a high sound absorption coefficients.

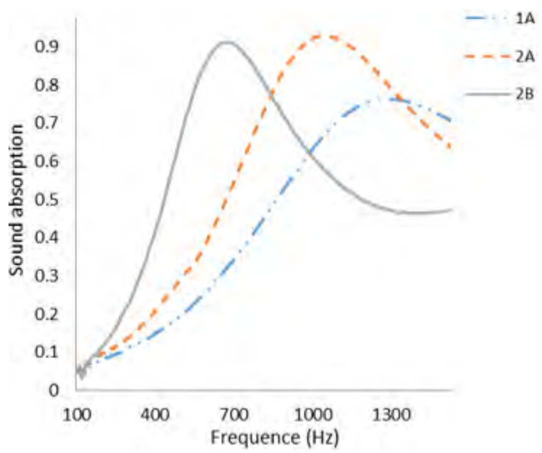

Figure 12: Sound absorption coefficient of each formulation

Conclusion

In this paper, a preliminary study on Typha-clay agromaterial was performed. Two strategies of Typha production were presented as well as their impact on the material behaviour. A first cutting mode consisting of fractioning the Typha's rod longitudinally and a second transversely. The results show that the flexural strength for a formulation composed of Typha cross-section is slightly better by 10%. This level of resistance is multiplied by 4 when the Typha portion in the mixture is divided by 2. Concerning the MBV, the longitudinal fraction improves moisture buffering by almost 35% (from 5.08 to 3.75 g.m^{-2}. %.RH^{-1}). However, for a Typha's transverse fraction, it decreases about 15%. Finally, acoustic tests show that the compositions whose granulate is the most porous (transverse cut) absorb the energy of the sound wave better with a coefficient close to 0.92. The decrease of the amount of transverse fraction makes it possible to maintain the maximum sound absorption level for medium frequencies.

Abstract: In countries with large import dependencies, several studies on strategically important metals have classified raw materials as being critical by combining supply and vulnerability risks. In case of availability, the most critical raw materials are metallic ores and industrial minerals. Within the scope of developing resource efficient buildings, innovative building technologies, such as renewable energy systems, are becoming increasingly integral parts of buildings. Since critical raw materials are essential components in building technologies, they will also play an important role in the housing sector. In this context, it is crucial to consider how sustainability goals in the housing sector are affected by raw material criticality. This paper addresses supply and vulnerability risks of indium, which is contained in thin-film photovoltaics, in order to identify their impacts on future developments in the housing sector. Raw material availability is significantly influenced by the demand and supply of raw materials. To implement risk factors for a criticality assessment in sector-specific material flows, their impacts are analysed and modelled using a dynamic, macro-economic approach. Assuming different energy scenarios in the German housing sector up to 2050, the model reveals the raw material criticality by pointing out supply risks in order to derive recommendations.

Keywords: criticality, raw materials, thin-film photovoltaics, indium, system dynamics

Introduction

The housing sector plays an important role in reaching sustainability goals by resource efficiency improvement. The German strategy follows two objectives in the housing sector to reach a nearly climate-neutral state by 2050: (1) energy consumption reduction and (2) increasing renewable energies use (BMWi, 2015; Bürger, 2016). These plans require innovative technologies like cooling systems, photovoltaics or energy storage systems. Increasing requirements on building technologies lead to increasing needs of scarce resources like metals and industrial minerals. In this context it is crucial to consider if following sustainability goals in the housing sector creates problems of availability or environmental impacts induced by criticality of raw materials.

The availability of raw materials, which meet the needs and requirements of future technologies, is an important issue of technology-driven economies. Import dependencies on strategically important resources force affected economies to argue with risks created by concentrated resource availability. The assessment of raw materials criticality resulted in several studies within the last decades. Raw materials are classified as critical by risk indicators which can be categorized into supply risks, related to the availability of raw materials and vulnerability risks, related to the effects of shortages on the demand side. Affected raw materials are mainly metals and industrial minerals. (EU, 2014; Brandenburg et al., 2016; Marscheider-Weidemann et al., 2016)

Since critical raw materials are essential components in the abovementioned building technologies, they will also play an important role in the building sector (Marscheider-Weidemann et al., 2016). One example for a critical raw material in innovative building technologies is indium used for thin-film photovoltaics. This paper analyses the criticality risks of indium with respect to different market penetration scenarios of thin-film-photovoltaics in the future as a part of sustainability goals in the German housing sector.

Criticality assessment

Photovoltaics (PV) in combination with energy storage systems are assumed to play an important role for the expansion of renewable energy sources. Integrated in the housing sector, PV generates electrical energy not only for heating devices but also provides energy for lighting, household electricity and even other sectors like electric mobility (Öko-Institut e.V., 2015).

Thin-film photovoltaics open up possibilities for technical and aesthetic integration as they can be integrated on the building envelope (Hegger et al., 2016). Currently market-relevant technologies are amorphous silicon (a-Si), micromorphous silicon (µ-Si), copper-indium-disulphide (CIS), copper indium gallium diselenide (CIGS) and cadmium-telluride (CdTe). The critical raw material analysed for thin-film PV is indium, contained in CIS and CIGS technology, which is indicated as CI(G)S. CdTe also contains indium, but is not regarded further as this technology is assumed to be phased out of the German market due to the lower efficiency developments compared to other thin-film technologies and the contained potentially toxic cadmium. In addition, the a-Si technology contains small amounts of indium in the indium-based ITO TCO substrate. Since it is assumed that this substrate will be substituted within the next decade, this technology is also not further considered. (Wuppertal Institut, 2014)

The criticality of indium is reasoned by its vulnerability risks, which is given by high importance for future technologies with expected market growth, like indium tin oxide (ITO), a key material for manufacturing liquid crystal display (LCD) panels. In addition, indium is not substitutable for the required functionality. Indium also experiences high supply risks, which are another important factor in its criticality. Crucial indicators for those are the by-product dependency on zinc production, the country production concentration, country risks and the missing secondary supply by recycling. (Erdmann, 2011; EU, 2014; Marscheider-Weidemann et al., 2016)

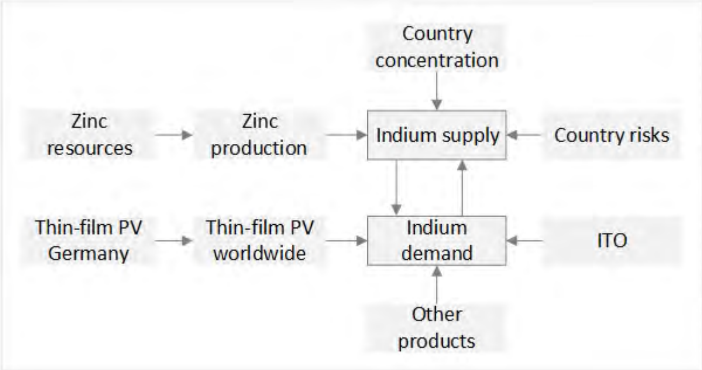

Figure 1. Criticality of indium – considered aspects

The availability of indium is significantly affected by the ratio of supply and demand. All the risks which classify indium as critical have impacts on demand or supply of indium. Even country risks, which include different political and social aspects, can limit the available indium supply. To take that into account the assessment of criticality is based on sector specific material flows. The identification of risk impacts on future scenarios requires a dynamic approach to analyse the developments until 2050.

This is done by a system dynamics (SD) simulation model. The SD approach was created at the Massachusetts Institute of Technology in the 1950s by Forrester and allows the simulation of non-linear behaviour of socio-economic systems over time (Bossel, 2004). For this analysis it is used to model material flows by stocks and flows in order to simulate potential future developments. Future developments of thin-film PV are therefore based on a Wuppertal Institute study, which worked out different scenarios of photovoltaics installation for Germany up to 2050 based on another seven studies on energy scenarios for Germany (Wuppertal Institut, 2014). The indium model is simulated up to 2050 based on these scenarios. As this is a long time-frame with high uncertainties the simulation results are additionally marked with the year 2035.

Simulation model

Main objective of the simulation model is to quantify the supply and demand ratio of indium within the next decades assuming different possible future scenarios in order to assess criticality risks of indium and derive recommendations.

System boundary

The modelled system is based on the global indium supply and demand. As a by-product of zinc, the indium-supply is linked with zinc mine production and is thus limited by zinc resources, defined as currently known mineral deposits (Graedel et al., 2014). Furthermore, indium supply is affected by country concentration and country risks. Indium demand is composed by global demand of thin-film PV, ITO and others. In turn, thin-film PV developments in Germany are linked to the global market.

Model

The supply of indium is based on zinc production, as more than 95% of primary indium is produced as by-product of the zinc refining process (Schwarz-Schampera, 2014). Currently 1.9 * 109 metric tonnes (t) of zinc are known to exist within the earth’s crust (USGS, 2017). The current economically mineable zinc reserves amount to 220.000.000 t (USGS, 2017). The annual production of zinc refinery is defined by zinc refining rate, which is related to previous developments depending on global economy growth. For the indium model, the growth rate of zinc refining is determined by the conservative estimation of 2% up to 2020 (Dorner, 2015). The indium supply is calculated by the indium concentration in refined zinc ores, which ranges between 0.002 and 0.02 percent (Schwarz-Schampera, 2014). The average indium concentration depends on the supply-demand ratio. If demand increases, more of low concentrated ores will be needed and vice versa.

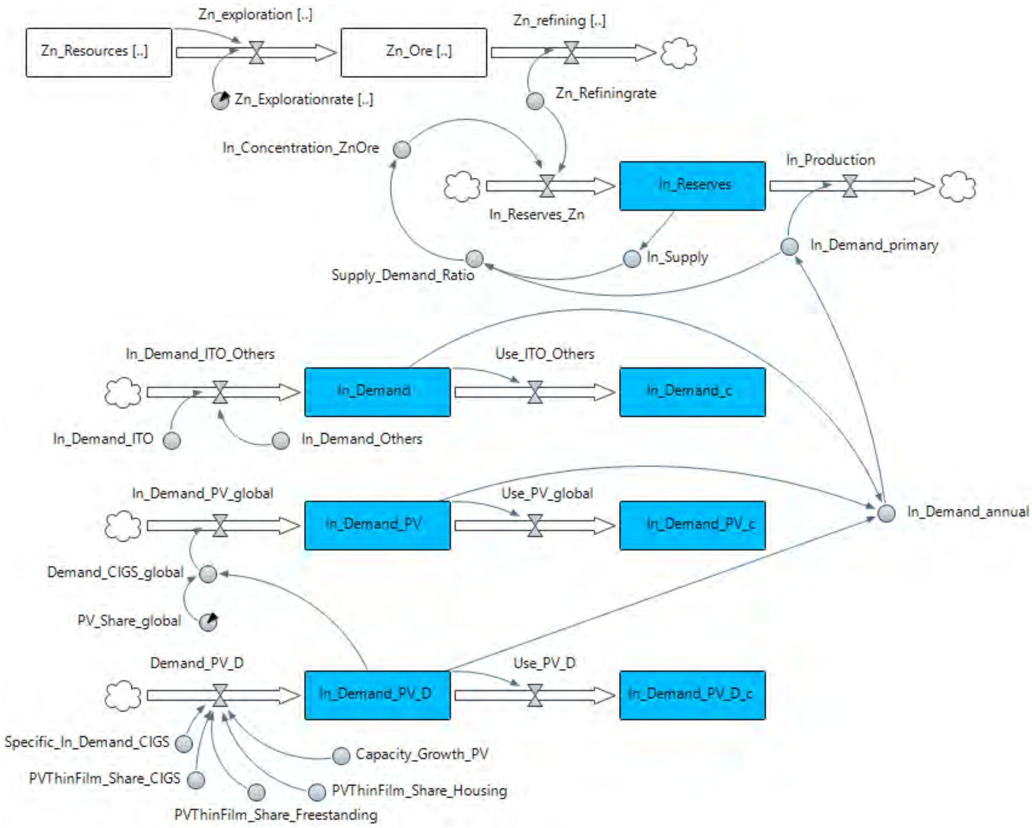

Figure 2. Indium model

An important risk factor for indium supply is the country concentration. If individual countries have a very high share of the world production of a specific raw material, they can influence the quantity of traded raw materials as well as dictate market conditions due to their market power. The country concentration is mostly measured by the Herfindahl-Hirschman Index (HHI) and is calculated as the sum of the squares of market share (Buchholz et al., 2014). In case of indium, which is a by-product of zinc production, high country concentrations affect zinc refining as well as the indium primary production. The share is broken down as follows: zinc refining production: China 34.1%, Rep. of Korea 6.7%, India 5.4%, others 53.8%. Indium production: China 55.2%, Rep. of Korea 18.0%, Japan 8.6% and others 18.2% (Brandenburg et al., 2016).

Another risk factor of indium supply is the country risk. The assessment is based on the World Governance Indicators (WGI) of the World Bank, shown in Table 1 (EU, 2014). This indicator also includes social aspects of resource supply, as it includes measurements like voice and accountability or corruption.

Table 1. World Governance Indicators (World Bank, 2016)

Indicator	Description
Voice and Accountability	Measures the possibility of country's citizens to participate in selecting their government and includes freedom of expression, freedom of association and free media.
Political Stability and Absence of Violence/Terrorism	Measures the probability of political instability and/or politically motivated violence and terrorism.
Government Effectiveness	Assessment of the quality of public services, civil services and their independence from political pressure, policy formulation and implementation and the credibility of governments commitment.
Regulatory Quality	The indicator assesses the ability of the government to implement laws and regulations that permit and promote private sector development.
Rule of Law	Assessment of confidence in and abide by the rules of society. It also includes quality of contract enforcement, property rights, police, courts and the probability of crime and violence.
Control of Corruption	Measures the extent to which public power is exercised for private profit, all forms of corruption and "capture" of the state by elites and private interests.

The governance indicator is measured on a scale from approximately -2.5 to +2.5. Higher values correspond to better governance, whereas the lower values correspond to higher risks. Regarding the WGI of the main zinc and indium producing countries, two countries have noticeable risks: China and India. In China all Indicators, except for government effectiveness, have negative values. The voice and accountability is particularly low, with a value of -1,58. India has similar values, but lower risks in voice and accountability (World Bank, 2016). To assess the risks depending on production countries within the indium model, the material flow of zinc and indium production is divided into the three main producing countries and others. Countries with high risks indicated by WGI were taken into account by subtracting their material flow in alternative supply scenarios. In case of indium a scenario without the supply from China is simulated.

The demand of indium is calculated by the sum of demands for thin-film PV, ITO and other products containing indium. ITO had a share of indium demand of 55 % in 2013 (Oakdene Hollins Research & Consulting, 2015) and is considered to be a growing market. Taking into account for the development of future demands and growth rate, the ITO indium demand would reach 274 t in 2035 (Marscheider-Weidemann et al., 2016). The annual demand for other products containing indium includes alloys, solders, LEDs, batteries, thermal interfaces as well as semiconductors and is assumed to be a constant 87.45 t per year.

The demand for thin-film PV is calculated in different scenarios based on the study by the Wuppertal Institute, which worked out different possible roadmaps for the development of thin-film photovoltaics in Germany, divided into rooftop installation, building integrated and freestanding. The scenarios are varied by the following scales: PV capacity increase, share of thin-film technology for each installation type (rooftop, building integrated, freestanding) and share of CI(G)S technology in thin-film PV. In addition the specific indium demand in CI(G)S is needed to calculate indium demand for CI(G)S technology in Germany. The specific indium demand includes developments of resource efficiency in the production of CI(G)S technology (Wuppertal Institut, 2014). Thin-film technology is a niche market, which has still growing potential worldwide. For the demand calculation it is assumed that the global demand growth of CI(G)S technology is proportional to Germany, with the current German share of worldwide installed PV of 16 % (Fraunhofer ISE, 2016).

Scenarios for Simulation

The criticality of indium depends highly on the global supply and demand ratio. As the exact estimation of future developments is not feasible, there are different possible scenarios simulated to cover the range between conservative to very high indium needs. Regarding the considered PV market for Germany, the demand side is simulated with three different demand scenarios of indium based on the Wuppertal Institute study. The minimum demand is given by a low growth of PV market and a continuous low share of thin-film PV (installed PV capacity 2050: ca. 50 GW). The maximum growth rate of PV market is combined with a growing share of thin-film PV (installed PV capacity 2050: ca. 260 GW). On the supply side two variants are simulated: the indium supply as a result of a conservative growth of zinc refinery and a variation of that without the supply of China.

Table 2. Energy scenarios for Germany based on (Wuppertal Institut, 2014)

PV capacity growth	Low	Intermediate	High
Installed capacity 2050	50 GW	120 GW	260 GW
Low share of CI(G)S	1,33%	1,33%	1,33%
High share of CI(G)S	34,88%	34,88%	34,88%

Results

The simulation results in Figures 3.1 and 3.4 show that under conservative estimations of indium supply, as a by-product of zinc refinery, the resources can meet the needs of indium even if the maximum demand scenario would occur. It can be assumed that the development of thin-film PV is not restricted by shortages of zinc or indium supply. However, the simulation shows that the demand supply ratio in the case of maximum demand can become low, especially when other sectors would grow more than currently expected. That can lead to economic risks regarding the price development and market power of the producing countries and mining companies.

The analysis of the supply risk indicators of indium has shown that the recycling potential of indium from end-of-life products is currently not developed to be economically feasible. The share of CI(G)S of the indium demand starts at 6 % and reaches a maximum of around 42% within the analysed scenarios (Figures 3.2 and 3.5), the German demand reaches a maximum of 8%. Forcing end-of-life recycling by collecting and developing recycling technologies only for CI(G)S PV modules will thus not recover considerable amounts of indium demand. Nevertheless, appropriate product design towards circular economy within the housing sector can be a possibility to minimize the large dependences on primary indium supply.

Besides the reach of indium to satisfy growing needs, the fact that 82 % of indium production comes from three countries, has different dimensions of risks. In particular, China produces more than half of the world's indium and is a country with high country risks, according to the World Governance Index. The exemplary simulation without indium supply from China (Figure 3.3 and 3.6) shows the big dependencies in case of rising indium demand. Economic risks by market power and shortages if China would limit delivery due to political instability or weaknesses in government can for example increase price volatility. Other than the primary raw material supply, this can affect further steps in the supply chain through to end products.

Another important issue which has to be mentioned is the effect on the environment, including social issues such as freedom of association and probability of violence. The aforementioned social risks indicated by the WGI raises the question whether supporting a system where the conditions for human work is not clearly defined agrees with sustainability goals aimed by using thin-film PV. In addition these country risks make it more difficult to regulate and control environmental impacts concerning ecological problems. Although the toxicity of indium is low and harmful effects are not reported, the available data about environmental exposure is not sufficient to make reliable assessments. (Schwarz-Schampera, 2014)

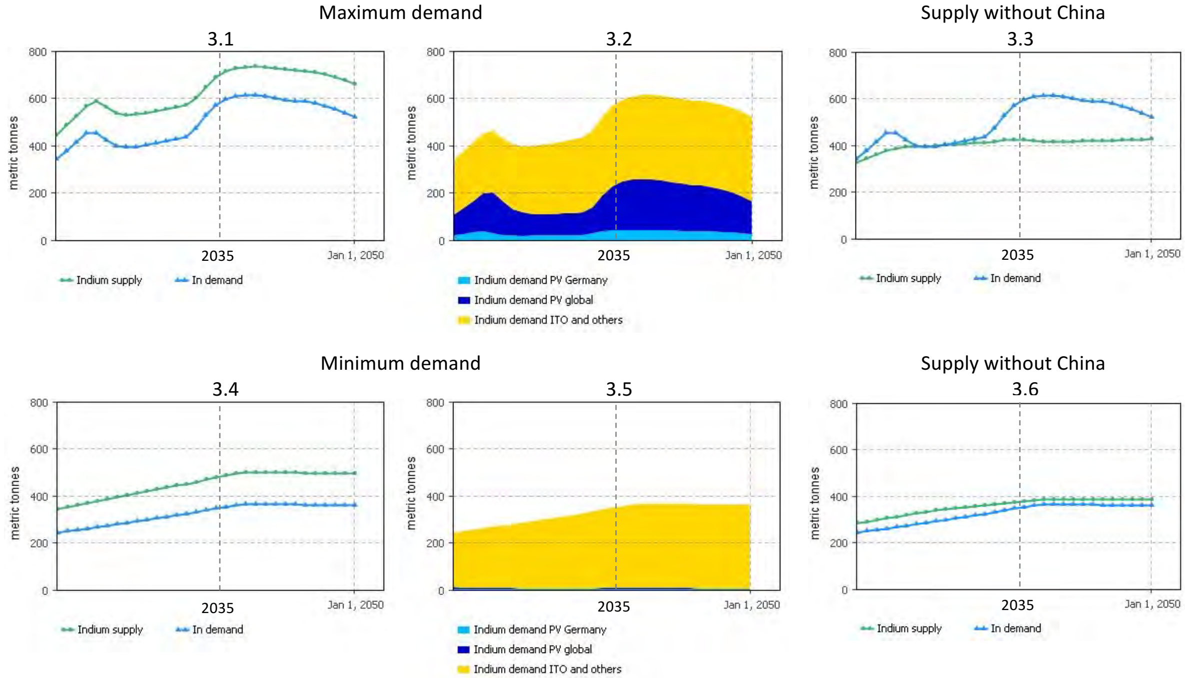

Figure 3. Simulation Results

Conclusion and Outlook

Regarding the indium supply under different thin-film-PV growth scenarios it is shown that current zinc refinery growth is enough to meet potential demands. Only the highest growth scenario can lead to a supply demand ratio which may influence competitive situation regarding the ITO market and commodity prices. Nevertheless, 82 % of indium production comes from three countries and more than the half of indium production is done by China. Reaching sustainability goals by developing resource efficient buildings can currently not be realized without accepting political, environmental and social risks due to the production of indium. Social risks are not easily quantified and difficult to verify as reliable information on mining conditions is rarely available. It has to be asked if and how the discussion about environmental impacts of raw materials mining should be included in aiming sustainability goals for the housing sector.

Should the CI(G)S technology for thin-film PV become a leading technology to reach sustainability goals it is recommended to develop economic recycling technologies to build up a relevant market for secondary supply. End-of-life recycling as a secondary material source can reduce risks induced by country concentration, as production of secondary material will be more widespread than primary production. In addition, conditions of secondary material production can be defined and controlled to meet sustainability goals also in social and ecological aspects. Therefore it has to be discussed how the housing sector can impact developments towards end-of-life recycling or even solutions for circular economies regarding innovative building technologies.

Evaluating the hospital building sustainability: Applying a screening LCA and LCC to the new general hospital in Mechelen

Milena Stevanovic[1,2], Karen Allacker[1], Stéphane Vermeulen[2]

[1] KU Leuven, Faculty of Engineering Science, Department of Architecture, Leuven, Belgium, milena.stevanovic@kuleuven.be;
[2] VK STUDIO Architects, Planners & Designers, Roeselare, Belgium

Abstract: The past decade has been marked by an increased interest in the way hospital buildings are designed and operated. With the urge to decrease the negative impacts of the building stock around the world, healthcare facilities are equally called upon to respond to this matter. In order to assess the sustainability of hospital buildings, a quantitative approach using a life cycle thinking perspective, seems to be an appropriate method. However, due to the complexity and various medical preconditions a hospital needs to fulfil, no such method that would facilitate its sustainability assessment has yet been proposed. An attempt has been made to gain better insight in the environmental impacts and financial cost of a hospital building in Flanders. For this purpose, a screening Life Cycle Assessment (LCA) and Life Cycle Costing (LCC) study has been carried out on the new general hospital Sint-Maarten in Mechelen. This paper focuses on the results of the aforementioned analysis. The aim is to pinpoint the major obstacles for such a quantitative analysis as well as to identify the hotspots from both an environmental and economic point of view. Furthermore, the results will serve as one of the important inputs in laying the cornerstones for the development of the quantitative sustainability assessment method for hospital buildings in Flanders.

Keywords: hospital, life cycle assessment, life cycle costing, sustainability

Introduction

Hospital buildings in Belgium, similar as for hospitals all over the world, are facing the challenge of lowering their environmental impact, while remaining focused on offering affordable and quality medical care to everyone (Stevanovic et al., 2017). As medical preconditions, such as hygiene and patient safety, prevail over any other in hospitals, it is not surprising that these settings have been slower than other corporations in implementing sustainable technologies.

Some efforts to facilitate the sustainability evaluation of hospital facilities have been made in the course of the past decade. This is reflected in the proliferation of the certification tools developed specially to address healthcare buildings. Among the best known ones are BREEAM, LEED, Green Star and DGNB. Most of these tools use a qualitative approach, i.e. they consist of a list of measures which are assumed to be sustainable and work on the principle "the more measures taken, the more sustainable the building". Regardless of their popularity among different building practitioners, resulting from their ease of use, the subjectivity in their assessment approach causes doubts whether the use of these schemes leads to truly sustainable buildings (Aspinal et al., 2012). An approach based on the life cycle thinking perspective, seems to be more appropriate when analysing the sustainability of hospital buildings (Stevanovic et al., 2017). However, a method relying on such an approach in the context of hospitals is still lacking to date. Please note your original selection of forum may have changed to another considered more appropriated for your paper. This information is available when you upload your final paper.

Scope

The main goal of this paper is to gain better insights into the environmental impacts and costs of hospital buildings in the Flemish region. For this purpose, a screening Life Cycle Assessment (LCA) and Life Cycle Costing (LCC) study has been carried out on the general hospital Sint-Maarten in Mechelen (expected to be finished by 2018). The aim of applying the aforementioned study, is to unravel the major obstacles for a quantitative approach when assessing the hospital building sustainability, as well as to identify the hotspots from both an environmental and economic point of view.

The subsequent paragraphs describe the methodology used and discuss several important methodological issues worth the attention when proposing a more holistic quantitative sustainability assessment method for hospitals.

Methodology

Life cycle assessment (LCA)

Life Cycle Assessment (LCA) is a standardized methodology for tracking and reporting the environmental impact of a process or product (i.e. good or service), including a building, over its entire life cycle (ISO 14040, 2006). Though it is still advancing, especially in the aspects dealing with ultimate impacts on human health and ecosystem quality, the technique has become an internationally recognized approach to assess the environmental impact of products or processes (Trusty et al., 2007). For the assessment of the hospital in Mechelen the MMG ("Milieugerelateerde Materiaalprestatie van Gebouwelementen") method is used. The MMG method is a Belgian LCA method developed for assessing building components and buildings (Allacker et al., 2013; Trigaux et al., 2013). A detailed description of the MMG method can be found in Trigaux et al (2014). The MMG method was converted into an Excel-based tool at the Architectural Engineering research division of KU Leuven and this tool was used for the screening LCA of the hospital building. The considered environmental impacts covered in the MMG method consist of the impact categories as defined by the CEN TC350 standards (CEN, 2011). These are referred to as CEN indicators in the method and are listed as follows: global warming potential, depletion of the stratospheric ozone layer, acidification of land and water sources, eutrophication freshwater and marine, photochemical oxidant formation and abiotic depletion of non-fossil resources. Additionally, based on the International Reference Life Cycle Data System (ILCD) Handbook (2010) and in consultation with the Flemish-Belgian policy makers, a list of other impact categories were added, further referred to as CEN+ indicators. The list of additional indicators include human toxicity (cancer and non-cancer effects), particulate matter formation, ionising radiation (human health), ecotoxicity (terrestrial, freshwater and marine), land use: land occupation (agricultural/forest and urban) and land use: land transformation (tropical rain forest).

Life cycle costing (LCC)

Besides the environmental impact, costs are an important issue in the sustainability context to guarantee affordability. Affordability does not only relate to the investment costs, but also to costs for operating the building and costs for replacements and refurbishments. The financial implications of the general hospital Sint-Maarten in Mechelen are assessed through the life cycle costing (LCC) approach, a well-known approach to estimate the costs related to different life stages of a building. Within the LCA tool developed by the division of Architectural Engineering, also a module is included to calculate the life cycle costs of the building. The tool hence allows for simultaneous estimations of both environmental impacts and financial costs (Wijnants et al., 2016). To allow for decisions based on environmental impacts and financial costs simultaneously, it was necessary to have an equal unit for both. For this reason, the environmental impacts are translated into monetary values by calculating the external environmental cost. For the assessment of the hospital building, the tool of the Division Architectural Engineering was used for the calculation of the life cycle environmental impacts (LCA) and financial costs (LCC).

The building life cycle considered within the LCA and LCC method, was divided into four phases according to the European CEN standards (CEN 2011). The phases include production, construction, use and end-of-life (EOL) (Figure 1).

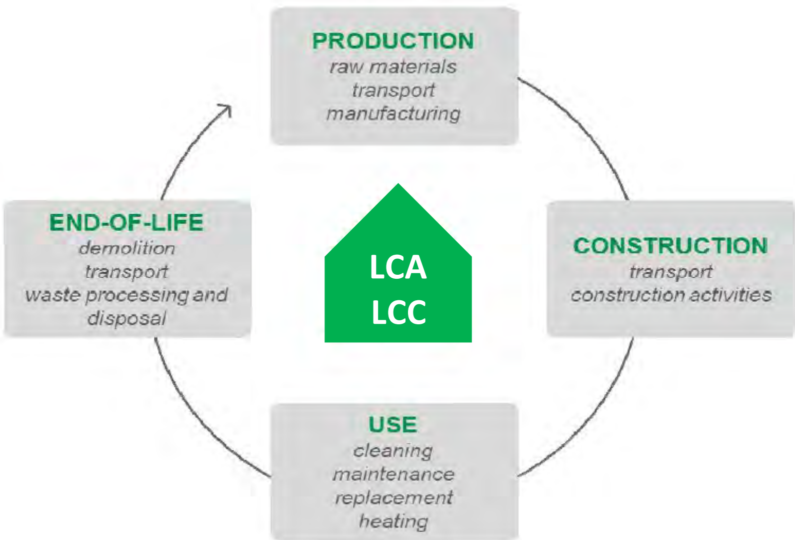

Figure 1. Life cycle phases (adapted from Trigaux et al., 2014)

Case study

Over the past twenty years, a sharp reduction of patient beds and acute care in Flanders has caused hospitals within the same network to merge into one new building, often relocated outside the city centre. This movement was largely encouraged by the Flemish government and VIPA ("Vlaams Infrastructuurfonds voor Persoonsgebonden Aangelegenheden") based on the strategic plan for changing the healthcare landscape. This plan provided infrastructure grants to hospitals moving to a new campus outside city centres (Van den Holen et al., 2008).

In 2007, a competition for the general hospital in Mechelen, fusing three campuses of the Sint-Maarten network into one new construction, was launched. This new, 723-bed hospital was chosen as case study for the screening LCA and LCC study. The project is a result of the collaboration between VK Architects & Engineers, a company with expertise in design and engineering related to the healthcare buildings and Ingenium, a consultancy office specialized in sustainable solutions in the built environment. The first company provided the solutions for the architecture, hospital programming, landscape design and fire safety, façade and acoustical engineering; whereas the second was responsible for the implementation of all technical equipment typical for the hospital.

The building is located nearby the ring road of Mechelen (Belgium) (Figure 2). To achieve a more compact setting, and thus reduce the envelope, construction cost and energy loss, the designers have opted for a monoblock hospital (hospital building typology is described in Prasad (2008) and Wagenaar (2006)).

Figure 2. Location of the hospital (left, © Google maps) and the construction site progress in November 2015 (right, © VK Architects & Engineers)

Data collection and assessment scope

The scope of the screening LCA and LCC study was defined as limited to the building without it surroundings. All life cycles of the hospital building are included in the scope. Moreover, all building parts are included except for the technical installations for heating, cooling, ventilation and medical apparatus. The latter were excluded in the screening study because of lack of data and because these are less influenced by the building design. A lifespan of 30 years is assumed.

For the life cycle inventory phase, a two-step procedure is used. Firstly, data regarding the materials used, energy demand, water consumption, and quantities of building elements were searched for. These were all provided by the company VK Architects & Engineers. The information received consisted of building plans, detailed specifications of materials used and Excel files with quantities of building elements. Based on this information, 93 building elements were defined as the main construction components of the hospital. Based on the BB/SfB classification system implemented in the LCA and LCC method (Trigaux et al., 2014), the building elements were classified into ten categories: (1) floor on ground, (2) external wall, (3) loadbearing internal wall, (4) non-loadbearing internal wall, (5) storey floor, (6) stairs, (7) column (free-standing), (8) flat roof, (9) windows and (10) doors. Secondly, the inventory for each of the materials and processes identified had to be collected. For this step the Ecoinvent database version 2.2 was used and adapted for the context of Belgium (Trigaux et al., 2013). Many of the products/processes were already included in the calculation tool (developed prior to this research). Several were however lacking as the tool was originally developed for residential buildings. The lacking materials, specific for hospital buildings, were modelled and exported from the SimaPro software.

Results

The results of the environmental and financial costs are presented at the building level. The electricity demand is estimated at 136 kWh/m².year based on the VIPA's standards. This includes electricity for ventilation, lighting and medical apparatus. The hospital is heated with natural gas with a gross heating demand of 118 kWh/m².year (net value received from the VK Engineering, system efficiency of 85 % is assumed).

Figure 3 shows the environmental impact of the various life cycle phases, expressed in euro (external environmental cost) per m² floor area. The most impactful phases concerning the CEN indicators include the production, heating and electricity use, covering 10%, 32% and 53% of the life cycle environmental cost respectively. Regarding the CEN+ indicators, the most responsible phases include production (25%) and electricity use (62%), followed by heating (3%), water consumption (2%), cleaning processes (2%) and demolition (2,5%). The remaining 3,5% is distributed between transport to site, construction, small and big maintenance, replacement, refurbishment of the work sections and building elements and transport to EOL and disposal phases.

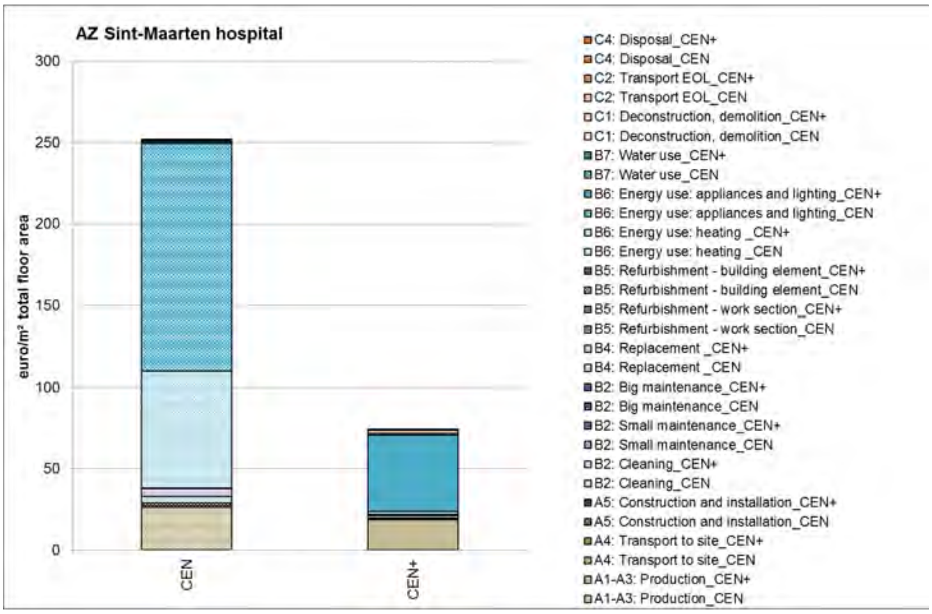

Figure 3. Environmental impact of the Sint-Maarten hospital subdivided per life cycle stage

Figure 4 shows the contribution of the various impact categories to the overall environmental impact. In the group of CEN indicators, it can be clearly seen that the most significant impacts are global warming and eutrophication, covering 92% and 7% of the total environmental cost. Within the CEN+ indicators, the impacts contribute mostly to human toxicity, both cancer and non-cancer effects (46% and 15%), particulate matter (33%) and land use (4%).

From a financial point of view, the most important life cycle stages are the construction of the building and operational electricity use, followed by spatial heating, cleaning and water use (Figure 5). The total financial cost of the hospital's life cycle amounts to 2447,61 euro/m² total floor area, while the investment cost equals 946 euro/m² total floor area (i.e. without technical services). The costs are based on data from a Belgian generic cost database (ASPEN, 2015). The investment cost estimated by VK Architects & Engineers was 10% higher compared to the cost estimation with the KULeuven-MMG model. Based on this validation, the latter is found sufficiently accurate.

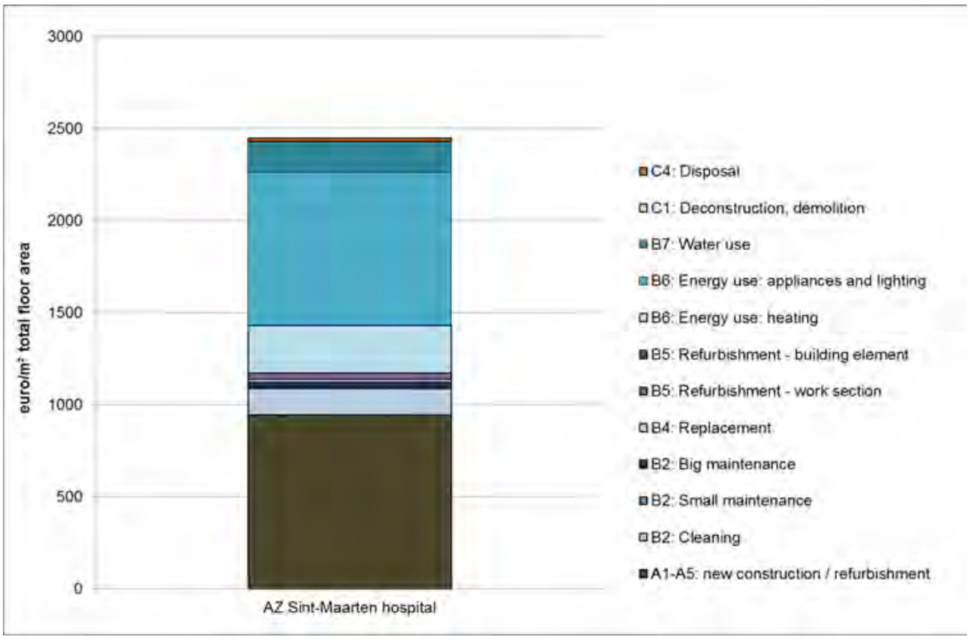

Figure 5. Financial cost of the Sint-Maarten hospital, sub-divided per life cycle phase

Conclusions and further research

This analysis is seen as one of the valuable steps towards the development of a more holistic sustainability assessment of healthcare settings. The screening LCA and LCC of the Sint-Maarten hospital led to several important learnings.

First of all, it was clear that the existing methodology of the research division 'Architectural Engineering', combining the LCA and LCC approach, needed several adaptations to ensure its applicability to hospital buildings. For example, freestanding columns (a common element in hospital buildings) were lacking in the original tool and had to be added. In the context of the Sint-Maarten hospital, the columns are modelled in reinforced concrete, however in future different materialization should be taken into account. Hospital doors (hermetically sealed) differ from the ones used in residential buildings due to cleaning regimes and prevention of cross-contamination through bacteria build up, these had to be added to the MMG database. Many other building components and materials had to be added which are not used in residential buildings, such as for example several floor coverings including a cavity floor structure of steel, sandwich panels for the cold storage and freezer units, a polished concrete floor (technical rooms) and a suspended ceiling made of steel slats used to cover technical pipes. Furthermore, the analysis revealed that often hospitals are more complex than residential buildings, requiring the combination of many more building components. This higher level of complexity required some adaptations to the original model. Finally, for the LCA analysis, many of the inventory data were extracted from the BIM model provided by VK Architects & Engineers. This step revealed that the structuring of the BIM model was not always in line with the MMG – LCA structuring and required quite a lot of time to calculate the correct bill of materials. In order to make this step more smooth, the BIM model will need to be better aligned with the LCA structure in future.

Secondly, the analytical results allowed to identify three major hotspots: a) electricity use for hospital appliances (HVAC and medical apparatus) and lighting, b) spatial heating and c) material production processes.

In the next phase, based on the outcomes of this study, the first cornerstones for the development of the quantitative sustainability assessment method for hospitals will be laid down. One crucial step to be made is to elaborate an extensive database with predefined technical solutions for each of the building elements to be used in the early design phase. This would allow the designers to make a screening LCA without the need for extensive data input. A second step in the further elaboration of the method, is to the heating, ventilation and air-conditioning (HVAC) installations typical for hospitals and integrate these into the LCA and LCC method. A third issue that will be focused on is the integration of transport from and to the hospital in the sustainability assessment method.

Acknowledgements

This study represents a part of the doctoral research, funded by Flanders Innovation & Entrepreneurship (VLAIO), formerly known as Agency for Innovation by Science and Technology (IWT). Finally, the authors would like to extend their gratitude to Erik Vereecken, Tom Debacker, Bruno Vanquaethem, Cindy Puystjens and Jos Vanbesien for providing all the data necessary for the analysis.

Abstract: Bricks are significant building elements that are heavily utilized, whether for structural or ornamental purposes. Nevertheless, little has been published on the relationship between brick bonding, shape, and extrusion, and the impact on energy performance. This paper investigates the impact of different brick bond types and projections on building energy using a custom algorithm. This investigation was conducted in two phases on 24 cases for a south façade. The first phase investigated three different brick bonds for their thermal performance: Running, English and Flemish bonds. The second phase involves parametric simulations to evaluate energy consumptions for three extrusion values [baseline "no extrusion", ¼ brick extrusion, and ½ brick extrusion] and four different extrusion percentages (ranging from 15% to 60%). The first phase results show no significant differences in energy performance for the base case. The second phase results show that the performance achieved was 26% less than the base case. This was accomplished using the Flemish bond with either 30% wall area extruded with half brick length, or 60% bricks extruded with quarter brick length. The preliminary findings indicate a relationship between extrusion and energy performance. Further studies should include in-situ testing and investigation of patterns under different climatic zones.

Keywords: Brick patterns, façade design, energy simulation, parametric tools

Introduction

Bricks were historically utilized as an exterior envelope material in buildings as well as a paving material in landscape applications. In exterior walls, bricks are often left to define the colour of the façade in addition to its structural role in the skin. Bricks may be painted or covered with plaster or cladding of different materials depending on the type of bricks or façade design intent. The source of brick manufacturing can vary by mix and additives with the intent to improve strength, aesthetic colour and look. Using bricks as an ornamental feature of the exterior wall appears in a number of architectural styles. Little is mentioned in the literature on the role of brick bond types, projections and ornaments and few discuss the role of brick formations and bonds in the thermal performance of the wall. The goal of this paper is to provide an exploratory investigation of the impact of different brick bond types and variation in the associated brick projections on building energy use. The research objective is to utilize parametric and thermal analysis tools to develop wall configurations that are sensitive in their look and form to solar radiation; and thus a performance driven design for the determination of wall design thickness and thermal mass to impact the overall building energy use intensity.

Literature Review

To approach the research goal, we conducted a literature review in three primary related areas: (1) Traditional Brick Properties & Patterns, (2) Performance and Energy Analysis of Brickwork, and (3) Potentials and Limitations of Parametric Techniques in Brick Wall Design. A number of studies discuss traditional brick properties and patterns. Among the recent studies, Asdrubali et al. (2014) clarified the importance of material thermal flux to evaluate the in situ thermal transmittance of a material to determine actual wall performance. Lucchi (2017) explored the different thermal properties of brick masonry though a comparative analysis and in situ experiment on industrial bricks used today in Italy versus historic brick masonry. The regular measures taken simulators to examine the thermo-physical behaviour of traditional masonries were presented. The base of the evaluation was built on conventional research of brick masonry geometrical survey, VI, IRT, and hot-disk techniques.

Several studies evaluated the thermal performance and energy analysis of brick work in exterior walls, but generally with traditional and static brick configurations. Rhee-Duverne and Baker (2013) examined the experimentation procedures and modelling software used in testing the thermal performance of various types of traditional solid brick walls. Few studies took into consideration the different brick bonding arrangements to achieve indoor thermal comfort. The Brick Industry Association (B.I.A., 2016) demonstrated some of the significant parameters influencing building envelope performance, including mass, wall thickness, and thermal resistance, and highlights the importance of modelling and simulation to conduct thermal analysis especially for complex buildings.

Several approaches have been adopted to demonstrate the potential and limitations of parametric techniques, mainly in the use of generative and parametric modelling in the design, configuration, and construction of brickwork. Cavieres et al. (2011) used generative rules and functions to inform the construction of load bearing concrete masonry during conceptual and design development phases. The work of Al-Haddad et al. (2012) investigates the link between the structural representation of complex brickwork and its physical construction using parametric modelling. Gentry (2013) explored the prospects of reaching a middle ground between brickwork design flexibility and allowing for design reasoning and material logic exploration.

As for performance based approaches, most of the research is directed to exploring the relation between brickwork configurations and daylighting analysis. Several techniques have been adopted in that regard, especially using genetic algorithms. Little has been done to explore the potential of optimizing thermal transmittance in unconventional brickwork configurations. Genetic algorithms have been widely discussed and adopted in this context for form generation, daylight analysis and structural performance evaluation. According to Omidfar (2015), these approaches allow designers to examine the details of different façade variables using shading systems with decorative patterns. Based on the previous review, a gap in current research is evident in the exploitation of parametric and generative modelling techniques in the reduction and optimization of thermal transmittance in typical brick wall configurations.

Approach

The overall research approach follows the framework shown in Figure 1 in three parts; a) Descriptive, b) Analytical using simulation software and in situ measurements, and c) Comparative approach between simulation results and in situ measurements. The descriptive part addresses building typology and characterization. The analytical part uses parametric simulations and in situ measurements to identify optimum wall characteristics, and the comparative part aims to compare between the simulation results and in situ measurements to recommend and validate best cases and explore the impacts of promoting or optimizing a specific bonding and projection type. The overall approach is shown in Figure 1, however, the main scope of this paper is the investigation of the thermal performance simulation part, as highlighted below.

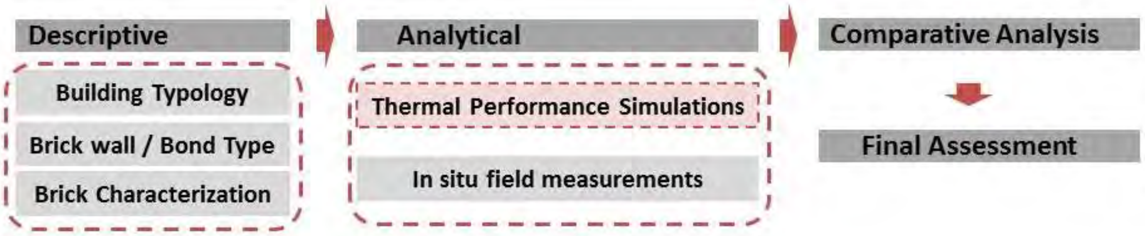

Figure 1. Research Approach

Evaluation method

The evaluation method takes the form of an input-output I/O model as in Figure 2, comprised of four steps; 1) determination of inputs, 2) thermal performance simulation, 3) performance evaluation using analytical tools, and finally 4) tabulation of the outputs.

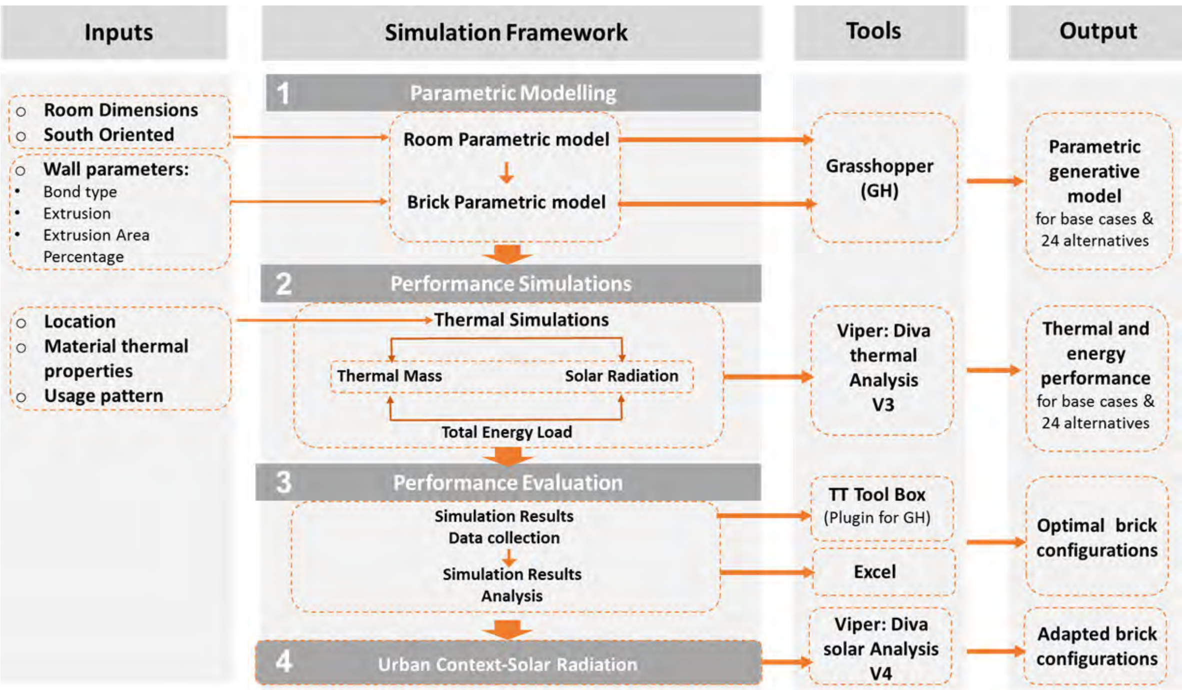

Figure 2. Research Methodology

Preliminary study

The research integrates energy consumption and solar radiation with solar parametric optimization algorithms using Grasshopper and DIVA-for-Grasshopper respectively to conduct multiple thermal simulations. Annual thermal simulations were conducted on a residential space with different brick configurations and extrusion values. A south oriented enclosure was modelled using Grasshopper to test the thermal performance of different brick bonds in a hot arid climate zone. The brick wall was positioned as the southern facade. A brick size of (20cm x 10cm x 6cm) is used in the construction of all wall types. The detailed parameters are shown in Figure 3 and Table 1.

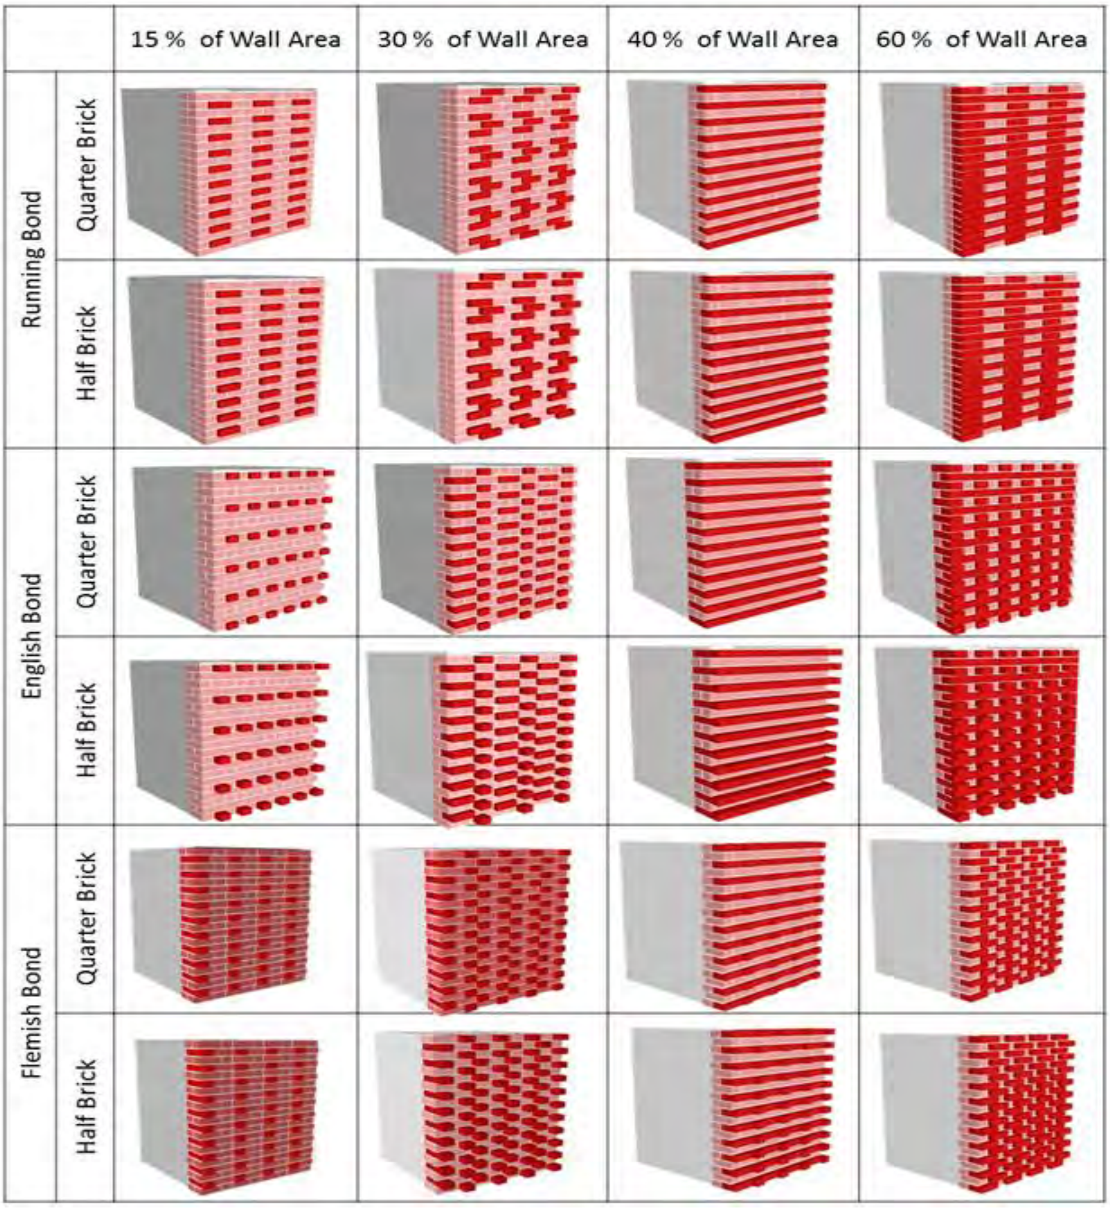

Figure 3: Different area percentages of extruded bricks and values of extrusion for the tested cases

A script in Grasshopper was developed to generate brick wall design variations based on three types of brick bonds; Running, Flemish and English bonds. The three types of bonds that represent the baseline case (zero brick extrusion) are shown in Table 2. The script initiates a basic brick unit with a number of runs and iterations. 24 cases of different brick wall types and different projections were simulated. The figure below shows a matrix relationship of bond type denoting the extent of projection (quarter or half brick size) and the percentage of wall extruded (15%, 30%, 40% or 60%). Later in the paper we will refer to a specific selection as bond type (x brick size, y %).

Table 1. Simulation Parameters

Space Parameters	
Climate Zone	Hot Arid
Floor level	Ground floor
Orientation	South
HVAC set points	
Heating set point	22° C
Cooling set point	26° C
Space thermal properties and material reflectance	
External wall U-Value	Custom 3-layered material: (brick, mortar & brick) with 35% reflectance
Internal walls /Ceiling /Floor	Adiabatic

Table 2. Extrusion values in the three types of bonds

	Running Bond	**Flemish Bond**	**English Bond**
Baseline case: Zero Extrusion			
Extrusion value: Quarter of a Brick			
Extrusion value: Half of a Brick			

Procedure

The brick configurations were based on two main sets of variables: (a) area percentage of extruded bricks, and (b) extrusion distance. Four cases were tested for the area percentage of extruded bricks: 15%, 30%, 45% and 60% respectively. The extrusion value was represented by two steps: ¼ brick and ½ brick extrusion, as shown in Table 3. The simulations were conducted in two phases. First, a set of base case simulations were conducted for three different brick wall bond types: Running Bonds, English Bonds and Flemish Bonds. Second, the annual energy consumptions were calculated for the three extrusion values (baseline, ¼ brick and ½ brick extrusion) and the different percentage of the extruded bricks on the facade (from 15% to 60%).

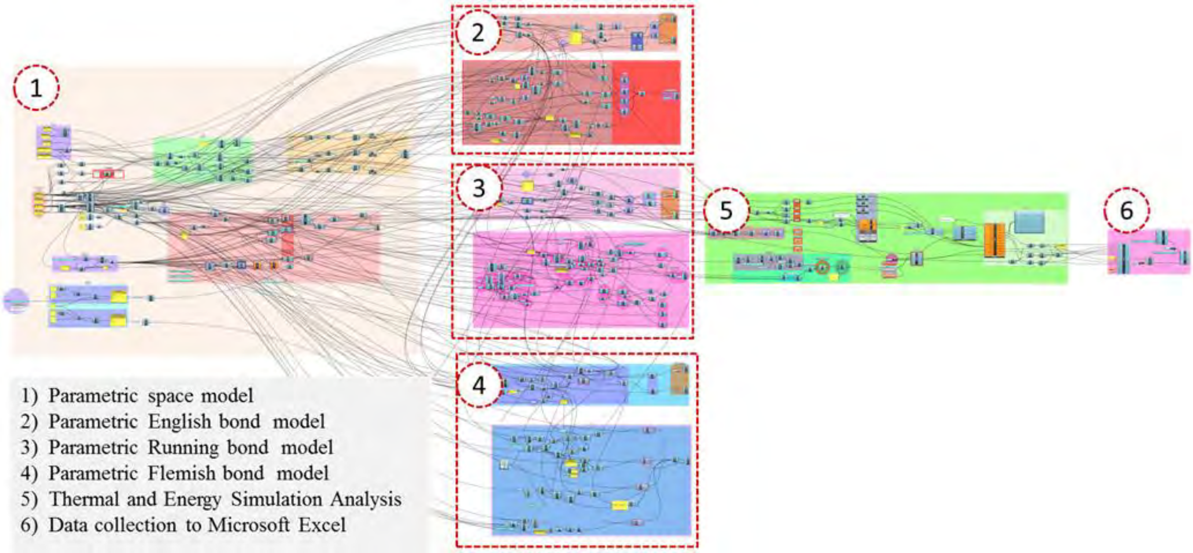

Figure 4: The comprehensive parametric definition in Grasshopper

A closed parametric loop was developed using Grasshopper and DIVA to evaluate the thermal performance of the three brick configurations (Running, English and Flemish bonds) with different brick extrusion values (baseline, ¼ brick and ½ brick extrusion) and different percentages of the extruded bricks' area from the facade (15% to 60%). A large number of simulations was conducted to reach the optimum bond case and optimum percentage of extruded bricks. Subsequently, an annual energy simulation was conducted for a south oriented residential space with different brick configurations.

Output results

The results were classified into three cases: ¼ brick extrusion, ½ brick extrusion, and base case (without any extrusion value) for each bond (Running, English and Flemish), as shown in Table 3. The best performing types resulted from the Flemish bond configuration, with 60% of the wall area made of (¼ brick extrusion) and with 30% of the wall area made of (½ brick extrusion) with a lowest energy consumption of 97 kWh/m^2, as highlighted in Table 3. The worst case however with the highest energy consumption rate at 133.14 KWh/m^2 was the English bond with 15% ¼ brick extrusion. Table 3 reveals that the ½ brick extrusion in the Flemish bond achieved the best energy consumption with extrusions ranging from 15% to 60%.

This is confirmed as the highest thermal mass wall of the ½ brick extrusion Flemish bond achieves the best energy consumption results. By looking closely at each bond type, it is obvious that the Flemish bond case achieved are the best performing, followed by the English and the Running bonds. The extrusion percentage seems to play a significant role in the results of the English and the Running bonds. For example, the ¼ brick English bond results all performed better than the Running bond, except for the 15% extrusion in the English bond.

Table 3. Results of normalized energy use intensity (EUI) for each case in Kwh/m^2

Bond Type	Percentage of wall Extrusion of brick	15%	30%	45%	60%
Running Bond	Base Case	133.53			
	Quarter Brick Extrusion	115.75	112.78	107.01	101.82
	Half Brick Extrusion	109.97	105.17	102.60	128.64
English Bond	Base Case	133.43			
	Quarter Brick Extrusion	133.14	108.33	104.04	100.90
	Half Brick Extrusion	129.27	102.15	103.29	100.17
Flemish Bond	Base Case	131.90			
	Quarter Brick Extrusion	107.46	100.29	99.19	97.46
	Half Brick Extrusion	103.45	97.90	99.02	100.55

As shown in Figure 5, the lowest energy consumption rate is achieved at the 15% extrusion of the wall area in all cases except for the ¼ brick extrusion in the Running bond. Also, the 60% extrusion seemed to give the best energy consumption rates in most cases, as it increases the thermal mass of the wall, except for the ½ brick extrusion in the Flemish bond and the ¼ brick extrusion in the Running bond.

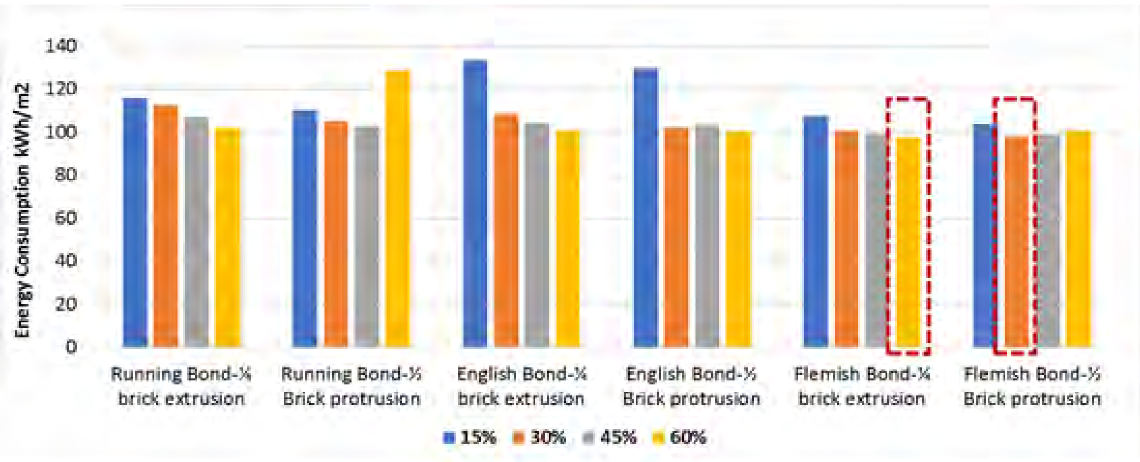

Figure 5. Graph comparing between the energy consumption in each case

Conclusion

It is evident that a relationship can be observed between the brick bond types, their brick projection and the percentage of both this projection and the volume of this projection for the tested cases. The increase in the thermal mass resulting from brick projection has an obvious impact on the thermal performance of the wall. It is also worth noting that the work presented is theoretical in nature, future development of this work may include in-situ field testing for the nominated wall types under the specific conditions relevant to the hot arid climate zone, and investigation of the different patterns that can be generated in relation to different orientations and climatic zones.

PLEA 2017 EDINBURGH
Design to Thrive

From Sink to Stock: The Potential for Recycling Materials from the Existing Built Environment

Irmak Turan[1], John E. Fernández[1], Christoph Reinhart[1], Paulo Ferrão[2], Elsa Olivetti[1]

[1]Massachusetts Institute of Technology, Cambridge, Massachusetts, United States
[2]IN+ Center for Innovation, Technology and Policy Research, IST, Lisbon, Portugal

Abstract: The urban built environment maintains the alluring prospect of being a source for our future resource needs. This work imagines new local recycling paradigms for concrete and masonry waste within an existing urban environment. Using Lisbon, Portugal as a case study, we proposed three context-specific material recycling scenarios to make use of mineral construction waste generated as the city's aging residential building stock is replaced over the next 30 years. We compared four scenarios – three recycling proposals and standard landfill disposal – in terms of production potential, land use, greenhouse gas emissions, and cost. The results show that from both an environmental and economic standpoint, recycling is not always the optimal solution. The impacts depend not only on the recycling processes and end uses, but also the avoided and added burdens consequent to changes in the existing system. Through this analysis, we identified the limiting factors and potential opportunities for improvement in the current processes of construction material reuse and recycling, in Lisbon and beyond.

Keywords: construction materials, circular economy, recycling, construction and demolition waste (CDW)

Introduction

Construction of buildings and infrastructure in cities accounts for over 35% of total global raw material consumption (Krausmann *et al.*, 2009). The injection of construction materials happens primarily while a city is growing, as the built environment expands to serve the increasing population. In the 20th century, post-World War II urbanization fuelled tremendous growth, resulting in the first wave of major worldwide construction material consumption. As new cities continue to grow over the next century, we will face a second upsurge of material consumption (United Nations Department of Economic and Social Affairs, 2014).

While new construction is projected to grow, the existing building stock is simultaneously aging. Buildings that were constructed during the urban boom of the last century are approaching the end of their useful lifespans. Arguably, these buildings are not old. However, many are not well maintained and this is accelerating their demise. Over two thirds of Europe's housing stock was built after WWII and much of it is in need of major repair and renovation.

When these buildings are ultimately demolished (as projected in the coming decades), most will be sent to landfill (Thomsen, Schultmann and Kohler, 2011). Currently in Europe, roughly 530 million tonnes per year or 2 tonnes per capita of construction and demolition waste (CDW) is generated annually. Individual CDW recycling rates vary from one EU country to another, depending on each country's own regulations. In Denmark, for example, the reported recycling rate is 94% while in Greece and Portugal, the recycling rates are less than

10%. Regardless of the current rate, it is assumed that the amount of construction waste generated will continue to increase, roughly at the same rate as each country's economy (Bio Intelligence Service, 2011).

Instead of seeing the material in existing buildings as waste, is there an opportunity to see it as a reservoir for imminent construction needs? Namely, through deconstruction and recycling. Deconstruction is the methodically planned and highly controlled processes of taking apart a building with the aim of separating components and materials "to avoid down cycling, energy transformation and deposit into landfill as much as possible" (Thomsen, Schultmann and Kohler, 2011). In this work, we imagine the potential for implementing a deconstruction and material recycling scheme in an existing urban context.

Methodology

We imagined three new local recycling schemes for concrete and ceramic waste within Lisbon's existing urban system. The work is organized in three parts: First, we estimated the current material stock and projected material output based on the future end-of-life of the buildings. Second, we envisioned the waste processing scenarios (both the existing disposal scheme and proposed recycling alternatives) for concrete and ceramic waste. Finally, for each of the scenarios we calculated the production potential, landfill requirements, global warming potential, and economic cost.

This work examines a set of existing buildings in Lisbon, Portugal. The area of study consists of seven mixed-use, but primarily residential, neighbourhoods. We considered 750 single-family and multi-family buildings within the site, all constructed between 1946 and 2011. Data pertaining to the buildings was collected as part of the larger MIT Portugal Program's SusCity Project (Sousa Monteiro, Pina and Ferrão, 2015).

Current and Future Material in the Building Stock

The urban building stock is a reservoir for future "extraction." To evaluate the feasibility of this idea, we estimated the material intensity and throughput -- the inputs, outputs, and storage – over the buildings' lifetimes. Then, we probabilistically estimate the end-of-life of the buildings to determine when the embedded materials will become available.

Figure 1: Building archetypes and their material profiles

To estimate the quantity of materials in the existing buildings, we utilized five building archetypes that represent the buildings' architectural qualities and material compositions. The archetypes were developed by Sousa Monteiro, Pina, and Ferrão (2015).

An aging building with little architectural heritage value is especially susceptible to removal, due to real estate and economic market factors (Thomsen, Schultmann and Kohler, 2011). Most of the sample buildings are of this condition, and thus susceptible to this demise. Assuming that the buildings will reach their end-of-life as projected in the coming years, we calculated the concrete and ceramic output every decade from 2020 to 2049. The decadal averages provide a sense of the lower and upper bounds of the potential material output of the site. To calculate the output we employed a Weibull time-to-failure function (Bekker, 1980), adopting the shape and scale parameters from a similar study of US residential building lifetimes (Aktas and Bilec, 2012).

CDW Disposal and Recycling Scenarios

Currently most of the concrete and ceramic waste generated during demolition in Portugal is sent to landfill (Martinho *et al.*, 2015). We assumed the existing condition to be the default waste removal scenario. We envisioned three localized recycling scenarios as alternatives to the default (see Figure 2), each designed to keep the material within the local region to establish a circular economy of construction materials. In each case, a particular end use was specified for the recycled material: road construction, concrete paver block production, and structural concrete in building construction.

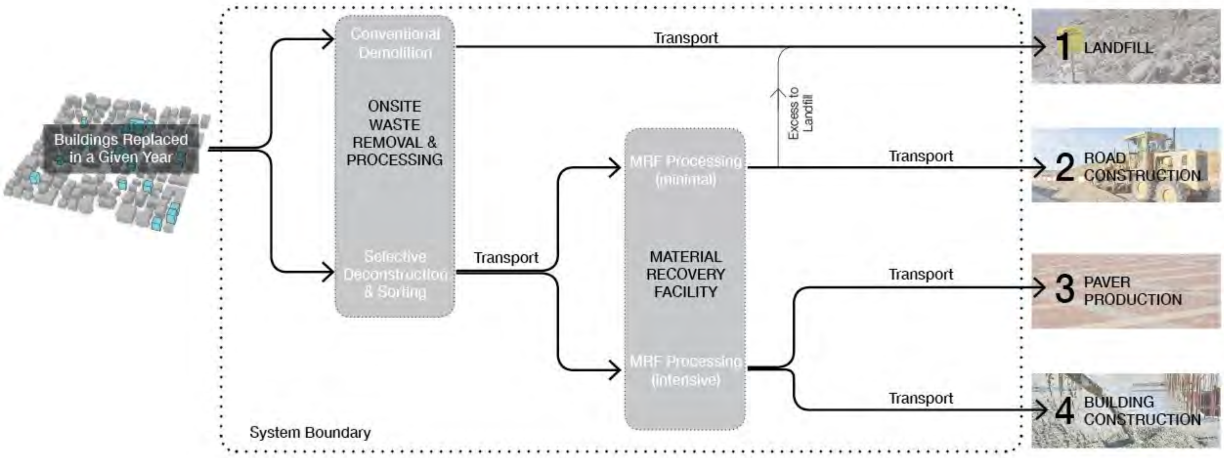

Figure 2: Concrete and ceramic waste processing and recycling scenarios.

The waste processing system includes the demolition or deconstruction of the buildings, the processing of waste into recycled aggregate and all transportation until permanent disposal or sale for use, as shown in Figure 2. The waste processing boundary does not include impacts on the end uses for the recycled aggregate or landfilling. These impacts, henceforth referred to as the *added and avoided impacts*, are considered separately. Transportation, particularly road transport via trucks, has a large impact on the environmental and cost impacts of CDW processing. To make any of the scenarios economically and environmentally viable, we limited the transport distances to reduce the impacts from trucking. Waste processing was limited to a distance of 25 km; landfill and end use drop-off was limited to 50 km; and raw material sourcing was limited to 100 km. The envisioned transportation pathways for each scenario are illustrated in Figure 3.

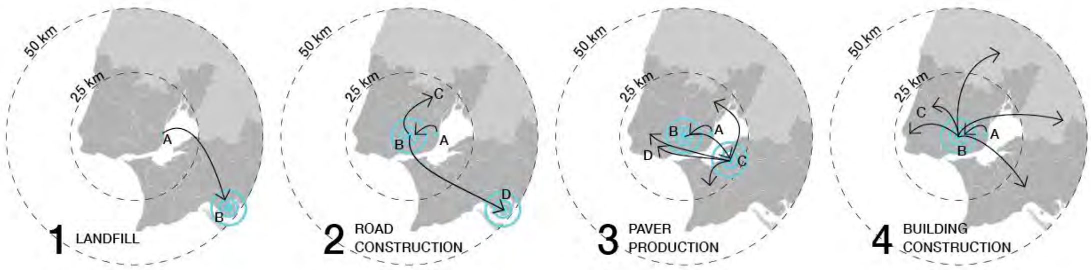

Figure 3: Proposed transportation pathways for the waste processing in the Lisbon metro area.

Calculating the Impact: Production Potential

Concrete and ceramic waste can be processed into recycled aggregate, which feeds a variety of secondary production processes. We considered three possible secondary end uses for the recycled material: *road construction*, *concrete paver block production* and *structural concrete*.

Recycled aggregate is often used as a sub-base layer in road construction. The 2-lane roadway considered in this scenario is based on an assembly proposed by Herrador et al. for an access road in Spain (2012). It consists of a 14cm pavement surface over a 30cm aggregate base layer, over is a second 50cm base of artificial aggregate. The recycled aggregate layer is composed of 75% concrete, 20% asphalt and 5% ceramic material, as per specifications provided by Herrador et al.

Concrete paving blocks used to create pedestrian walkways are a preferred application for recycled aggregate because, like in road construction, it allows for flexibility in quality and purity of the recycled material. The paver production considered in this scenario is based on a pre-cast concrete block proposed by Poon and Lam in their study of aggregate-to-cement ratios for this type of application (2008).

Using recycled aggregate for structural concrete in new buildings is the most appealing of the recycling proposals considered because it is the only truly closed loop system. The concrete mix considered consists of 50% recycled aggregate and 50% raw aggregate, based on Swiss data from Knoeri, Sanye-Mengual, and Althaus (2013). The use of recycled aggregate reduces the structural quality of the concrete, and necessitates a modified concrete mix in order to meet buildings regulations. Specifically, the mix requires an additional 10% cement, 10% fly ash, 50% water, and 30% superplasticizer. This modifications in the mix are considered in the secondary production calculations.

Calculating the Impact: Landfill Area Requirements

Landfill area is required for waste that is not processed and used as recycled aggregate. We assume that in the default demolition scenario, all the waste goes to landfill. In the recycling scenarios, some of the concrete and ceramic waste can go to landfill, as it may not satisfy the recycled aggregate quality required by the secondary uses. We size the landfill requirements based on numbers provided by Butera, Christensen and Astrup (2015): 1500 kg/m3 and 10m height.

Calculating the Impact: Global Warming Potential

Global warming potential (GWP) is a measure of the heat trapped by a greenhouse gas in the atmosphere. It is often measured, as it is in this analysis, over a 100-year period. For each scenario, we added the GWP of each process and activity to get a total GWP value. We employed lifecycle inventory data from the EcoInvent 3 database using SimaPro and the IMPACT 2002+ impact assessment method (PRe Sustainability, 2014; Wernet *et al.*, 2016).

Calculating the Impact: Costs

We estimated each scenario's overall cost based on recycling and waste processing industry data for Portugal (Coelho and de Brito, 2011; Coelho and De Brito, 2013). The cost includes all processes that are within the waste processing system boundary, from demolition to delivery of the recycled aggregate to the end use. For the three recycling scenarios, we also considered the potential earnings from selling the material. It is assumed that the concrete portion of recycled aggregate is sold at a rate of €2.76/tonne while the brick waste is given away at no cost (Coelho and de Brito, 2013).

Results

Production Potential

We assumed that 90% of the concrete and ceramic waste coming out of the sample buildings goes to the material recovery facility (MRF) for processing (and the remaining 10% is lost in onsite processing). This amounts to 19,910 tonnes per year recovered; of which, roughly 60% is concrete and 40% is ceramic. We assumed that, once in the MRF, 68% of the waste material is turned into recycled aggregate and 32% is lost as fines (Weil, Jeske and Schebek, 2006). Based on the material output from the MRF, we calculate the production potential of each recycling scheme:

In scenario 2, we estimated that annually 8,000 tonnes per of concrete aggregate and 5,500 tonnes of ceramic waste is available for use in the road. The production is limited by the amount of recycled concrete aggregate available, therefore only 500 tonnes of the ceramic waste is utilized. The remaining 5,000 tonnes of ceramic is assumed to go to landfill. Based on the amount of concrete recycled aggregate supply, approximately 1.5 to 2 km of new roadway can be constructed. Using the recycled aggregate results in 12,000 tonnes per year of avoided natural aggregate use.

In scenario 3, we assumed that 100% of concrete and ceramic recycled material, or 13,500 tonne per year, is used for paver production. The recycled material provides enough aggregate to produce 5.8 million paver blocks, enough to pave 35 to 40 km of 3m-wide pedestrian sidewalks. Using the recycled aggregate results in the avoided use of roughly 14,000 tonnes per year of raw aggregate.

In scenario 4, we assumed 100% of the concrete and ceramic recycled material is used as aggregate. This quantity can replace half of the natural aggregate required for the structural concrete, avoiding 23,700 tonnes of raw limestone sourcing per year. The mass of avoided raw material is greater than the mass of recycled aggregate used because of the difference in densities: 1890 kg/m3 for natural aggregate versus 1374 kg/m3 for recycled aggregate. The recycled aggregate coming from the buildings stock supplies enough material for roughly 19,700 m3 of structural concrete per year, enough to construct about 12 multi-family apartment buildings.

Landfill Area Requirements

In scenario 1, we assumed that all of the waste coming out of the buildings goes to landfill requiring a total area of 40,000 m^2 for waste over the 30-year period. In scenario 2, the road sub-base layer requires a mix of 75% concrete, 20% asphalt and 5% ceramic aggregate. Roughly 5,000 tonnes per year of ceramic aggregate is unused and assumed to be disposed in landfill, requiring a total area of 10,000 m^2 over the 30-year period. In both scenario 1 and 2, the landfill area was sized for the material output over the full 30-year study period (2020-

2049), as CDW landfills require long-term planning and land allocation. In scenarios 3 and 4, all of the concrete and ceramic-based recycled aggregate is used, thus there is no material sent to landfill. Material that is lost as fines during the recycled aggregate production process in MRF was excluded from the estimates in all cases.

Global Warming Potential

Global warming potential (GWP) results are presented first for the primary system (i.e direct impacts) and separately for the added and avoided impacts (Figure 4). For the primary system alone, scenario 1 resulted in the least amount of GWP. This is expected since the other scenarios have added activities and transportation associated with recycling. This is particularly true for scenarios 3 and 4, due to the added processing and transportation needed for a higher grade recycled aggregate. This result is in line with other similar studies of CDW recycling (Blengini, 2009).

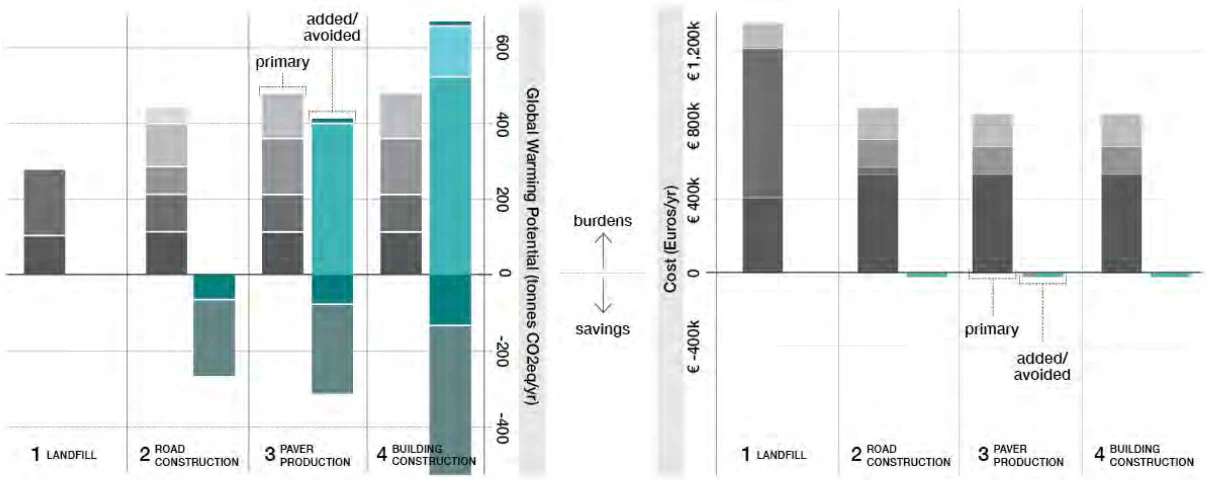

Figure 4: Global warming potential (tonnes CO2 eq per year) and costs (euros per year) for each process. The direct impacts in the system boundary are in grey; the added and avoided impacts of the associated end use processes are in color. Positive values are GWP/Euro burdens or “costs,” negative values are savings.

The changes in the end uses resulting from the application of the recycled aggregate are significant and, if allocated to this system, can influence the GWP results greatly. In all recycling scenarios, there is a negative GWP for avoiding the use of natural aggregate. At the same time, in scenarios 3 and 4 there is an added impact for the increased use of cement and other materials to make up for the loss in strength of the concrete. Due to the high carbon intensity of cement production, the added GWP from the increased use of cement is about as much as the whole waste recovery and recycling process itself.

The added and avoided activities in the end uses could be alternatively allocated to the secondary processes. If this were the case, then these impacts would *not* be included in the analysis of these scenarios. Whether the impacts are included or not, it is useful to see the magnitude of environmental consequences resulting from the changes required in the end use processes relative to the waste recycling processes.

Costs

The costs include all processes within the waste processing system boundary, from demolition to delivery of the recycled aggregate to the secondary end use. For the three recycling scenarios, the potential earnings from selling the material were also considered. All three recycling scenarios have lower net cost than the disposal case primarily due to the high landfill tipping fees (Figure 4). The tipping fee is assumed to be €41/tonne for mixed CDW as per Portuguese industry data (Coelho and de Brito, 2011). The results show that while the recycling schemes have added processing and transport activities, the high fee for disposing the material in landfill results in roughly 50% increase in cost over any of the recycling scenarios. It should be noted that the cost analysis does not consider changes in the cost of the secondary end use production.

Results Summary and Analysis

	1 LANDFILL	2 ROAD CONSTRUCTION	3 PAVER PRODUCTION	4 BUILDING CONSTRUCTION
Production Potential (variable)	-	2 km new roads per year	35 km new sidewalks per year	12 new apartment buildings per year
Landfill Area (m2)	40,000 m2 for 30 year period	10,000 m2 for 30 year period	-	-
Global Warming Potential (tonnes CO2eq/yr)	274 (+/- 84)	174 (+/- 230)	572 (+/- 221)	616 (+/- 302)
Cost (euros/yr)	€ 1,358,000 (+/-67,000)	€ 885,000 (+/-88,000)	€ 845,000 (+/-88,000)	€ 845,000 (+/-88,000)

Figure 5: Summary of results for the four scenarios.

There is no scenario that is advantageous across all categories, as illustrated in Figure 5. In the three recycling scenarios, waste has a production value and contributes to the creation of something new (either roads, pedestrian pathways or buildings). The societal value of each end use depends largely on the local demand for the product in question. The environmental impacts – measured in terms of GWP (a global impact) and land use for landfill (a local impact) – have an inverse correlation. Namely, the recycling scenarios require additional processing and transportation, increasing the overall GWP; at the same time, using the material means that less waste is sent to landfill. Lastly, the landfill disposal scenario costs over 50% more than all of the recycling scenarios. This is due to the high landfill tipping fees. There is a minor cost distinction between the recycling proposals themselves, as the waste processing to create the aggregate is similar in each case. However, this cost analysis does not consider additional or avoided expenses in the secondary production processes. In summary, based on the four impacts considered, there is no clear winning scenario. The preferred option is in large part dependent on the local needs, economic conditions and environmental priorities.

Conclusion

Can we utilize the materials embedded in our existing buildings as a resource to feed the next generation of cities? In this work, we examined this question by analysing three site-specific schemes to locally recycle concrete and ceramic waste. We considered the impacts of each scheme in terms of production potential, land use, global warming potential, and cost. The results show that, from both an environmental and cost standpoint, the circular material paradigm is not always the optimal solution. The impacts depend not only on the recycling processes and end uses, but also the avoided and added burdens consequent to changes in the existing system. The results highlight the need for a nuanced approach to the topic of waste management and resource recovery. It is often the case that recycling is an environmentally preferable alternative to landfilling. However, as shown in the results of this analysis, there are exceptions. Ultimately, we must develop more thoughtful, efficient, and long-term holistic solutions for material use and reuse in construction.

PLEA 2017 EDINBURGH
Design to Thrive

Vernacular Architecture: Advocating Volcanic Stone Construction as a Viable Alternative to Fired Brick in Mountainous Areas of Southwestern Uganda

Peter Wasswa[1] , Achilles Ahimbisibwe[1], Alex Ndibwami[1]

[1] Faculty of the Built Environment. Uganda Martyrs University, P.O. Box 5498 Kampala, Uganda. aahimbisibwe@umu.ac.ug, andibwami@umu.ac.ug, wasswapw@gmail.com

Abstract: Natural stone possesses physical properties suited for structural walling, yet in Uganda it is habitually specified for its aesthetic finish. Kisoro, Fort portal, and Bushenyi are naturally endowed with abundant volcanic stone, yet residents still opt for brick walling despite the poor soils in the area, which produce low quality bricks. In comparison to Compressed Earth Block (CEB) and Compressed Soil Block (CSB), stone barely features as a sustainable walling option. Industry, economics and Infrastructure development have each played a significant role to interrupt the success of sustainable development particularly with regards to fired brick. Swamp destruction, air pollution, and unregulated indiscriminate deforestation linked to fired brick production are entirely ignored. Uganda loses 3% of its forest cover every year raising carbon emissions in 2013 to 0.134 tons per capita. Efforts to avail more environmental, ecofriendly and socially relevant alternatives to fired brick have done little critical interrogation on case-by-case basis for rural communities around the country. This paper presents volcanic stone as a viable walling material in areas where it is abundant.

Keywords: Vernacular, Stone Construction, Sustainable development

Introduction

Natural stone possesses physical properties suited for structural walling however; in Uganda it is habitually specified for its aesthetic finish *(floor surfacing and wall cladding)*. In comparison to Compressed Earth Block (CEB) and Compressed Soil Blocks (CSB), stone has not been explored as a potential front-runner among sustainable walling alternatives. Kisoro, Fort Portal, and Bushenyi are endowed with abundant volcanic stone, however, yet residents still opt for brick walling despite the poor soils in the area, which produce low quality bricks. While developing countries like Uganda struggle to meets the Sustainable Development Goals, little is being done to empower local communities to meet their own local aspirations. Industry, economics and urban Infrastructure development have each played a significant role to interrupt the progress of sustainable development particularly with regards to fired brick. The swamp degradation, air pollution, and unregulated indiscriminate deforestation linked to fired brick production have all been ignored to favour what is considered an inexpensive walling material. According to (NEMA 2002: 122), Uganda loses 3% of its forest cover every year raising carbon emissions in 2013 to 0.134 tons per capita. This raise in emissions can be traced back to the triumph of fired brick. Efforts to interrogate environmentally, eco-friendly and socially conscious alternatives to fired brick require a critical case-by-case approach to distinctive rural communities around the country. This paper, presents volcanic stone as a viable walling material in areas where it is abundant.

The use of stone in the construction is not completely alien to this context. According to Nnamdi (1997), stone construction in Africa dates back to over 10,000 years ago. In fact, Shadmon (1996) writes that Stone was used for construction way before man ever started using metallic tools. Stone construction in Africa was popular in hilly parts of Africa creating what was known as the "hill style", Nnamdi (1997). More recently, residents in the hilly areas of Bunyaruguru and Kasese have constructed and actually live in stone buildings as shown in *Figure 1*. In parts of Kabale stone construction is evident in their stone garden perimeter walls, and stone cooking fireplaces.

Figure 1: Stone Cottage in Fort Portal and abundant stone in south western Uganda

Fired brick is not indigenous to Uganda's material palette, in fact it was never used, at least not until a century ago, when the biggest Cathedrals were constructed at Namirembe and Rubaga (Moon, 1994). The complexity of the then imported Gothic and Romanesque style cathedrals could not be achieved using the popular vernacular materials of the time like reeds, mud and thatch. Therefore, the British and French architects resorted to a more structurally capable material; the fired clay brick (Olweny, 2007). Banking on the lush forest environment that existed at the time and swamp clay around Lake Victoria, the stature and magnificent of these cathedrals gave rise to a wave of change in Uganda's construction industry. Industry demand is consistently impacting Uganda's forest cover. World Bank (2015) estimates that Uganda's formerly lush forest cover is now a mere 8.6% of the country's total land area. This massive deforestation is to a large extent linked to fired brick production. An independent student in the Nkozi village found that on average its takes over 9 tonnes of wood fuel to fire a medium sized kiln for 20,000 Bricks (Ahimbisibwe et al, 2016). Further, artisans keep the firing period and temperature low to save on fuel (*which is increasingly harder to come by*), this in turn results in low quality bricks up to 45% of the entire production. More bricks are lost when it rains or on nights a cool breeze. Naturally occurring forests as well as recently planted forests are being cut down for wood to fuel brick production as well as to serve as construction timbers such as formwork and other structural supports. However, it's not just forests that have suffered at the expense of the growing popularity of fired clay brick in the country. Swamps too are being destroyed and depleted of clay. According to SSA: UHSNET (2015), good clay is becoming increasingly scarce in Uganda. This has crippled the already struggling pottery industry in Uganda.

Worse still, the local brick industry is highly unstandardized and because of this there is an inconsistent quality of bricks most of which are irregular. Further, some bricks are made from poor quality soils (locally know as *kifufu*) and are significantly weaker than the ignorant public expects. Irregularities in brick configuration have led to the wasteful use of mortar as the masons attempt to deliver straighter walls. Additionally, weaker bricks contribute to heaps of waste noticed on numerous construction sites as in *Figure 2*. The cost of brick construction is even higher in the mountainous areas of Southwestern Uganda where good clay soils hardly exist. Brick are transported large distances to service these areas; further increasing the economic and environmental cost of construction. Brick transportation in the popular diesel trucks used in Uganda countries for partly loaded, small to medium gasoline trucks over rough roads could consume as much as 5MJ/tonne for every kilometre (Fraser et al, 1995). Transportation delivers an avoidable carbon load of up to 0.0741 $KgCO_2$ per kilometre (Quashning, 2016).

Figure 2: From Left to Right, Fired Brick waste at Kiln, in Construction and heaps left over after construction

World Bank estimated that by 2012, 19.5% of the country's population was below the poverty line, majority living in rural communities of Uganda such as those that make up most of the mountainous southwestern parts of the country. As a consequence, reducing the cost of construction is crucial for the success of vital infrastructure developed such as housing. "The cost of an average home mortgage in Uganda is about $30,000" Muhumuza (2016). However, according to the World Bank development indicators (2016), Uganda's Gross National Income is $670. On a monthly basis, that is an average of $56. This means that on average a Ugandan committing up wards of 30% of their annual income to service a mortgage, would require 144 years for one to pay off the loan. These sums are inflated when interest is compounded. This indicates that even a middle-class Ugandan would need to spend well over 50% of their income to afford decent housing. Yet still, low cost housing in Uganda is considered by Ministry of Lands, Housing and Urban development, to be that which doesn't exceed more than 30% of the homeowner's income (Muhumuza, 2016).

Unfortunately, architects in practice are not helping the situation. Most architects in the country persistently avoid rural commissions because few, if any, people there can afford their professional fees. As a consequence, the low-skill level *"Fundis"* and draftspersons that take on these rural projects generally work with a *"standard"* brick palette as taught in technical schools. Potentially viable materials and construction techniques in rural societies are not being unexplored for their economic and environmental merit.

However, involvement of Ugandan architects in rural construction projects is also unlikely to yield any appreciation for those local materials since according Olweny (2006), most architecture schools in Uganda are making no efforts to involve technology as an important aspect of architectural design. This has resulted in minimal efforts by architects to research and creatively come up with new ways to improve and use vernacular materials. Moreover, even the schools that do incorporate technology in the student's design process, have their efforts let down when students go into the field and become negatively influenced by senior architects with contrary education, field and construction experience. The result of this is architecture that is not primarily informed by its context. No wonder, foreign architects undertake most contextually responsive commissions in the country.

Another factor at play here is the existence of urban-rural links across the country. According to Odongo (1977), when people migrating from rural to urban areas succeed in Urban areas, they go back to their rural homelands and set up big houses as a sign of their success. These houses are in most cases copies of similar houses in urban areas built mostly with fired brick. Locals then begin to associate not only clay brick but also other wasteful materials to wealth and prestige and therefore strive to liken their houses to the town brick house, giving no chance to other viable local materials or construction techniques. This further creates an industry of local artisans who develop their skillset exclusively to support the "fired brick" market. Furthermore, low levels of income in rural areas cannot allow these artisans to develop skills in constructing with local materials and construction techniques which are not in demand.

There are three dormant volcanoes in southwestern Uganda, and these include: Muhavura, Bufumbira and Fort Portal. According to Shadmon (1996), in the eruption of a volcano, as hot Larva reaches the earth's surface, it quickly cools down, forming crystals of igneous volcanic rock. Some of these rocks include andsite, basalts, purnice, and rthyolite. It is important to note that any one of these stones have a higher compressive strength than the popular fired brick. Take for example basaltic rock that is most abundant in these areas, has an uniaxial compressive strength ranging between 12-63 Mpa, Schultz (2012). Which is higher compared to the average compressive strength of fired brick that ranges between 5-10 Mpa.

An interview held with the locals revealed the residents' general perception that stone construction is expensive. The locals even refer to it as the *rich man's material*. According to the locals, stone construction requires a lot more sand and cement mortar than fired brick. Also, due to low popularity of the material, skilled masons in the area are rare and expensive. Interviewed residents revealed that the construction process too takes a long owing to longer durations required to dry the huge chunks of mortar. The delicate process of laying the uneven stone to form regular walls, also contributes to the prolonged construction process.

However, stone has always been used as construction materials in the area. The residents say that before the popularity of brick in the area, vernacular architecture was constructed using mud and wattle like in other indigenous communities of Uganda. However, unlike in other areas, people in Kisoro added small volcanic stones to the mud to create firmer walls. The walls were then finished with chalkstone dissolved in water to create a smooth surface. Today, there are few stone buildings in the area mostly owned by the rich. The difference being that the wealthy use sand and cement, yet the rest use mud mortar. However, the result is not sturdy and for this reason, some residents in search for better quality buildings opt for fired brick rather use stone with mud mortar.

Interviews revealed a latent optimism towards stone construction. However, mortar was presented as the major hindrance to stone construction, cement and sand mortar is too expensive and mud mortar is low in quality. The solution to this is dry stone construction. Dry stone construction involves careful selection of irregular stone to be stack together without slipping, forming a firm freestanding wall. Dry stonewalls are typically wider at the base and are much narrower higher up. According to Gray (2015), dry stone structures gain strength from the weight of stone pushing inwards and settling, causing the stone to lock together forming a stronger structure. This type of construction does not require any special tools or materials. However, it requires a skilled craftsman to choose and place the stone together. This type of stone construction has so far succeeded in Kenya mainly in the residential sector mainly due to durability, low construction costs and the simple structures of residential buildings (Ochola, 2016). Ochola adds that volcanic stone has an outstanding ability to retain heat. Heat retention is of great advantage in parts of southwestern Uganda where temperatures fall as low as 5 °C.

One good practice example in a similar context is Butaro hospital by MASS design group architects located in Butaro, Rwanda just a few kilometers from Kisoro with similar climate, terrain and abundance in volcanic rock. This project made use of the local volcanic rock, but also successfully convinced the society through the quality of the physical structure, that there is potential in this long-ignored material. With the society convinced, a new industry of stone dressing, marketing and construction has been able to kick off in Butaro, creating jobs that otherwise didn't exist as Benimana (2016) explains. Similarly, The artisans who hand-crush stones for aggregates in Southwestern Uganda can be further commissioned to shape volcanic stone to more regular blocks that can be assembled with less mortar. Further, in this same context, there is an existing trade of hand-crushed stones for construction aggregates. Stone crushers stand a chance to make additional income from stone dressing like their counter parts in neighbouring Kenya as shown in *Figure 3*.

Figure 3: Ugandan students learning how to dress soft Stone from an artisan in Machakos, Kenya.

It all comes down to equipping communities with the necessary knowledge and skilling a few artisans to enable them better evaluate their decisions. If architects with projects in rural areas made an effort to understand and develop the available local materials and construction techniques, and most importantly, involve the locals in this process, community transformation will then be possible. Schools of architecture, too, need to educate built environment professionals to be more open-minded and to take pride in the heritage of this country, and the materials and opportunities that our context has to offer. This can be achieved by questioning how we build and who builds if we are to transform rural communities all over the world.

Thermal comfort and overheating investigations on a large-scale Passivhaus affordable housing scheme

Andrea Botti[1]

[1] Centre for Environment and Sustainability, Faculty of Engineering and Physical Sciences, University of Surrey, Guildford, UK, a.botti@surrey.ac.uk

Abstract: The uptake of the Passivhaus standard has rapidly increased in the UK during the recent years, in line with the improvements in the energy efficiency standards for new dwellings. This paper builds upon a recently completed post-occupancy study for a Passivhaus-certified large-scale affordable housing development, specifically focusing on summer thermal comfort. Assumptions and predictions of overheating risk made at the design stage are analysed and compared with the indoor temperatures measured during summer 2015. In this study, interviews and questionnaires are overlaid with quantitative data in order to explore occupants' comfort perception and improve the understanding of the inter-relationships between aspects of building design, occupant behaviour and the risk of overheating. The analyses showed a high frequency of overheating, diverging significantly from the estimates made using the PHPP tool. This is due to a combination of factors, such as higher internal heat gains arising from higher occupant density and usage of internal appliances and, in some cases, insufficient reliance on natural ventilation to purge excess heat. Given the difficulty in predicting in-use occupancy patterns at the design stage, a more robust design strategy is recommended, which could include measures to minimise summer overheating and future-proofing against a changing climate.

Keywords: passivhaus, PHPP, overheating, monitoring, post-occupancy-evaluation

Introduction

There has been an increasing up-take of housing schemes built to Passivhaus standards in recent years, in line with Government policy trends that have encouraged improvements in the energy efficiency standards for new-build developments. In an effort to tackle fuel poverty, which still affects 10.6% of English households (DECC, 2016), social housing developers are expected to be the frontrunner for building energy efficient for their social renters (McManus et al., 2010).

Buildings designed and built to Passivhaus standards are considered to be highly energy efficient, due to a highly insulated and airtight building envelope, as well as to the optimisation of passive solar gains and heat generated from building occupants (McLeod et al., 2011). While these measures can significantly reduce the energy use as well as improve thermal comfort in the winter months, a growing body of literature suggests that unintended consequences may arise during the summer months, contributing to the risk of indoor overheating (Dengel & Swainson, 2012; McLeod et al., 2013; Jones et al., 2016).

Despite the recent adoption of the Passivhaus standard in the UK (Passivhaus Trust, 2016), a growing number of research studies are focusing on the overheating assessment of Passivhaus buildings, by means of both thermal simulation modelling and of in-use data monitoring (McLeod et al., 2013; Sameni et al., 2015). The risk of summertime overheating has been documented for Passivhaus buildings in Northern Europe (Larsen & Jensen, 2011), and it has the potential to be severe in the UK as a result of climate change (Jenkins et al., 2009). For Passivhaus built in urban locations, McLeod et al. (2013) warned that active cooling may become a requirement in the near future, unless the minimisation of future overheating risk becomes a key design objective.

In order to obtain Passivhaus certification, designers have to consider summer thermal comfort and are required to provide evidence the risk of overheating is minimised. However, the assumptions made in the PassivHaus Planning Package (PHPP) design tool are often standardised, thus they may not accurately reflect the conditions observed in reality. Opening windows for purge ventilation may be limited or not at all possible in urban locations. Furthermore for certain types of occupancy, such as social housing tenants in the UK, research has suggested that occupant density and internal heat gains may be significantly higher than the standardised assumptions included in the PHPP (McLeod et al., 2013). As it has emerged in the recent years, building overheating is a complex issue and there is a lack of conclusive evidence on how the risk predictions produced using simplified methodologies compare to the in-use performance (ZCH, 2015).

Methodology

Case study

This paper builds upon a recently completed POE project carried out for an affordable housing scheme, located in the London Borough of Havering and completed in 2015. The scheme is one of the first large-scale 100% affordable Passivhaus-certified housing developments in the UK, with a total of 51 dwellings, comprising one-bedroom and two-bedroom flats, and three-bedroom and four-bedroom terraced houses.

The study involved monitoring a sample of 9 homes during the first year of occupancy (Table 1), in order to gain an understanding of residents' experiences and behaviour. Both quantitative and qualitative methods were used, where environmental data was collected from the main rooms and questionnaires were prepared for the purpose of conducting in-depth interviews with the residents. By overlaying the two information sets, a rounded understanding of the relationship between building performance and occupant behaviour was gained, including how far different behavioural patterns deviated from the typical design assumptions. This paper narrows down the broad focus of the POE project to look more specifically at summer-time thermal comfort. The extent of indoor overheating is assessed for monitored temperatures and compared to the predictions made at the design stage, allowing to quantify the performance gap and to identify the main causes for it.

Table 1. Total units and sample units selected for the POE study

Block	Unit types	Total no of units	No units in POE study	Short names
Block A	1B, 2B flats	16	4	A08, A10, A11, A16
Block B	4B house	13	0	
Block C	3B house	8	2	C01, C06
Block D	4B house	13	3	D11, D12, D14

Thermal comfort assessment criteria

Buildings seeking to achieve Passivhaus standard have to be modelled using the PHPP design tool developed by the Passivhaus Institut (PHI). For summer thermal comfort, the PHPP sets out a maximum temperature threshold, intended as a comfort limit, and using steady-state calculations it predicts the frequency which temperatures are expected to exceed it. Such overheating risk is expressed as a percentage of the occupied year, which for a dwelling is taken as 365 days (Passivhaus Institut, 2014).

$$T > 25°\text{C } (= T_{max})\ for\ more\ than\ 10\%\ annual\ occupied\ hours$$

While meeting the 10% target is mandatory in order to achieve the Passivhaus certification, the guidelines recommend that the frequency of overheating does not exceed 5% in order to guarantee high summer comfort in a changing climate (McLeod et al., 2011).

Review of the design assumptions in the PHPP

While a comprehensive in-depth review of the PHPP as a design tool is outside the scope of this paper, the present study follows two lines of investigation:

a) how different are the risk estimates made for the different unit types at the design stage, and why;
b) how far the risk estimates are reliant on assumptions of in-use occupant behaviour.

As such, for the purpose of this study only the factors leading to different estimates are reported (Table 2). In terms of heat gains, this means solar gains resulting from different block orientations and internal gains from different assumptions on household size. With respect to heat losses, including natural ventilation by means of window opening.

Table 2. Factors defining heat gains and losses during the summer as calculated through the PHPP tool (v8.5)

PHPP v8.5				Heat Gains			Heat Losses		
				Solar Aperture (for solar gains)		Int. heat gains	Ventilation (ach)		
	TFA (m^2)	No units	No occupants	total (m^2)	(m^2/ m^3)	Specific power (W/m^2)	via MVHR	Via windows	OH Risk
Block A	1311	17	37.5	35.6	0.03	2.9	0.34	0.0	2.6%
Block C	639	8	18.3	22.5	0.04	2.3	0.30	0.1	2.3%
Block D	1476	13	42.2	68.4	0.05	3.5	0.40	0.2	8.3%

Quantitative data collection: monitoring equipment and external weather

Monitoring of indoor environmental conditions was carried out using HOBO UX100-003 Temp/RH 3.5% data loggers to record indoor temperature and relative humidity (with ±0.2°C accuracy) and HOBO UX90-001 State/Pulse/Event to record window opening. The UX100-003 loggers were calibrated in an indoor environment, revealing a ±0.15°C difference which was deemed acceptable for the purpose of the study. The UX100-003 loggers were placed on top of door frames, away from sight, direct sunlight and active heat sources and data was recorded in 15-minute intervals. HOBO UX90-001 were fixed onto window frames.

The focus period chosen for this paper ranges from 21st June to 21st September 2015, herein referred to as ‘summer 2015’. During this period a short ‘hot-spell’ was experienced, from 30th June to 2nd July, with temperatures exceeding 30˚C on two days.

External weather data was obtained from Gravesend-Broadness weather station, using the MIDAS data archive system (Met Office, 2012). A comparison between the monthly weather data used in the PHPP calculations with mean monthly values calculated for the Gravesend-Broadness weather station (Table 3) shows no significant difference other than for the month of July, partly due to the hot spell. While it is likely that had an impact on the 25C exceedance, this assessment has not been the focus of this research, as all units were impacted in a similar manner.

Table 3. Monthly data for design weather, compared with mean values recorded during summer 2015

Location / type of data	Distance from site	Jun	Jul	Aug	Sep
Hemsby (East Anglia) / generated from historical data	~100 miles	15.2	16.7	17.4	14.9
Gravesend-Broadness (Kent) / calculated from data collected during summer 2015	~10 miles	15.9	18.1	17.7	13.6

Qualitative data: occupant perception and behaviour

The broader study relied on questionnaires and one-to-one interview, including both ranking and open questions, to collect background information about the household composition, occupants' background, perceptions of their thermal environment and interaction with it. For the purpose of this paper, an extract of the questionnaires for the summer period was considered, particularly the section exploring thermal comfort perception, when asked "H*ow has your home been over the summer?"* participants could choose from: "*comfortable"*, "*sometimes too hot"*, "*always too hot"*. As for window opening behaviour, when asked "*When did you open windows?*" they could indicate "*never*", "*out of habit*", "*when too warm*", "*all day*" for day-time and "*never*" and "*always*" for night-time.

Results

One of the early findings of the POE project was the discrepancy between the standard occupancy assumptions and those actually observed, in terms of both size of households and occupancy patterns. Table 4 provides a summary of such patterns, indicating the typical pattern for the adult (block A) or the adults (blocks C, D) for each households.

Table 4. Comparison between actual size of households and PHPP assumptions

		Household size		Occupancy pattern	
Block	Unit	Actual	Assumed	Actual	Assumed
Block A	A08	2	2.2	works part-time	standard
	A10	2		home most days	
	A11	2		works part-time	
	A16	2		works part-time	
Block C	C01	4	2.3	both home most days	standard
	C06	5		partner home most days	
Block D	D11	6	3.2	both home most days	standard
	D12	5		both home most days	
	D14	5		both work full-time	

Internal temperatures were very high during the whole period, with median often above 25°C, as shown in Figure 1. However, different building unit types showed different temperature distributions: most notably, much greater ambient temperatures swings were observed in the houses' (block C and D) if compared to the flats (block A), which were mostly ranging between 24°C and 26°C.

The occurrence of overheating for the summer period, i.e. a 25°C exceedance expressed as a percentage of annual occupied hours is shown in Figure 2. The chart provides a comparison between the predicted risk of overheating (black bar), expressed as a summary figure for a whole block and calculated using monthly average values, and the much more granular data - logged sub-hourly - for individual rooms in each unit. This approach can reveal the limitations of using simplified tool when trying to capture a complex phenomenon such as indoor overheating.

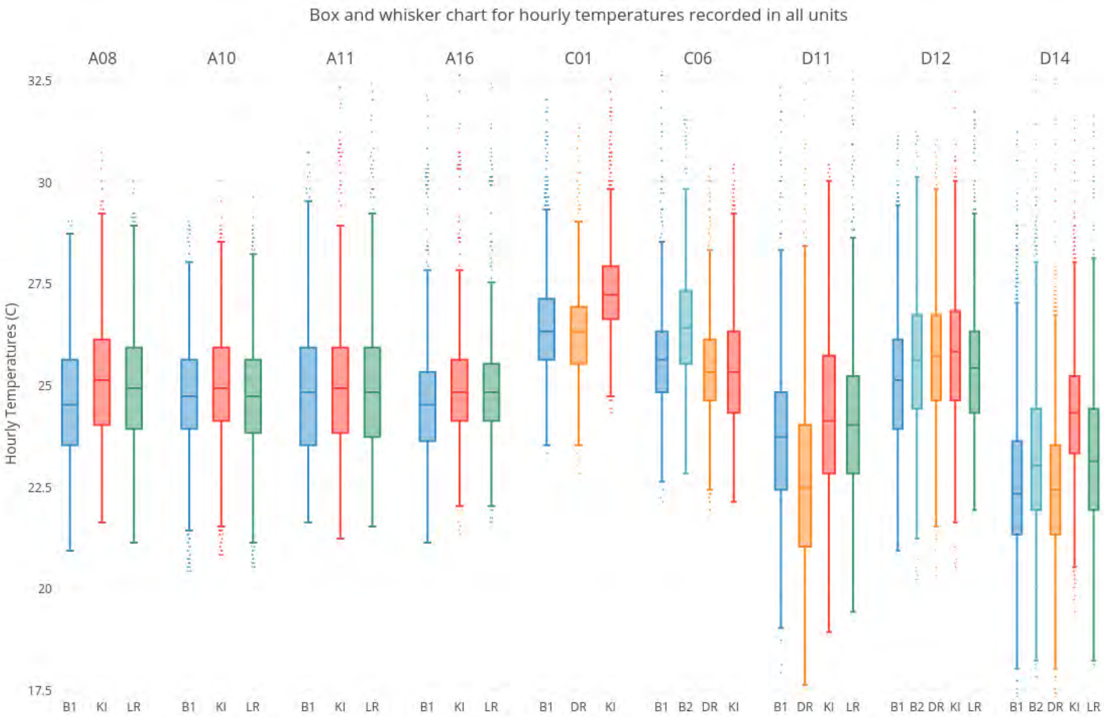

Figure 1. Box and whisker chart of indoor temperature observed during summer 2015, colour coded based on room type (i.e. blue=bedroom1, cyan=bedroom2, red=kitchen, yellow=dining room, green=living room)

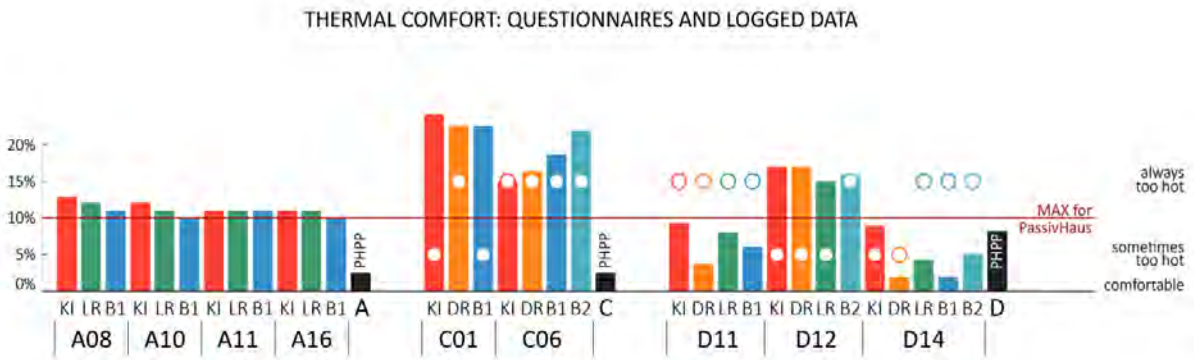

Figure 2. Number of occupied hours above 25 ºC for all monitored rooms, expressed as a percentage of total occupied hours during the period (right) as well as for a whole year (left).

While all flats (block A) failed the overheating criterion and greatly exceeded the PHPP predictions, their thermal performance was fairly homogeneous. On the other hand, a notable difference could be observed for the houses, suggesting the impact of occupants' behaviour, both in terms of internal heat gains and natural ventilation. Previous research has highlighted how using fixed W/m^2 internal gain figures for each building type, while convenient as a design aid, can lead to anomalies at extremes of building size and occupancy (Grant & Clarke, 2014). Given assumed internal gains are largely proportional to occupancy, the discrepancy between those and the actual figures is a key factor behind the gap displayed in Figure 2.

Window opening behaviour

An indication of the impact of building occupancy on thermal performance for all units was obtained by combining residents feedback included in questionnaires with window opening captured by data loggers. This allowed a reciprocal validation of the two data sets. As shown in Figure 3, data showed heavy reliance on natural ventilation for household D11, where windows were mostly open at day and night and, to a lesser degree for D14, where the rooms at ground floor level where only ventilated during the day and rooms at the upper floors both at day and night. C01 and C06 opened windows during the day and kept them closed at night, whereas D12 only appeared to be opening those in the main bedroom (B2).

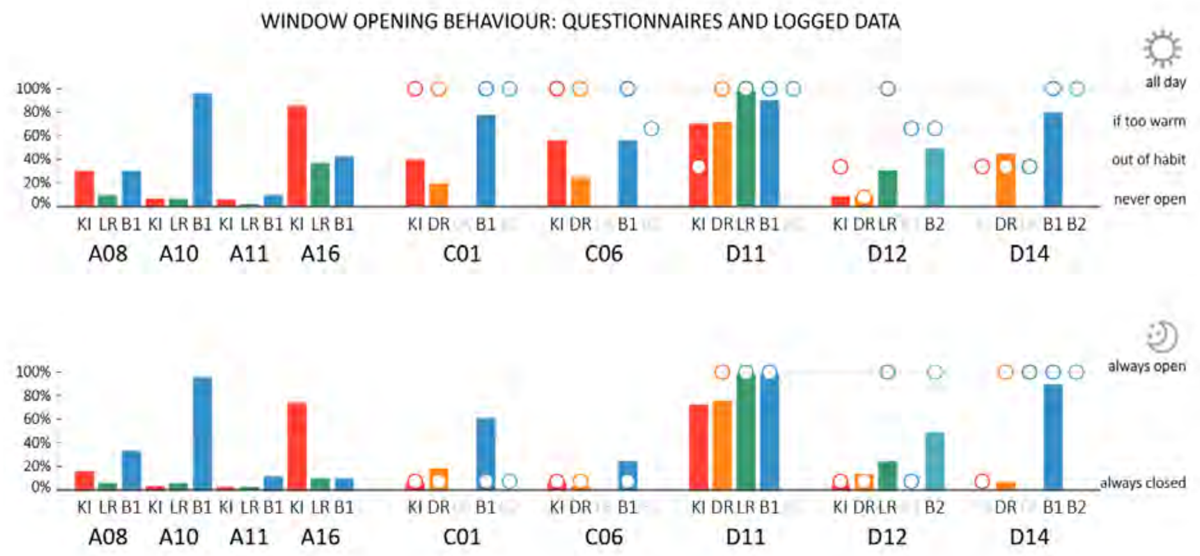

Figure 3. Reponses from residents' questionnaires (circles) and monitored data (bars) for window opening during day-time (above) and night-time (below)

Discussion

Discrepancies were found between different properties under study, and between measured and predicted summer thermal performance for nearly all of these. This was due to a combination of design aspects and, most crucially, occupant-related factors that were not predicted – or could not be predicted – at the design stage.

Solar shading

The estimated solar gains, as indicated in Table 2, where much greater for block D than block C (ca.133 vs 91 kWh daily solar load). However, it was observed that properties in block C made little or no use of internal shading (e.g. internal curtains or blinds), even during the warmest days, as opposed to households D11 and D14, were dark curtains were used. The discrepancy between different households in block A was less noticeable, given they all benefitted from solar shading provided by balconies on the south façade. In this regard, occupant behaviour could help justify the different performance observed among the households, as no discrepancy with the PHPP estimates was found.

Internal heat gains

A significant difference was found between what assumed at the design stage and what observed in reality. While the PHPP assumed values for the houses in block C (2.3 W/m^2) to be nearly 35% than those in block D (3.5 W/m^2), information gathered in one-to-one interviews suggested this was not the case. C06 made extensive use of energy-intensive plasma screens throughout the summer, to watch TV on the main living room and to play games console in bedroom2. D12 and C01 also made an intense usage of appliances during the summer period, running the washing machine and the dishwasher every day (up to 3 times/day for C01).

Ventilation via window opening

A dramatic difference was found between different properties with regards to natural ventilation, as shown in Figure 3. In one-to-one interviews, residents were asked to further comment the data collected from window loggers helping to uncover scenarios where ventilation rates were significantly reduced, which were not captured by window loggers. This revealed how household C01 had often been using window restrictors during the day and always closed windows at night, mainly for fear of burglar and insects. Furthermore, all internal doors were kept closed, impeding cross-ventilation and as such greatly reducing the capacity to purge heat.

As for the flats, which were not surveyed using the questionnaires for budget limitations, a scarce reliance on natural ventilation (except for bedroom in A10, where nonetheless windows were left open with security restrictors) seemed not to affect thermal comfort as much as it did for the houses. This, combined with the information gathered during the interviews, confirming lower occupant densities and less time spent at home, suggested internal heat gains were the most impacting factor on overheating.

Ventilation via MVHR

While the primary function of an MVHR system is to provide fresh air, rather than purge heat (air extract/supply rates are not sufficient per se), the usage of MVHR in by-pass mode (i.e. excluding the heat exchange) was accounted for in the PHPP as a contribution to summer cooling. Furthermore, guides and user manuals distributed to residents seemed to be identifying mechanical ventilation as the main cooling strategy.

Following the summer study, an inspection was commissioned by the client, revealing how due to lack of maintenance and air filter replacement, the MVHR were providing insufficient low ventilation levels for block D and nearly no ventilation for the units in block C, requiring re-commissioning. This is believed to have exacerbated overheating, given the scarce reliance on window opening observed for some of the monitored households.

Conclusions

Overall, the monitored properties showed a poor thermal performance and a high occurrence of summer overheating, both above the PHPP predictions and the maximum allowed exceedance (10%) for the Passivhaus standard. However, this occurred with different degrees of severity and no factor alone was found to be responsible for it.

All properties were occupied by social housing tenants. The flats had smaller households and were not heavily occupied during the day. The houses, occupied by bigger families who stayed at home most of the time, showed more intense occupancy pattern and a more intense usage of appliances leading to high internal heat gains. This was true for all properties with the exception of D14, who showed the lowest occurrence of overheating.

Given the underperformance of the MVHR, cooling was entirely dependent on window opening. PHPP conservative assumptions only accounted for low air exchange rates through opening windows, and as such only the households who allowed abundant natural ventilation benefitted a lower occurrence of overheating compared to the PHPP predictions.

The PHPP, despite being a robust and extensively validated tool, may be inadequate to assess the full extent of the risk of overheating. While standardised assumptions are usually acceptable when seeking Passivhaus certification, a careful evaluation of critical factors such as occupancy patterns is crucial, if the PHPP overheating risk assessment is to be interpreted as an indication of present and future in-use performance.

Climate-Responsive Façade Design for Office Buildings in London

Herman Calleja[1,2]

[1]ChapmanBDSP, London. herman.calleja@chapmanbdsp.com
[2] Architectural Association, London. herman.calleja@aaschool.ac.uk

Abstract: Cooling demand accounts for approximately 25-30% of the total regulated energy consumption of an office building in London. This is mainly a consequence of the high internal heat gains and large unprotected glazed façade areas. The cooling load is expected to increase further due to the city urban heat island (UHI) effect and climate change.
Through parametric analytical work, this research assesses the impact of overheating risk and design potential for free running offices in London, when considering CIBSE TM49 2050 weather data; thus, omitting the need to rely on mechanical cooling systems during the warm season. The results indicate the possibility to design out the need for cooling. The study also finds a strong relationship between overheating and the maximum average hourly internal heat gains, thus establishing a recommended early design stages threshold.
Subsequently two office projects where parametric environmental design has been used to inform the façade design are illustrated.

Keywords: parametric environmental design, overheating, office, facades

Introduction

Today's availability of algorithmic tools allows environmental performance data to inform the design process instantaneously. In such cases, targeting the right criteria or threshold is critical. The study has undertaken iterative dynamic thermal modelling to assess the potential of free running office buildings that comply with CIBSE Technical Manual (TM)52 when applying CIBSE TM49 2050 weather projections for London.

Iterative analytical work was carried out to assess simultaneously both thermal and visual comfort for a base case office. The assumptions and the inputs selected in the modelling reflect closely the mode of operation of a typical UK office. Based on the results of the analytical work executed, a recommended maximum threshold of internal heat gains was identified.

The application of internal and solar gains threshold and the potential of integrated parametric thermal modelling is illustrated through two projects that are currently being developed.

Aim of Study

Both in the academia and in professional environmental design consultancy, raises the request for a study to inform the façade shading strategy. The research explores which are the potential façade shading and glazing ratios strategies that would allow an office building in London urban area to achieve occupant visual and thermal comfort without relying on auxiliary cooling, achieving a free running environmental performance through parametric dynamic thermal modelling (DTM).

Methodology

Iterative simulations varying the glazing ratio from 20% to 100% and shading intensity, that is, shading element depth to spacing ratio (D/S), from no shading to 1.2D/S for an office space were carried out. Thermal and visual comfort has been assessed for these multiple simulations. The results were analysed to identify a common denominator that can be used as an initial indication of overheating risk in parametric environmental design. The studies were carried out on south and west-facing elevations which are the elevations that are mostly at risk of overheating. The study concludes by giving two applications of how façade design may be informed by this methodology.

Comfort Criteria

Thermal Comfort Criteria

Adaptive Comfort Model and Assessment

As shown by McCarthy and Nicol (2002) the temperature at which occupants feel at comfort is related to the running mean of daily average outdoor temperature. This is an additional refinement to an adaptive comfort criteria based on the monthly mean as proposed by DeDear and Brager (2002) and others. EN 15251 builds on the work of McCarthy and Nicol and today this comfort model equation is widely accepted and is also included as a design guide (CIBSE, 2015) for free running buildings as:

$$\theta_{comfort} = 0.33 * \theta_{rm} + 18.8^{o}C$$

Where θ_{rm} is to not exceed 30^{o}C and an additional ±3^{o}C comfort band may be applied for new office buildings that fall under Category II (Cat II: new buildings and renovations excluding spaces used by highly fragile occupants, such as sensitive hospital wards).

The overheating assessment was undertaken in line with CIBSE TM52 guide (CIBSE, 2013) which is based on the EN 15251 model. TM52 assesses three overheating criteria for the period of May to September for free running buildings. Any space that does not satisfy at least two of the three criteria is considered to have failed the assessment;

- Criterion 1: The operative temperature is not to exceed the upper comfort limit of the EN1521 comfort band by more than 1^{o}C for 3% of the occupied hours (i.e. 38 hours).
- Criterion 2: The summation of the number of hours exceeding the comfort band in a single day, multiplied by a respective factor of ΔT, is to be lower than 6.
- Criterion 3: The operative temperature is to be not more than 4^{o}C higher than the comfort band upper threshold.

Visual Comfort

In the UK the methodology most widely used in assessing daylight is the Daylight Factor. However, this is a metric that does not consider the influence of local geographic or climatic conditions. For a more accurate assessment Daylight Autonomy (DA), a climate-based daylight assessment method was selected. As recommended in various standards (CIBSE, 2015), an illuminance level of 300 lux – 500 lux is recommended for office spaces. What is still lacking agreement between authors is what is the correct upper threshold that defines over-illuminance or glare (Mardaljevic, 2015)? In this study a frequently accepted threshold of 10x the target illuminance (Reinhart, 2011), that is 5000 lux, was adopted. The Useful Daylight Illuminance and Annual Sunlight Exposure assessments were not considered as their thresholds, 2000 lux and 1000 lux respectively, are nowadays questioned (Mardaljevic, 2015).

Assumptions

Weather file

The selection of the weather data has a significant impact on an overheating assessment. The data used in this study is taken from CIBSE TM 49 (CIBSE, 2014 a) for London Weather Central station. The standard includes various weather data sources with projections for 2020, 2050 and 2080 based on UKCP09 climate projections considering the percentage of probability and global emissions scenarios. Considering the lifetime of a new building, this study was based on a 2050 projection considering medium (most likely) CO_2 emissions scenario. Although as shown in figure 1 the difference in emissions scenarios is quite low for 2050 projections. As highlighted by CIBSE (2014 b) the 50-percentile data is the most likely projection and hence this was adopted in the study to avoid under-designing (10-percentile data) or over-designing (90-percentile data).

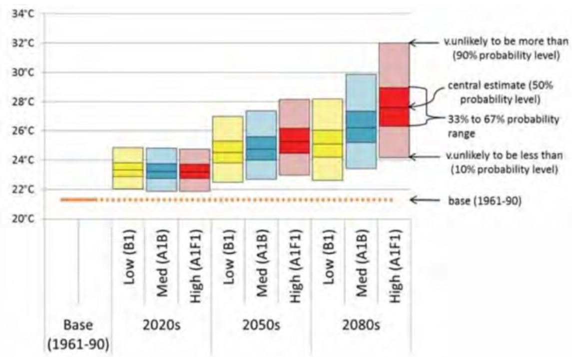

Figure 1 Summer mean daily maximum temperature for different emissions scenarios

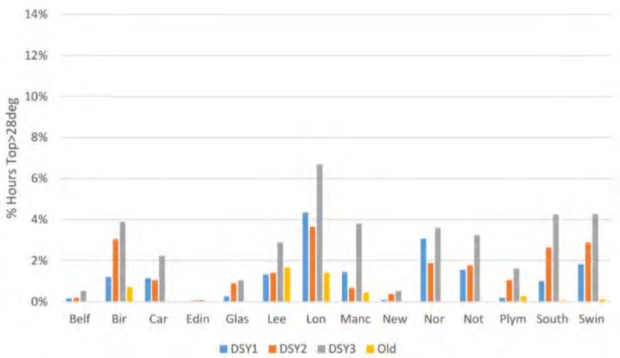

Figure 2 Percentage of occupied hours above 28^{o}C for an office using different current climate weather files

Finally, Design Summer Year (DSY) 3, a summer with a prolonged period of sustained warmth based on 1976 data (GLA, 2015) was selected, since as indicated in figure 2 this always results in the highest overheating risk for offices (Virk and Eames, 2016).

Internal conditions

National Calculation Method (NCM Activities 5.2.7) internal conditions, including small power loads, occupancy density and schedules, were applied to the office space thermal model, as these conditions are what is typically found in offices in England (DCLG, 2014). Daylighting control was applied to the artificial lighting to reduce unnecessary lighting gains.

Design Research

Tools

DTM was undertaken using EnergyPlus in Honeybee (Roudsari, 2013) through the Grasshopper platform within Rhinoceros NURBS modelling suite. Further analysis on load breakdown on Cases 1, 2 and 3 (identified in Fig. 5) were carried out through EDSL TAS. Daylighting studies has been conducted via DAYSIM using Honeybee plugins.

Test case parameters

For the purpose of this research a south-facing office with W x D x H dimensions of 10m x 6m x 3m has been assessed. The 6m depth was selected as this would be the area that is mostly influenced by the façade performance (Baker and Steemers, 2000; DCLG, 2014).

The building fabric properties are illustrated in table 1. The U-values applied are standard but not best practice performance (to allow for a wider applicability of the study), close to the building regulations Part L2A notional parameters. Since the aim is to achieve a free running office space, a low g-value (0.3) that however allows a good light transmittance (60%) was selected. For the daylight simulation, a more conservative 60% light transmittance has been used as a 70/30 glazing specification may be considered very onerous.

Table 1 Building fabric properties

	U-Value	G-Value	Frame factor	Light transmittance
	W/m².K	N/A	%	%
Opaque Wall	0.21	N/A	N/A	N/A
Window	1.70	0.30	0.15	60%

The weather data indicates an average diurnal temperature range of 9^{o}C throughout the period of overheating risk (May-September), a good indication for the application of thermal mass with night time ventilation as a cooling strategy (Santamouris, 2007). Thermal mass may offset 60% of the cooling load of a conventional office (Allard, 1998). As shown in figures 3 and 4 this strategy may reduce the resultant temperature by over 5^{o}C. In the study carried out, 50% of the internal walls area and the ceiling have high thermal mass. Furthermore, the percentage of openable façade area was kept as 25% throughout all the simulations. Each opening having a discharge coefficient of 0.61.

The iterative study was conducted on horizontal shading devices as this is the most effective strategy for this orientation as may be illustrated through shading masks. Studies were also carried out on a similar west-facing office, with vertical fins, to assess the facades with the highest overheating risk.

Results Analysis

The results indicate that it is possible to design offices that satisfy TM52 overheating criteria using TM49 2050 weather data without relying on auxiliary cooling. All the TM52 criteria were tested, however, figure 5 shows only a single criterion as it was the most decisive criterion. As indicated in figure 5, TM52 may be met by varying glazing ratios, up to not higher than 65% and varying shading density. However, if a relatively high glazing ratio, >60%, is selected the demanding shading density required results in poorly daylit spaces. As shown in figures 5 and 7 glazing ratios between 40% and 60% can provide a good level of daylighting and meet the thermal comfort requirements, when the correct shading density, illustrated on figure 5, is selected. The glazing area may be increased if a lower g-value glass is selected.

External temperature exceeds the comfort band upper limit for 131 hours, 10% of the occupied hours, which as shown in figure 9, coincides with the spikes of the office resultant temperatures. This indicates that daytime natural ventilation will not be an adequate cooling strategy during hot summer days, when the highest overheating risk occurs.

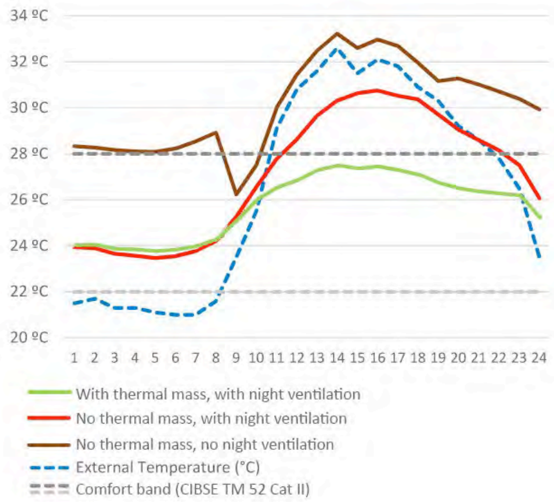

Figure 3 Summer day night time ventilation cooling

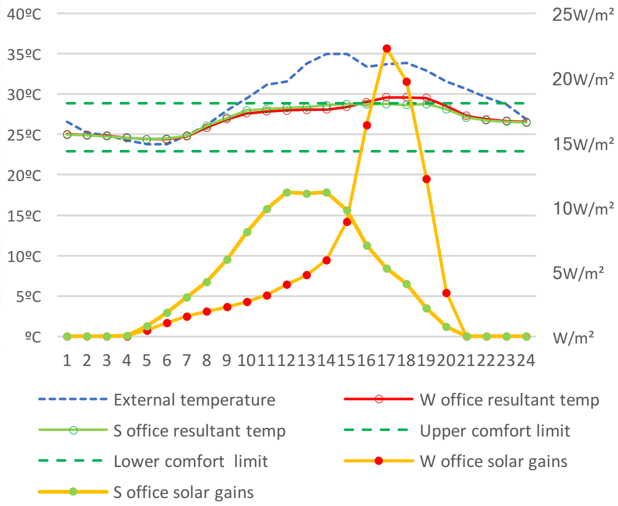

Figure 4 Summer day thermal mass effectiveness

Three simulations that are at the limit of satisfying the TM52 criteria (indicated on figure 5) were selected for further analysis; [1] 30% glazing with 0% D/S (unshaded), [2] 40% glazing with 20% D/S and [3] 60% glazing with 0.8 depth to spacing (D/S) ratio. As shown in figure 10, a common denominator of the three cases is that the average hourly internal heat gains, that is; occupant, equipment, lighting and solar gains. For the occupied hours (8:00 – 19:00), between May and September, this value is 28 – 29W/m² for the three cases. Simulations that failed to meet the overheating criteria (shown above the TM52 line in figure 5) have a higher value of internal gains. A similar study conducted on the West façade resulted in a threshold of 28W/m². This is close to a previous recommendation (OPDM, 2006) of 35W/m², however this study recommends a more challenging threshold of 28W/m². Nonetheless, this applies only for offices that benefit from night time ventilation and adequate thermal mass. It is interesting to note that excessive shading can result in a heat gains increment due to the use of artificial lighting (figure 10).

The analysis indicates that for a south-facing office, the average daily cumulative internal solar gains should not exceed 90Wh/m² (May to September). However, for a west-facing office, the internal solar gains for the same period need to be less than 75Wh/m². The solar gains threshold is lower for the west facade, since overheating risk on the west façade occurs during the late afternoon, from 3pm onwards. By this time of the day, the benefit of the night-time cooling is dissipated and the building has gained heat throughout the morning hours due to high external temperatures and gains from diffused solar radiation.

Furthermore, as indicated in figure 4, the solar radiation received by an office surges up very rapidly in a space of one or two hours from 4pm onwards due to the low sun position. Between May and September, the azimuth angle varies from 230^{0} to 260^{0} and the sun angle of elevation varies from 22^{0} to 36^{0}, being nearly perpendicular to the west elevation. Results indicate that the peak hourly solar gain should be limited to not exceed 25W/m² for 90% of the occupied time. These values are only indicative and are meant to guide the design in the early stages. Nonetheless, further investigation, considering different shading strategies and project specifics, may have to be undertaken to assess this parameter further.

Application of parametric dynamic thermal modelling

The availability of algorithmic tools allows performance data to inform a dynamic design process (Friesen, 2009), allowing the design to meet a 'dynamic equilibrium between aesthetics and optimization' (Burry, 2010). However, for the stochastic parametric design process to be meaningful, the right parameters need to be set. Hence extracting the correct threshold figure/s that can indicate compliance with the comfort criteria is an important initial step prior to undertaking parametric DTM. Two projects, conducted at ChapmanBDSP, where parametric environmental design contributed to the façade design are illustrated below.

This approach has been adopted during the façade design exploration process for a mixed-mode office in London. For the given orientation (figure 12), and programme, 165kW/m^2 in incident solar radiation for the occupied period between May and September indicated the most effective shading strategy, when comparing extent of shading surface area to the reduction in incident solar radiation. Subsequently different façade articulations (Fig 11) that allow the same amount of solar gains were explored together with the architect.

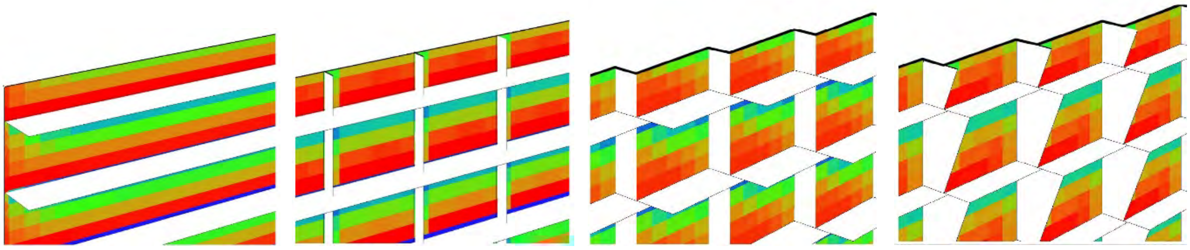

Figure 11 Façades articulations that allow similar amount of solar gains for a southwest orientated office

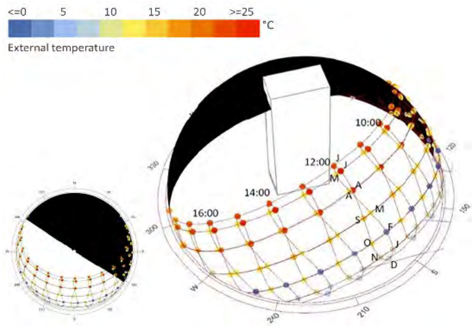

Figure 12 Office space shading mask analysis

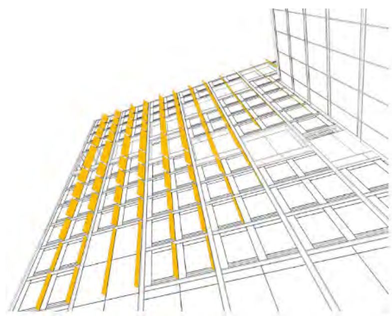

Figure 13 optimised vertical shading fins

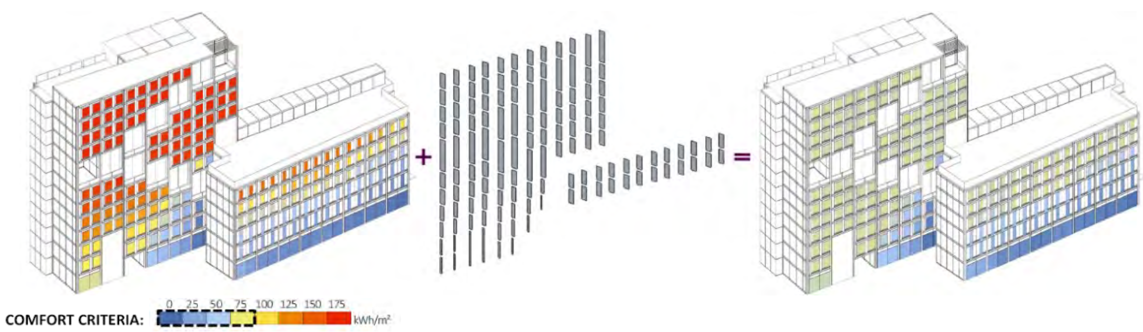

Figure 14 Façade shading optimisation for a naturally ventilated office building in London. Architect: RSH+P

In another office project, that is being designed to be naturally ventilated (architect: RSH+P), the maximum allowable incident solar radiation for an exposed cellular office was identified. Subsequently an algorithm was applied such that the incident solar radiation for an individual office does not exceed this value, thus avoiding over-designing the lower vertical fins since the lower part of the building was significantly overshadowed (figures 13 and 14).

Conclusion

The studies undertaken through dynamic thermal modelling show that with a well-designed façade, integrated with an adequate mode of operation, it is possible to achieve cooling-free offices in London, that comply with CIBSE TM52 for 2050 weather data when considering a medium (the most likely) global CO_2 emissions scenario.

Based on the analytical work carried out, an early design stage maximum average hourly internal heat gains threshold of $28W/m^2$ is recommended for naturally ventilated offices in London to future proof the building for 2050, based on TM49 weather data projections. As indicated through two case studies, this threshold may be used to inform parametric thermal dynamic modelling while exploring different generative morphologies.

Recommended further studies include considering varying orientations and urban contexts, different shading geometries, carrying out sensitivity studies on the adequate occupancy schedules and occupancy gains considering a variety of office spaces including areas for hot-desking, meeting rooms and study areas.

Abstract: Passive evaporative cooling methods using porous ceramics were widely applied in the Islamic culture to reduce ambient air and surface temperatures and thus improve thermal comfort conditions under hot-dry environments. However, the integration and performance prediction of evaporative Porous Ceramic Cooling (PCC) systems in contemporary architecture is still complex due to the large number of environmental and physical parameters involved. This paper explores alternative and more efficient applications of PCC systems: maximising cooling capacity, minimising water consumption and promoting the artistic expression of ceramics in architecture. Laboratory testing and fieldwork were conducted using an optimised prototype and monitored data provided with relevant information regarding cooling performance. The obtained data was used to calibrate a Computational Fluid Dynamic (CFD) model which was used to explore the performance of different ceramic designs exposed to a wide range of environmental conditions. The results were post-processed to develop a multi-steady state calculation tool to advise professionals on the design and performance prediction of PCC systems at early design stages. The system proved to be a good alternative to minimise local thermal discomfort, reducing ambient air temperature by 2°C and mean radiant temperature by 1.8°C on the leeward of certain PCC systems.

Keywords: evaporation, ceramic, cooling, performance prediction.

Introduction

The last decade has witnessed how passive cooling techniques have become increasingly attractive methods to architects for delivering healthy and comfortable environments as an alternative to the 'default' use of mechanical cooling systems. The significant benefits of natural ventilation over mechanical systems are now widely appreciated, highlighting the mitigation of sick building syndrome and the increase in occupants' productivity. The application of evaporative cooling methods in contemporary architecture is, however, less frequent, and is normally executed using misting systems or porous media (Ford et al., 2012). The applicability of these systems is also limited to hot and dry climates: high temperatures and low water vapour content on the air to allow more water liquid particles to evaporate. Recommended ambient wet bulb temperatures for a successful application of these systems range from 22-24°C (Santamouris et al., 1996). Although passive evaporative cooling methods have been successfully applied in architecture, the early integration of these systems in the design is often not considered, and usually delegated to specialists at later stages. This practice increases the risk of underperforming systems and not meeting the initial project requirements.

The benefits of addressing the integration of passive strategies from early stages are thus evident: delivery of a better space layout coupled with the system, improved efficiency and avoid of under/over-performing predictions. Simple steady-state and manual calculations are traditionally used in most fields to fulfil this task, and proved to be reliable and quick to use, providing confidence in the performance of the system. The physics involved in natural ventilation for convective cooling are manageable with manual calculations, and steady-stage tools have recently emerged to assist architects and engineers in the design of natural ventilation strategies. Optivent 2.0 (Aparicio, 2015) is in line with widely used design guidelines (ASHRAE, 2005 and CIBSE, 2016) and has been applied and validated in a large number of projects worldwide, providing a good basis for later stage more detailed analysis.

Coupling a natural ventilation strategy with an evaporative cooling method will improve the cooling capacity of the whole system, but the physics involved during the evaporation process are substantially more complex as more parameters are involved (porous surface area, system geometry, ambient vapour pressure, air velocity, etc.), making the performance prediction computationally intensive and not manageable with manual calculations. With limited time on early design stages to perform advanced simulations, designers usually lack confidence in the performance of the proposed cooling strategy, which often leads to banal assumptions on the cooling capacity of water bodies placed in the design.

This paper describes the development and the features of a multi-steady-state calculation tool to predict the cooling performance of wetted decorative porous ceramic systems in early stages of the design process. The tool is an outcome of a research which involved the design and manufacture of an optimised ceramic prototype, the monitoring of its cooling capacity through laboratory testing and fieldwork, and the execution of a parametric analytic work through the definition of an advanced CFD model. The tool is oriented to architects/designers and aims to promote the efficient use of alternative evaporative cooling methods, enhancing at the same time the artistic expression of ceramic elements.

The Wetted Porous Ceramic System

The use of ceramic in architecture is well spread in Europe and its application extends to walls, flooring, double skin façades or latticework. In Spain and Italy, for instance, the industry of ceramic is well stablished and expanding, and international Ceramic Exhibitions attract every year more than 80.000 professionals worldwide (Cevisama, 2017). Recent advances in material science, emerging technologies and production methods (Bechthold et al., 2015) bring architects the opportunity to rethink the application of ceramic in architecture and further develop other attributes, including evaporation over the porous surface.

This research involved the design and manufacture of an optimised extruded porous ceramic prototype that maximises cooling capacity and minimises water consumption. Among the main objectives of the design process were the increase of the ceramic surface to volume ratio, minimise airflow resistance and the supply of water directly to the ceramic surface. The prototype was manufactured by the Spanish company Ceramica Decorativa SA and was used to undertake experimental work and explore the potential of ceramic elements to induce evaporation. The system consists on tubular-shaped samples arranged over a vertical plane. Water is supplied from the top using a drip irrigation system, and engraved water channels distribute the fluid along the vertical direction, allowing a uniform water distribution over the ceramic surface. When the wetted surface is exposed to an airstream, water molecules separate from a liquid structure to the air, absorbing heat from the surrounding air (Figure 1). As result, an air temperature reduction and humidity increase is achieved in the leeward of the ceramic system. The heat content of the air and its capacity to hold vapour can be indicated by its dry bulb to wet bulb temperature depression (DBT-WBT).

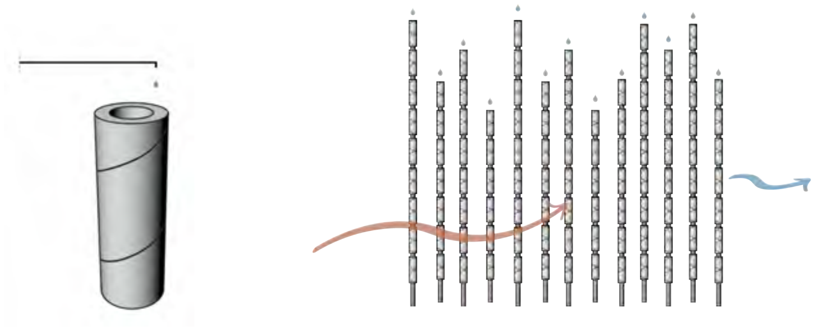

Figure 1. Extruded porous ceramic prototype and system concept.

Application

The system allows a wide range of applications, but its integration in architecture must be coupled with a ventilation strategy that drives air through the ceramic surface. Air can be driven passively by buoyancy forces, and excessive warm airflow rates should be avoided. The connection of two adjacent spaces presenting different air temperatures will drive the cool air to the warmer space, making the boundary between both spaces a desired location to place the PCC system. To maximise efficiency, the space layout and area of influence should also be carefully designed: excess of heat gains, exposure to direct solar radiation and poor user accessibility can lead to poor performance. These recommendations make the system suitable for semi-outdoor spaces, and ideally applicable to transitional spaces. Some application examples of PCC systems in architecture are reception spaces in atria, facades, or circulation areas around a central courtyard (Figure 2).

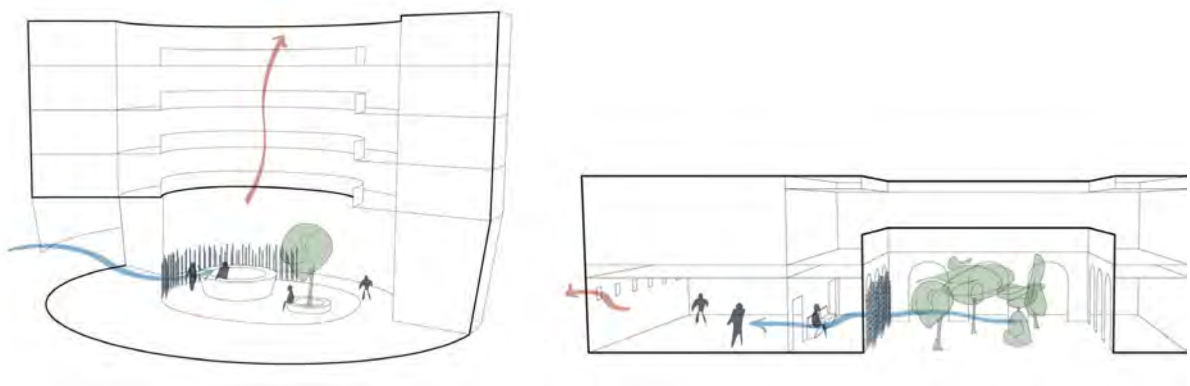

Figure 2. Application examples of PCC systems in architecture.

Experimental Studies

The conducted experimental studies aimed to monitor and evaluate the cooling capacity of the manufactured prototype when exposed to a wide range of ambient air temperatures, humidities and air velocities. The studies were first conducted under controlled environmental conditions (laboratory testing) using an environmental chamber; and second, in a semi-outdoor space (fieldwork) under the hot and dry conditions during the month of August in Granada, Southern Spain (Latitude: 37° 10').

Laboratory Testing

The laboratory studies explored the temperature reduction achieved and water consumption of different ceramic arrangements (and thus exposed ceramic surface areas) within a cross section of 500x500 mm^2 under wide range of environmental conditions. With the aim of improving the design and efficiency of the system, three arrangements presenting blockage ratios (opaque to free cross section area) of 25%,40% and 50% were tested (Figure 3).

The samples were placed in the centre of an 1800x500x500 mm insulated box, with an air intake and exhaust at the front and the back respectively. Temperature and humidity on the windward and leeward of the ceramic surfaces were constantly measured with nine Resistance Temperature Detectors (RTDs) and two Humidity probes in line with the Standard Test Method D3464-96 (ASTM,2014). The samples were initially saturated, and at the end of a fifteen minutes' analysis cycle they were weighted again to determine the evaporation rate and water consumption.

Figure 3. Laboratory work set-up and ceramic arrangements.

The collected data revealed the air temperature reduction achieved on the leeward of the ceramic system is directly proportional to the DBT-WBT (Figure 5). This confirms that warmer and dryer conditions yields to bigger temperature reductions, increasing its effectiveness. Moreover, the cooling achieved responded to the shape and number of ceramic elements: best results were obtained with ceramic arrangements presenting higher blockage ratios (50%), which confirmed the importance of maximising exposed porous surface area without compromising the airflow path. The results also suggest that a 2 degrees' temperature reduction is achievable with DBT-WBTs above 14°C (i.e. DBT:34°C & RH:25%).

Fieldwork

The experimental mock-up conducted in Granada aimed to evaluate the dynamic behaviour of a PCC System exposed to daily variations in environmental conditions. Measured air temperature during the operational period ranged from 24°C to 34°C, relative humidity ranged from 30% to 50% and air velocity ranged from 0m/s to 0.6m/s. A 2000x2200mm ceramic system presenting a 25% blockage ratio was built and placed on a transitional space, naturally ventilated, shaded and wind sheltered. Temperature and humidity on the windward and leeward of the ceramic surface were monitored using temperature and humidity sensors at 400mm, 2000mm and 5000mm distance from the ceramic walls (Figure 4).

Figure 4. Fieldwork PCC system mock-up.

The collected data confirmed an expected wider amplitude of ±0.3°C in the temperature reduction achieved, which mainly responded to air velocity variations. Moreover, these temperatures followed the same linear profile found in the conducted laboratory analysis, presenting higher temperature reductions with hotter and dryer conditions (Figure 5).

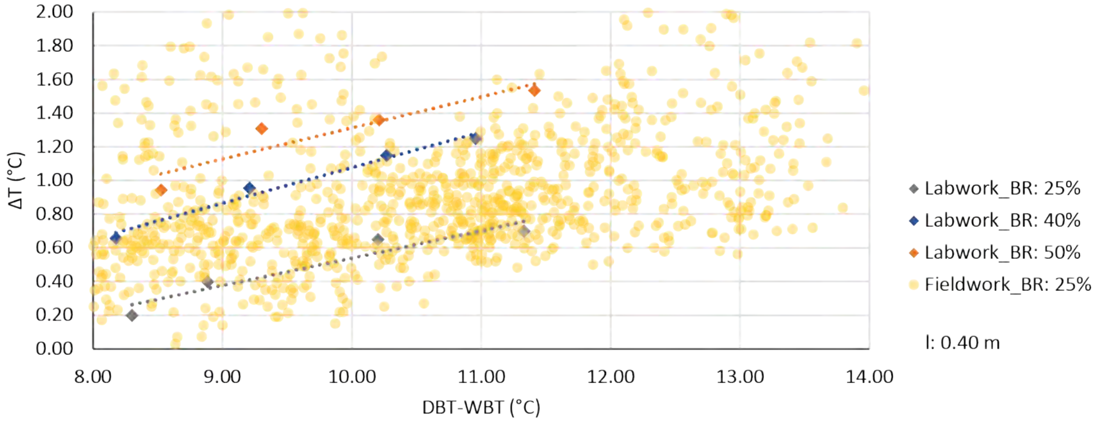

Figure 5. Laboratory & Fieldwork data- monitored temperature reduction achieved.

Computational work

A valid numerical model using the commercial CFD software Ansys Fluent® was defined to simulate the physics of evaporation on wetted ceramic surfaces. The model is a transient simulation with water phase change taking place on the ceramic surface, and consequently mass transfer from liquid to vapour in a rectangular prism (1000x1000x2000mm) fluid domain. An extensive parametric study using this numerical model was conducted to generate a database of PCC performance to be compiled in a design tool described below.

The parametric study consists of sixteen environmental conditions: four DBT-WBT (8,10,12, and 14°C) under four air velocities (0.25, 0.50, 0.75 and 1 m/s). Four ceramic shapes presenting different flow resistance (drag coefficient: 0.56, 1.10, 1.24, and 1.37) were analysed for four different arrangements (blockage ratio: 25,30,40 and 50%). Overall, the study involved 256 simulations.

Porous Ceramic Cooling System Design Tool

The tool is a multi-steady-state model designed to assist designers in the sizing and performance prediction of a PCC system in early design stages with minimum user inputs and time consumption. It also aims to raise awareness and knowledge on the benefits and limitations of this system. It estimates temperature reduction, humidity increase and water consumption of a PCC system exposed to any environmental conditions and for any ceramic shape and arrangement within the range of values analysed in the computational work.

User Interface & Methodology

The tool is structured in three main bodies: Microclimatic Data, Ceramic System Data and Evaporative Cooling Performance. The first two contain the user inputs to define the environmental conditions and the dimensions of the ceramic system. The last body outputs the cooling performance of the defined system.

Microclimatic Data

A 24-hour daily profile is generated from the definition of a maximum and minimum air temperature (Huld, 2006). Humidity is given as absolute value (g/kg), and air velocity in m/s, assuming both parameters constant for the daily period. Steady-steady tools like Optivent2.0 may assist in the definition of air velocity as result of a buoyancy driven natural ventilation strategy. Finally, a schedule to define the operation time will be consider to estimate the total water consumption of the system for the given day.

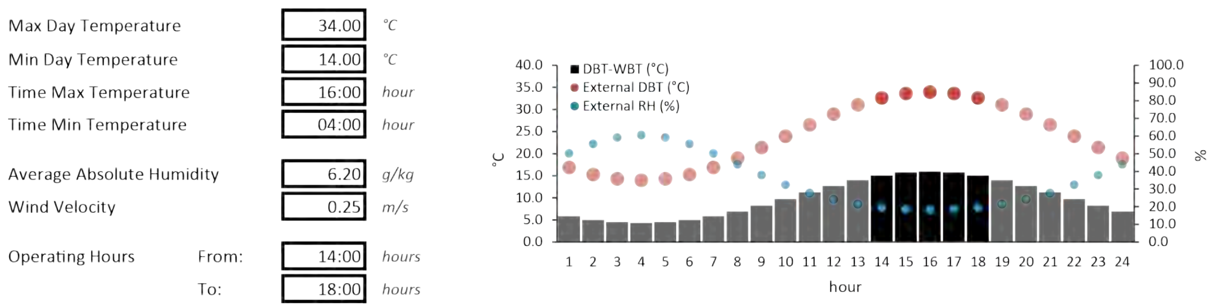

Figure 6. PCC tool – Microclimatic data input.

Ceramic System Data

The system is defined by providing the geometrical shape of the ceramic sample, which is associated to a specific drag coefficient; the total system (inlet) area, given by the corresponding width and height; and the number of columns arranged over the vertical plane. The tool then associates a blockage ratio to the upcoming interpolation process. Finally, a distance from the wetted surface can be set in order to obtain the results for the given point.

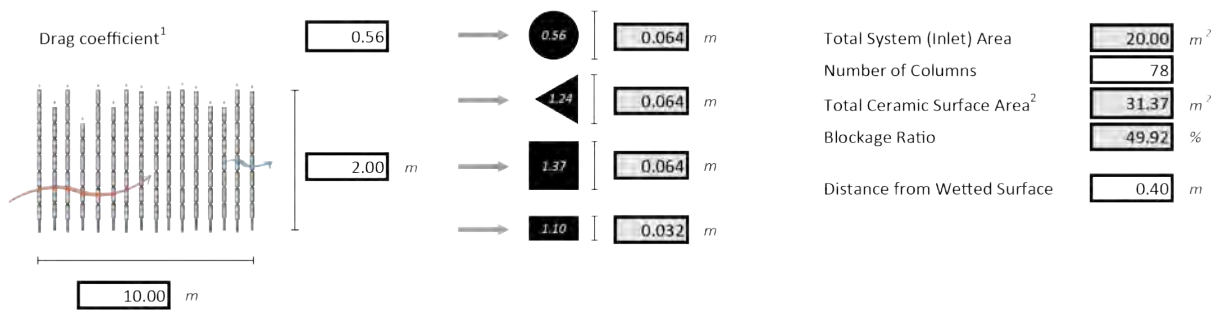

Figure 7. PCC tool – Ceramic System data input.

Evaporative Cooling Performance

The collected inputs (DBT-WBT, air velocity, drag coefficient and blockage ratio) are used to access the parametric database and perform a series of interpolations between the nearest values in a logical order to obtain the final output. These results include the mean cooling achieved, as well as the average sensible to latent ratio over the operational period. The calculation of sensible and latent cooling is in line with ASHRAE (2005), and they are proportional to the air density, specific heat or latent heat of vaporization, the airflow rate and the average temperature reduction or humidity increase achieved. Water consumption calculation derives from the latent cooling and is equivalent to the total amount of water evaporated per unit of time. Finally, a predicted air temperature, mean radiant temperature reduction and absolute humidity increase is plotted for each operation hour and for the defined distance from the ceramic wall.

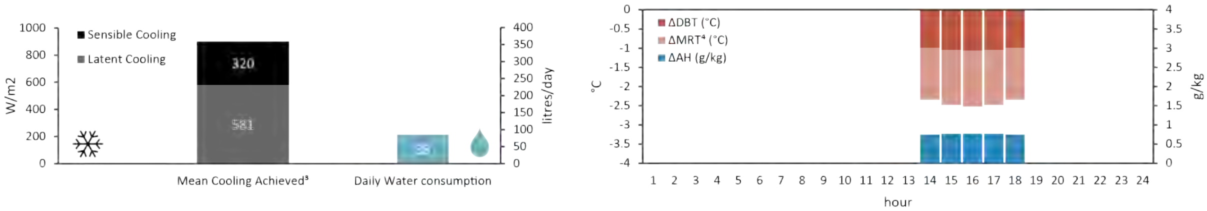

Figure 8. PCC tool – Evaporative Cooling Performance output.

Data Validation

The tool outcomes were validated using laboratory data. The tubular shaped samples presenting blockage ratios of 25,40, and 50% were used for the validation, and the predicted temperatures at 0.40m distance from the ceramic wall for a wide range of environmental conditions were compared against the monitored data. Following the same methodology, the water consumption for each hour of operation was also compared (Figure 9).

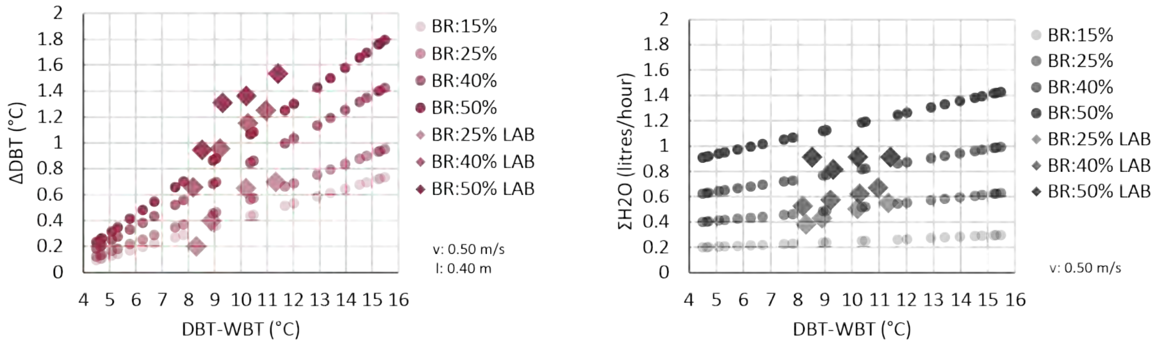

Figure 9. PCC Tool & Laboratory data – Predicted vs monitored temperature reduction and water consumption per square metre of ceramic system.

The above graphs confirmed the predicted temperature reduction and water consumption given by the tool are in line with the laboratory data, both presenting a linear relation with DBT-WBT for a constant air velocity of 0.50 m/s.

Discussion and Conclusions

This research explored the potential of alternative conductive and evaporative cooling techniques using decorative porous ceramic systems to reduce ambient air temperature. Monitored data confirmed the linear relation the between environmental conditions and the cooling capacity of a PCC system, and theoretical models allowed to explore the benefits of certain ceramic shapes and arrangements. Higher ceramic surface areas and aerodynamic shapes enhance evaporation, and the ceramic arrangement on the vertical plane must avoid wind-sheltered areas. Moreover, the temperature reduction and humidity increase achieved on the leeward of the ceramic surface reduces with distance from the ceramic wall, and confirms the small area of influence of the system, which in some cases remains below two meters long. The space layout and the human relation with the PCC system must be certainly considered on early design stages.

The multi-steady-state tool presented in this paper allows to predict cooling capacity and water consumption of a PCC system with a reduced number of inputs and accepting a wide range of ceramic shapes and arrangements. By using the tool, designers could predict, for instance, that a 30 m^3 PCC system built with tubular ceramic samples arranged in the vertical plane and presenting a blockage ratio of 50%, can reduce the surrounding air temperature by 2 degrees in the peak hours of the day (DBT-WBT≥14°C). The water consumption for one hour of operation is estimated 72 litres, half the average household water consumption in Europe. The mean radiant temperature (MRT) also makes a considerable impact on the human perception of the environment. Monitored surface temperatures (ST) during the experimental work responded to the expression ST= DBT-0.8(DBT-WBT) + 3 (°C), and MRT at any distance from the ceramic system can be estimated from the calculation method initially defined by Fanger et al. (1985) and adopted by ISO 7726 (1998) and ASHRAE (2005). Continuing with our example above, the MRT depression achieved downstream the ceramic surface is 1.8°C at 1m distance, and 0.5°C beyond 3m. By coupling the air temperature reduction, the achieved mean radiant temperature and the psychological cooling effect of air movement, the user perception of the environment is considerably improved, making the convective and evaporative PCC system a good alternative to minimise local thermal discomfort during hot and dry seasons.

Abstract: There are now more than four million refugees living in camps around the world. The majority of such camps are within inhospitable environments, often with extreme climates. This paper focuses on the thermal conditions of shelters in the Azraq refugee camp (Jordan), subject to an arid climate with high temperatures during the hot season. Due to political and other sensitivities, whole-, or multi-year monitoring of occupied shelters—and hence the empirical determination of overheating—is difficult. Instead, internal conditions in the shelters were monitored for three weeks in summer and used to validate computer models of the accommodation. These models were then used to generate annual predictions of overheating assessed through overheating criteria based on thermal discomfort and physiological indicators of heat stress. Building on these results, the performance of alternative designs specifications or shelter operation strategies were investigated through parametric analysis. The results show maximum indoor temperatures over 45°C. Overheating thresholds were exceeded for more than 20% of the year and physiological indicators suggest the possibility of health-threatening conditions. The use of alternative designs and strategies reduced overheating to nearly 2% of the year, with a steep reduction of severe heat stress indicators.

Keywords: refugees, shelters, overheating, health risk, thermal comfort

Introduction

The current number of forcibly displaced population in the world is among the highest on records of which a third, 20 million, are refugees (UNHCR 2017). The refugees from the Syrian Arab Republic alone represent 23% of the total refugee population with 4.9 million people. As part of the response to this crisis, they are often hosted in camps in neighbouring countries such as Turkey, Lebanon and Jordan. Given the location of camps and the severe conditions experienced in Jordan's climate, this paper investigates overheating discomfort and potential heat stress risk of refugees in these circumstances.

The thermal performance of shelters, and the indoor conditions they deliver, is a subject with a limited number of studies. One of the key concerns is the actual provision of a shelter as a humanitarian response. This constitutes a challenging task of paramount importance as it needs to deliver rapidly a scalable housing solution to an unexpected crisis of unknown duration. Among the few studies that focused on the thermal performance of shelters, there has been a greater number of studies dealing with cold environments (e.g. Crawford et al. (2005)) than hot ones (e.g. Cornaro et al. (2015)). This results in an underdeveloped area of research considering the number of people involved and the potential risks associated, especially for vulnerable occupants as children, one of the major refugee groups worldwide.

Consequently, this study evaluates the overheating risk in the Azraq refugee camp in Jordan (31.90°N, 36.57°E). Firstly, the application of different overheating metrics for discomfort and heat stress in the built environment is explored. Then, previous metrics are applied in the Azraq context to evaluate whether refugees are exposed to excessively hot indoor conditions regarding discomfort and heat stress. Lastly, the potential of passive strategies to reduce excursions from neutrality conditions to inform potential design improvements to current shelters is quantified. To accomplish these goals, the following hypotheses are established:

1. Refugees in considered shelters are exposed to indoor conditions outside the acceptable range established in the ASHRAE Std. 55 (2016).
2. Refugees in considered shelters are exposed to indoor conditions outside the recommended ranges for heat stress in the Pierce 2-node and Predicted Heat Stress (PHS) physiological models.
3. Current shelters cannot be optimized to avoid overheating discomfort through the passive measures considered.
4. Current shelters can be optimized to avoid severe heat stress through the passive measures considered.

Methodology

The study focuses on the Azraq refugee camp because of its exposure to the 'hot desert climate' (Köppen-Geiger zone BWh) and because it is based on a well-defined shelter design (figs. 1 and 2). As of April 2017, the camp hosts 53,914 refugees, of whom 57% are under 18 years old. Due to security concerns —among other considerations—, the structure of the camp and the arrangement of shelters cannot be modified. Owing to these considerations, the study was conducted in two phases. The first is a three-week field study, during which surveys and spot measurements of environmental conditions were collected. The second extrapolates annual overheating conditions via building and human thermal simulations.

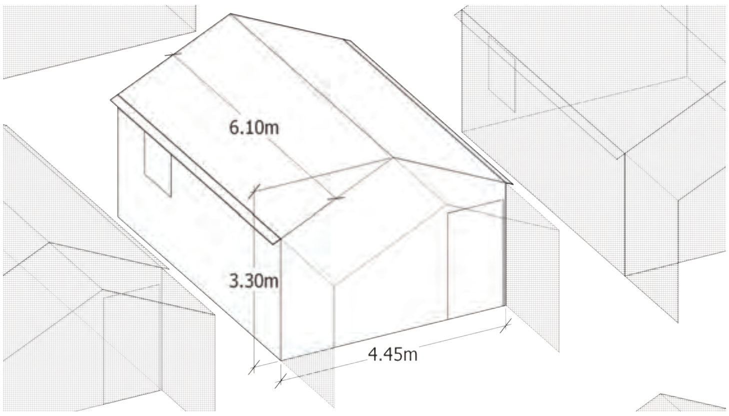

Figure 1. Description of the T-Shelter in Azraq refugee camp.

Figure 2. Example of shelter interior.

Field study

The field study was carried out from 31st August to 23rd September 2016. Here, randomly selected families completed a thermal and a social survey (n=36). The thermal survey included ASHRAE Std. 55 (2016) guidelines whereas the social one focused on factors such as perceived security, privacy or adaptation opportunities. Shelter units were documented 'as built' to track any discrepancies between the original specification and their actual conditions (e.g. shading devices, openings, insulation location, actual occupation…).

Simulation

The data collected during the field study was used to calibrate and validate the base shelter simulation. The model is based on the design specification (UNHCR 2016), were the findings of the social survey and shelter inspections completed missing information (e.g. occupancy pattern) or overrode contradictory ones (e.g. as built thermal insulation condition).

The spot measurements of different shelters were combined into a single time series and split into two groups, one to calibrate the model and another one to validate it. Uncertainties regarding model inputs were constrained to the following variables: infiltration (unknown; bounds estimated following construction details), ventilation effectiveness (unknown; e.g. surroundings influence on wind speed or discharge coefficients), occupation (variable between shelters) and U-value (bounded range of conductivity and thickness). A set of 72 simulations were used to calibrate these parameters and then validated with the remaining monitored data (fig. 3, EnergyPlus 8.6). The goodness of fit was evaluated through the peak and mean dissimilarity and the root mean square indicators (2.38, 0.36 and 1.47K, respectively). Given the between-shelter variability and the uncertainties in parameters such as ventilation and infiltration, these results were regarded as adequate for the purposes of this study.

Table 1. Parameters and cases to explore for the shelter design improvements (weather file: Guriat).

Parameter	Cases	Comment
Orientation [-]	[N, E, W, S]	One per cardinal direction.
Insulation [cm]	[1, 5, 10, 15]	Conductivity: 0.04 [$W{\cdot}m^{-2}{\cdot}K^{-1}$].
Thermal mass [-]	[light, heavy]	Light: current shelter composition. Heavy: 215mm perforated brick and plaster.
Thermal mass location [-]	[internal, external]	Relative position to the indoor space.
Occupancy [p]	[6, 12]	Original shelter design aims for 6p and surveyed occupation frequently reached 12p.
Shading [-]	[none, full]	None: current solar exposure (see fig. 1). Full: completely block solar radiation.
Ventilation strategy [-]	[daytime, always]	Daytime: as needed during 07-23h. Always: as needed (constant occupation).
Infiltration [-]	[original, reduced]	Original: current shelter estimated infiltration. Reduced: 25% of the previous value.
Opening effectiveness [%]	[10, 40, 70]	Multiplicative factor for opening areas. 10% is the fitted value in the calibration and 70% a value around illustrative reference levels (ASHRAE 2013).
Total	**3,072 models**	Every parameter-case combination.

The validated model was then used to extrapolate annual overheating performance. Given the limitations to monitor typical external conditions throughout the year in this location, the weather files for surrounding ones were used to derive plausible ranges (Guriat (Saudi Arabia), Queen Alia International Airport (Jordan) and Safawi (Jordan)).

In addition, the validated model forms the basis from which to explore design alternatives and shelter operation strategies (table 1):

- ‘Orientation’ and ‘Shading’ focus on a different arrangement of shelter units that alters their solar heat gains globally.
- ‘Insulation thickness’, ‘Thermal mass’, ‘Thermal mass location’, ‘Infiltration’ and ‘Opening effectiveness’ address different design specifications. In the case of

thermal mass, the baseline is the original lightweight construction (IBR sandwich panel with 15mm insulation). The alternative is a heavyweight envelope with a decrement delay[1] of 12h which aims to take advantage of the diurnal swing in desert climates.

- 'Occupancy' and 'Ventilation strategy' assume the same building characteristics but with different occupancy densities or operation modes. A minimum ventilation of $8l\cdot s^{-1}\cdot p^{-1}$ is considered despite the purge ventilation strategy.

Human thermal models

Refugees do not have access to electricity and the main cooling strategy at building level is natural ventilation. The social survey highlighted that coping mechanisms against heat were mainly to shower, to pour water onto themselves with their clothes on and to spray water on the floor. Other parameters such as clothing were adjusted within certain ranges (average summertime clothing insulation between 0.50±0.07clo (M) and 0.93±0.05clo (F)).

Annual overheating is first evaluated via the adaptive comfort model according to ASHRAE Std. 55 2013 (ANSI/ASHRAE 2016), calculating the running mean as the exponential moving average of outdoor temperature, $T_{rm}(\alpha=0.8)$. Discomfort is evaluated trough the temperature difference between the internal operative temperature and the adaptive comfort upper limit ($T_{lim} = 0.31\cdot T_{rm} + 21.3$). Illustrative limits of discomfort are established at 1% and 3% of the annual occupied time since the ASHRAE model does not suggest one. These values are on the lines of European recommendations (BSI 2007; CIBSE 2013) for temperature differences greater than 1K over the adaptive comfort upper limit.

Heat stress is evaluated through two rational thermal physiological models:

1. Pierce 2-node model: This is the updated version of the Pierce 2-node model (Gagge et al. 1971; Fountain & Huizenga 1997). It considers air and radiant temperatures, relative humidity, activity level, work efficiency, clothing and air velocity. The 'discomfort index' (DISC) is used to report heat strain as this index normalizes the effect of the inputs on the thermoregulatory system in a 7-point scale (-3 severe cold strain, 0 neutrality, +3 severe heat strain).
2. Predicted Heat Strain (PHS): ISO standard method (BSI 2004) to evaluate heat strain through required sweating and changes in the deep body temperatures presented by Malchaire et al. (2001).

The Pierce 2-node and the PHS models present technical barriers for their adoption in building simulation studies. Although the first is included in EnergyPlus, the user must introduce time-varying values for air speed and certain assumptions cannot be adjusted. The PHS is not part of building simulation suites and its implementation is computationally intensive for annual studies in large parametric analyses.

To overcome these issues, the models were implemented and validated numerically in a standalone application. For this study, the air speed has been estimated through the time-varying natural ventilation air flow divided by the cross-section of the shelter unit and fed into the calculation of operative temperatures (ASHRAE 2013). Regarding clothing, the aforementioned average of 0.93clo has been considered as a representative value.

[1] The time difference between external and internal peak temperatures in a 24-hour period.

Results and discussion

Current shelters

The results for extrapolated annual overheating in current shelters under typical weather conditions are presented in figs. 4 (discomfort), 5 (Pierce 2-node) and 6 (PHS). For the first two, severity is reported in the X axis (binned) and duration is reported in the Y axis for the three locations[2]. The PHS model follows an independent assessment scheme.

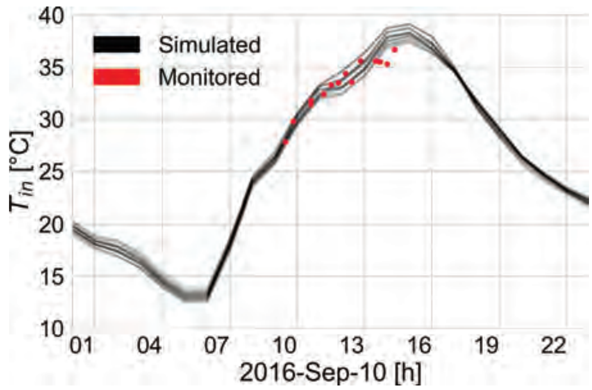

Figure 3. Current shelters: example of measured indoor conditions (red, n=14) and simulated models (black, n=72) over 24 hours.

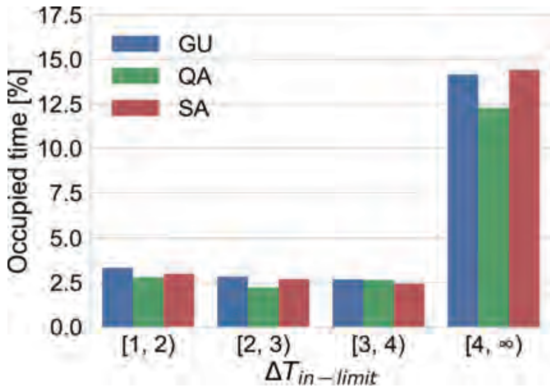

Figure 4. Current shelters: extrapolated annual overheating according to the Adaptive Thermal Comfort model (ASHRAE Std. 55)[2].

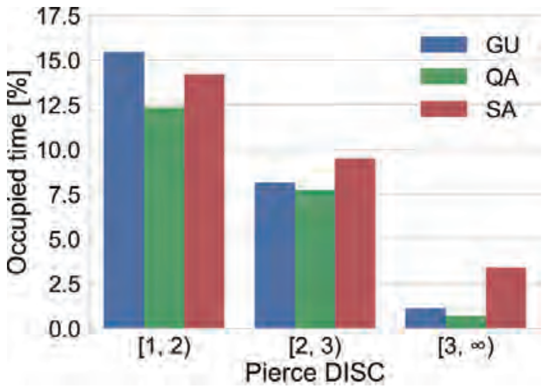

Figure 5. Current shelters: extrapolated annual overheating according to Pierce 2-node DISC[2].

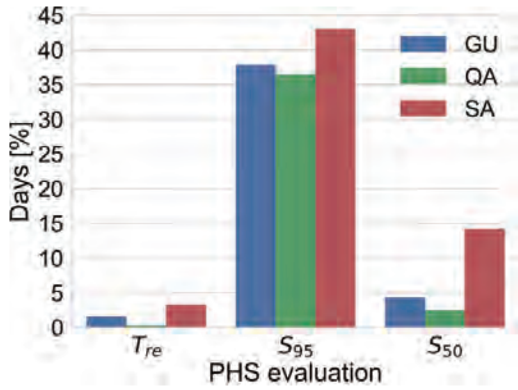

Figure 6. Current shelters: extrapolated annual overheating according to PHS[2,3] (n.b. Y axis scale).

The discomfort evaluation (fig. 4) shows that the adaptive thermal comfort upper limit is surpassed for more than 20% of the time, well beyond the maximum 1% (annual) or 3% (seasonal) illustrative limits. Of special concern is that more than 12% of the time the overheating is severe ($\Delta T \geq 4$), a trend that is consistent in the three locations considered.

The heat strain measured via the discomfort index in the Pierce 2-node model (fig. 5) indicates an unacceptable indoor environment from the physiological perspective, with a cumulative average greater than 20%. Unlike the previous, votes follow a diminishing progression towards greater strain. However, durations in the severest bins are well beyond what is deemed appropriate for comfort conditions.

The PHS provides greater insights to evaluate potential health risks. Here, each day of the annual building simulation is considered independent and simulated from 9 to 17h (a best-case scenario since physiological indicators are reset for the following day). Fig. 6 shows the percentage of days where limits for each variable are surpassed. Despite

[2] GU: Guriat (Saudi Arabia), QA: Queen Alia International Airport (Jordan), SA: Safawi (Jordan).

[3] T_{re}: Rectal temperature limit surpassed, S_X: Sweating limit surpassed for X% of the population.

occupants were considered adapted to hot conditions and able to drink water as required, the water loss due to sweat is evaluated excessive for 95% of the population for more than a third of the year and greater than 2.5% for the mean subject. A complementary indicator is the change in rectal temperature. Here, the upper limit of 38°C (ΔT=+1.2K) is surpassed in the three locations (≈0.28%, one day, for Queen Alia). Therefore, the evaluation indicates that indoor conditions cause both excessive water loss and changes in the deep body temperature in the refugee shelters under typical weather conditions.

Relative importance of design parameters

The main effects for each of the 23 parameter-case in the 3,072 model variants are presented in fig. 7 for discomfort duration and ranges of internal temperatures in fig. 8. Although this is an overview of performance, it is noticeable how 18 out of the 23 parameter-case span the wide minimum–maximum value range (≈2.5% and ≈20%, respectively). This indicates that shelters can be greatly optimized to cope with the hot desert climate despite the limited passive strategies considered.

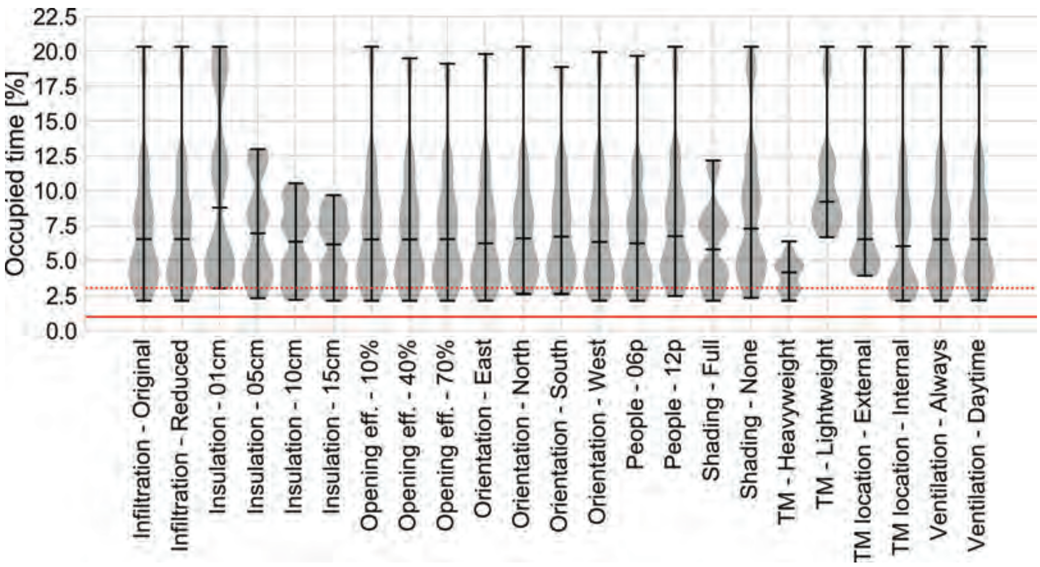

Figure 7. Overheating discomfort in proposals: main effects (plot indicates minimum, median and maximum (black segments) and variable distribution (shaded area); illustrative overheating thresholds in red: 1% and 3%).

Of paramount importance are insulation thickness, thermal mass and shading: they have a determining impact no matter the values of remaining variables. Additionally, they constitute robust solutions that do not depend on occupant behaviours. Changing insulation from 1cm to 5cm onwards almost halves the maximum overheating, although 1cm can deliver 3% overheating if care is taken in every other design parameter. The provision of sufficient thermal mass as to achieve a 12h decrement delay proves to be the most effective solution —even for 12-person occupancy (high internal gains)—, whereas the theoretical maximum shading performs similarly to 5cm insulation. Lastly, the fact that external thermal mass scores a minimum of 4% suggest that retrofitting shelter envelopes from the exterior could be an effective overheating countermeasure; notwithstanding, internal thermal mass is preferable.

Table 2. Proposals: best, median and worst cases according to annual overheating discomfort duration.

Orientation	Insulation [cm]	Thermal mass	Thermal mass location	People [p]	Shading	Ventilation	Opening effec. [%]	Infiltration	Overheating time [%]
East	15	Heavyweight	Internal	6	Full	Always	40	Original	2.2
South	1	Heavyweight	External	12	None	Daytime	70	Reduced	6.4
North	1	Lightweight	Internal	12	None	Daytime	10	Reduced	20.3

The best, median and worst cases (table 2) are analysed in the same way as the current shelters. Figure 9 highlights how the best case can diminish overheating duration to 2.2% while avoiding severe overheating (ΔT≥4K). The heat strain (fig. 10) features an equivalent reduction in overheating, with the median model avoiding the range [3, ∞). Lastly, excessive water loss due to sweating can be completely avoided for the mean subject or greatly diminished for the 95% population and changes in the deep body temperature can be kept below the recommended threshold in every case throughout the year (fig. 11).

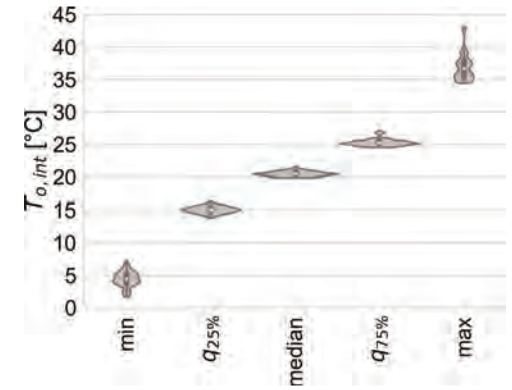

Figure 8. Proposals: indoor operative temperature ranges (n=3072; values computed independently for each case and aggregated into each violin plot).

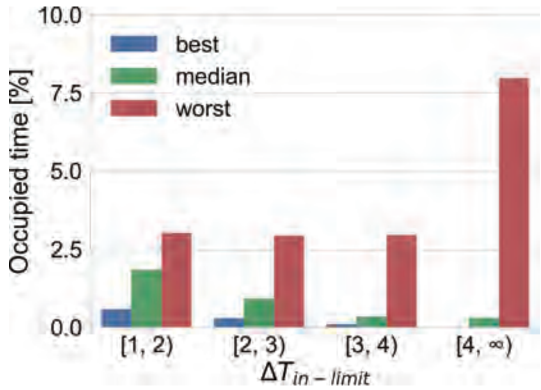

Figure 9. Proposals: annual overheating according to the Adaptive Thermal Comfort model (ASHRAE Std. 55 2013; n.b. Y axis scale).

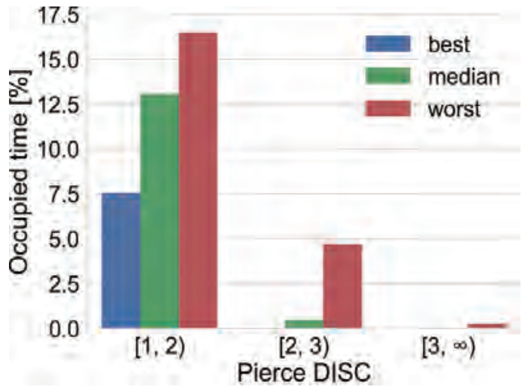

Figure 10. Proposals: annual overheating according to Pierce 2-node DISC (n.b. Y axis scale).

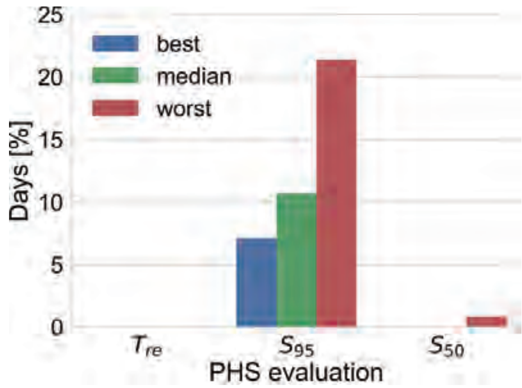

Figure 11. Proposals: annual overheating according to PHS[3] (n.b. Y axis scale).

Conclusions

The provision of adequate shelter for refugees is becoming an even more pressing issue than ever before given the increasing number of people involved worldwide. Owing to different humanitarian crises, refugees are often allocated in camps subject to harsh environments that can represent a threat to their health and wellbeing. Therefore, this paper presented the study of indoor thermal conditions in the Azraq refugee camp (Jordan) to evaluate the annual overheating risk of refugees from a discomfort and health risk perspective. Based on a three-week field study during summertime in the camp, overheating exposure was evaluated through adaptive thermal comfort and physiological models for heat stress. Extrapolated annual conditions via building and human thermal simulation suggest that refugees are subject to overheating for more than 20% of the year, surpassing recommended physiological thresholds for heat stress. Building on the efforts of involved agencies, the study presented a parametric analysis of passive strategies in 3,072 shelter variants. Results indicate that considered measures can reduce overheating to 2.3% of the year, with a drastic reduction in associated heat stress.

Design to Thrive

Contribution of Solar Protection in Windows for Reducing Building Energy Demand in the Climatic Zones of the Spanish Peninsula

María Gavira[1*], Enrique Larrumbide[1] and Virginia Sánchez[1]

[1] Quality in Construction Unit, Eduardo Torroja Institute for construction science, Spanish National Research Council (CSIC), Madrid, Spain.
*mariagg@ietcc.csic.es;

Abstract: The Spanish Building Code establishes in its "Energy saving" document, limitations on energy demand and consumption for residential building stock. In new residential buildings the energy demand requirements are establihed separately for heating and cooling. The heating demand limitation is determined based on the useful surface of the living spaces of the building, and winter climatic zone, while the cooling demand limitation is set based on the summer climatic zone. To achieve compliance with the regulation requirements, guide values of the characteristic parameters for the thermal envelope depending on the climatic zone are given: thermal transmittance of the roof, walls, floor and windows. To achieve compliance with regulatory requirements in accordance with these recommendations without the introduction of any design element you may need a significant thickness of thermal insulation in some climate zones, making the solar factor of the glass a crucial design element. The aim of the study is to analyze the energy demands of the building models chosen among different residential building types and representative climatic zones, with recommendations established by the Spanish Building Code to achieve compliance with regulatory requirements. Subsequently, it is proposed to place sunscreens on windows during the summer period, analyzing the reduction of cooling demand which will allow design flexibility indicators for the thermal envelope recommended in the Building Code, also complying with regulatory requirements.

Keywords: Energy saving, solar protection, residential building, building regulation

Introduction

Directive 2010/31/EU of the European Parliament and of the Council of 19 May 2010 on the energy performance of buildings, establishes a tightening of the minimum energy performance requirements for buildings, pursuing more ambitious objectives such as reaching near zero energy buildings.

40% of the total energy consumption in the European Union corresponds to buildings. Therefore, the reduction of energy consumption and the use of energy from renewable sources in the building sector constitute an important part of the measures necessary for reducing the Union's energy dependence and greenhouse gas emissions. Member States should take the necessary measures to ensure that minimum energy performance requirements for buildings are established in order to achieve optimum levels of profitability.

In this context, the Energy Saving Document (DB HE) of the Spanish Technical Building Code (CTE) is updated in 2013, which includes a limitation on the energy demand of the building separately for heating and cooling. The way of limiting the demand for heating is well studied by the insulation of the building, and the tightness against air infiltrations. The demand for cooling is usually controlled by the parameters of sun protection linked to the windows of the building envelope. But even more effective can be the control of this solar radiation from the outside, blocking it with shading elements.

The solar radiation received by the Spanish peninsula is much higher than that received by other countries of the European Union, as can be seen in figure 1. For this reason, and linked to the temperature increase due to climate change, better adapted solutions in buildings to this conditions should be outline.

In addition, within the peninsula there are varied climates depending on whether we are on the north coast, the peninsular meseta, the Mediterranean coast or the south of the peninsula. A variety of climates are presented to which the architectural solutions must be adapted in the best possible way.

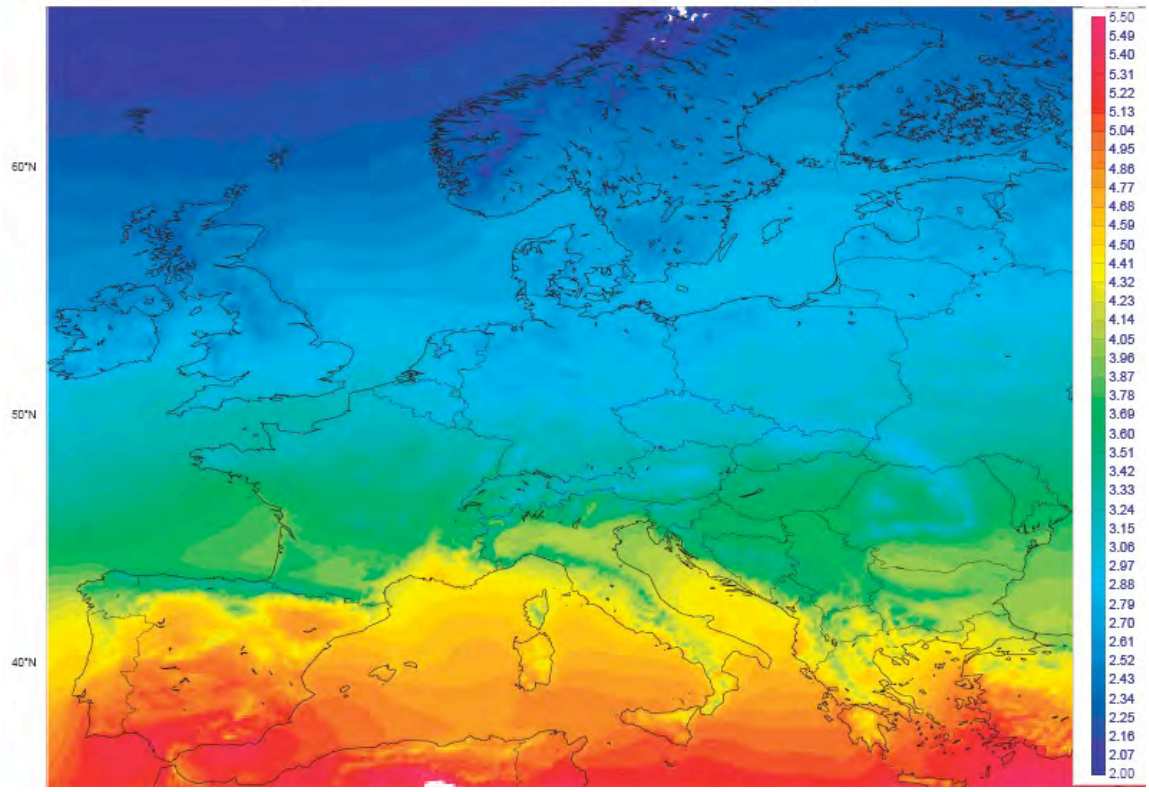

Figure 1. Global mean solar irradiatin in Europe (kWh·m^{-2}·día^{-1})

It is necessary to take into account that a good part of the Spanish territory has zones with severe winters and summers, and in each season will be demanded a different answer against the outside environment from the building. The monthly distribution of solar radiation is not homogeneous throughout the year, the central months of the year receive much more solar radiation than the winter months, so that the sun protection measures should be adaptable to the the building energy demand in every season of the year.

The present study aims to analyze the effect of the windows shading elements on the energy demand of three buildings representative of the private residential building stock in each of the winter climatic zones of the Spanish peninsula, considering those most critical regarding the summer climatic severity.

Methodology and study cases

The analysis of the energy demand is performed based on simulations using the Unified tool Lider-Calener, which is the reference tool for verifying compliance with the requirements of energy saving Spanish Building Code (CTE DB HE).

To perform this study, three types of building have been considered, among the typical housing construction in Spain: a multifamily housing, a single-family house and a semi-detached house as seen in figure 2. The parameters that define the model for each type of building are collected in table 1.

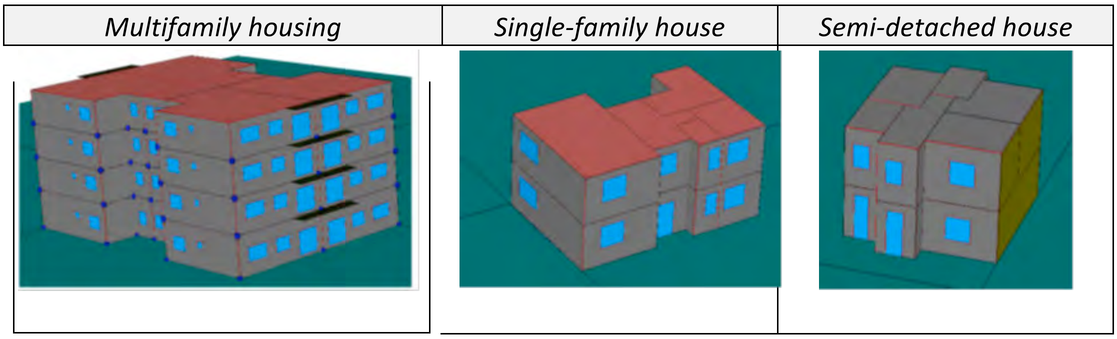

Figure 2. Types of building models

Table 1. Geometric parameters of the building models

TYPE OF HOUSING	LIVING AREA (m^2)	COMPACTNESS (m)	VOLUME (m^3)	ENVELOPE AREA (m^2)	WINDOWS %
Multifamily housing	1674	2,5	5231	2100	16
Single-family house	134	0,9	307	185	14
Semi-detached house	102	1,3	293	214	14

The thermal transmittances of the envelope elements are taken as reference values from the guideline values given in appendix E of the Energy Saving Document of the Spanish Building Code. In any case, some values have had to be reduced in order to achieve compliance with the minimum energy demand requirements.

Table 2. Envelope elements transmitances

Element transmitance ($W/m^2 \cdot K$)	Climatic Zone				
	A	B	C	D	E
U_M	0,50	0,38	0,29	0,27	0,25
U_S	0,53	0,46	0,36	0,34	0,31
U_C	0,47	0,33	0,23	0,22	0,19

To reach the objectives of the work, a series of cases have been set out, varying the parameter of interest, which is the shading coefficient of the awnings for each type of building.

Orientations

The different types of buildings have been analyzed for the East-West orientation as it is the most unfavorable for the overheating of buildings in summer season. In the North-South orientation, lower cooling demands are obtained than in the studied orientation.

Climatic Zones

To analyze the influence of the awnings in the energy demand, the building models has been studied in five representative climatic zones according to the Spanish regulation, corresponding to the five winter climatic zones in the peninsula, with representation of the most severe summer climatic zones, E1, D3, C4, B4 and A4.

The Spanish Building Code defines several climatic zones to establish the energy requirements for buildings. This climatic zonification corresponds to the division of the Spanish territory depending on the winter climatic severity and the summer climatic severity, as seen in chart of figure 3. An approximate distribution of the Spanish peninsula in winter climatic zones can be seen in the map of figure 3.

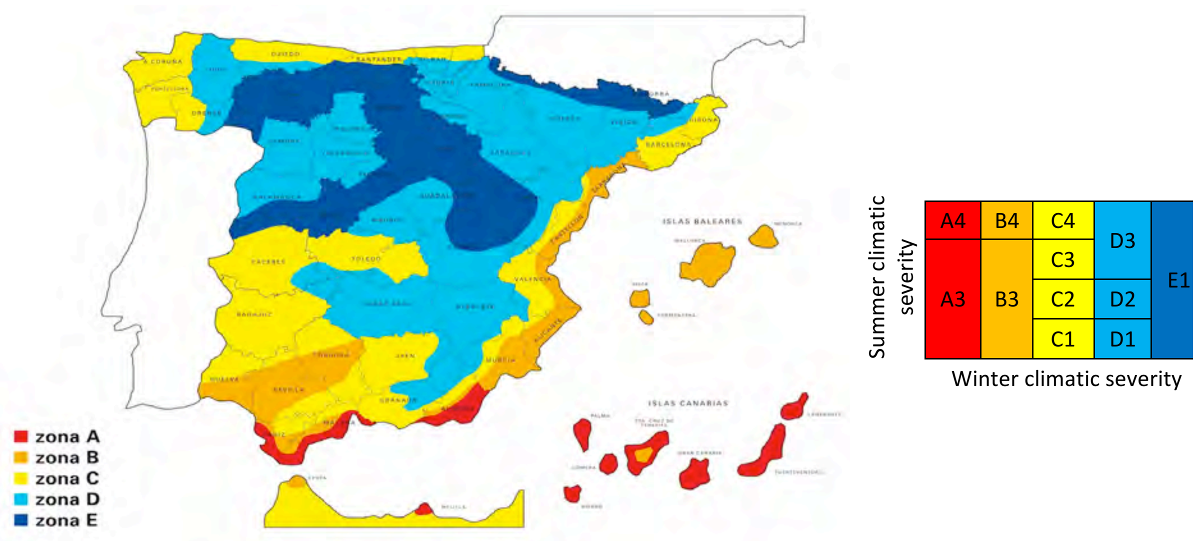

Figure 3. Spanish climatic zones

Shading elements

For the different buildings studied, opaque fabric awnings with different inclinations have been used as shading elements. The values of the shading coefficient corresponding to each awning inclination are given in Table 3.

Table 3. Shading coefficients

	Angle	Orientation	
	**α**	**SE/S/SW**	**E/W**
	30	0,02	0,04
	45	0,05	0,08
	60	0,22	0,28

Results

The thermal transmittance values used have been adjusted to meet the minimum demand requirements established in the Energy Saving Document of the Spanish Building Code. To evaluate the average performance of the envelope, the K value is defined as a weighted average of the transmittances of the elements that compose it (facade, roof, floor, windows) in relation to the area of the element with respect to the global envelope area.

In the graph of Figure 4, it can be observed how the lowest values of the global K coefficient are established for the areas with coldest winter weather severity, E, D and C. If we compare the values of K defined for each building, we can observe that the single-family house has, in general, the lowest K values, the most demanding, while the multifamily housing is the one that usually has a higher K value. This is related to the compactness of each building, where the lowest K value corresponds to the building with lower compactness and the highest value of K corresponds to the building with higher compactness. Indeed, the compactness of the building, determines the amount of envelope surface exposed to the outside, and with it, the greater need of a good envelope insulation to avoid energy losses.

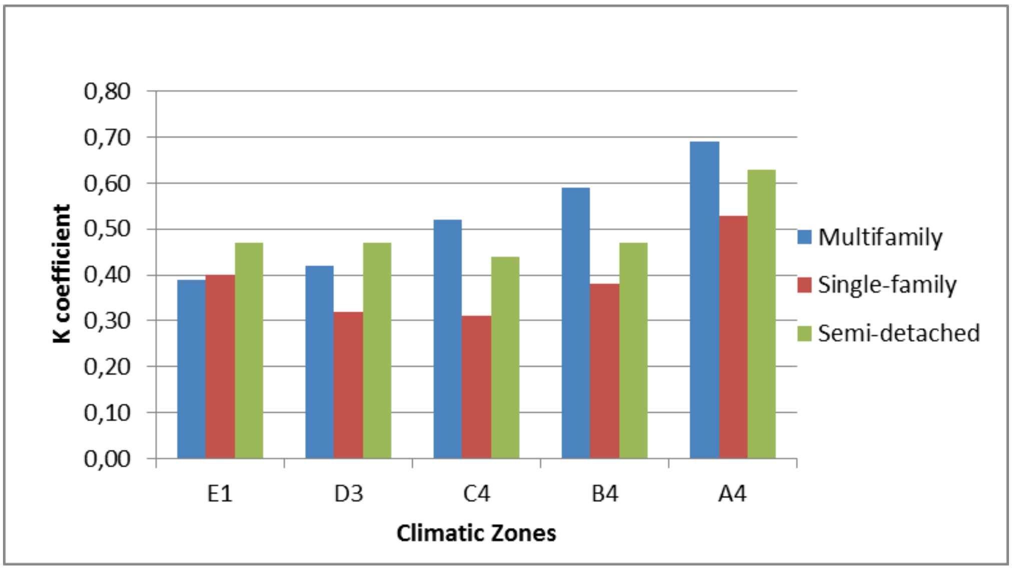

Figure 4. K coefficients of the buildings analyzed in each climatic zone

Multifamily housing

In Figure 5 we can observe the energy demands obtained for the multifamily housing in the different cases studied. It can be seen that, through the placement of awnings, the cooling demands are below the value of 15 kWh/m^2·year in all climatic zones. It can also be observed that the values of cooling demand with awnings at different inclinations are very close, there is little difference of demand between them.

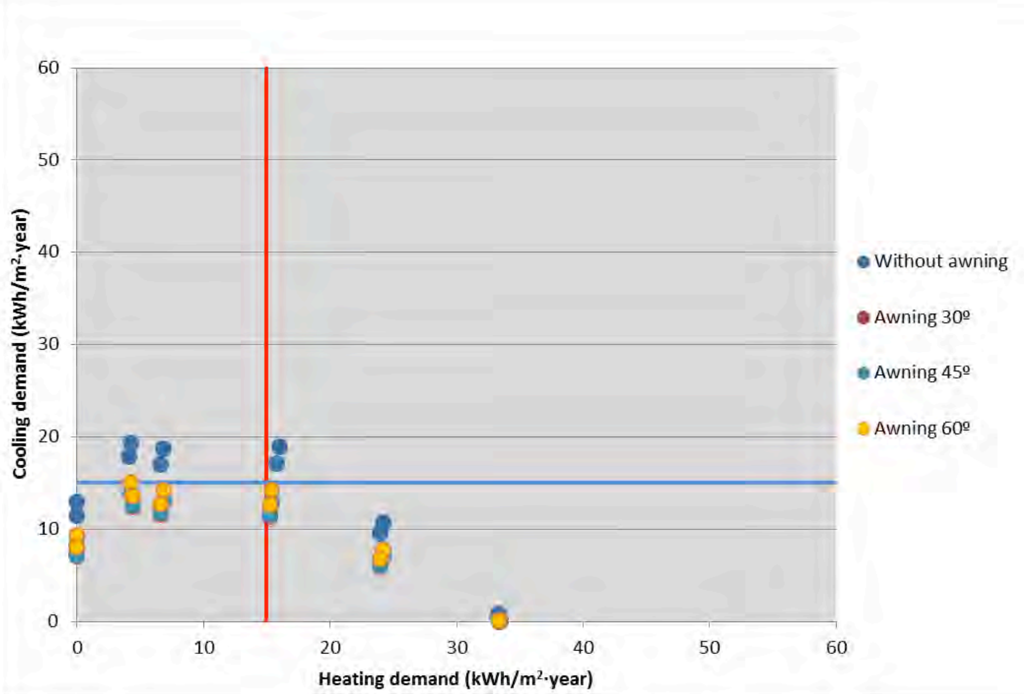

Figure 5. Multifamily housing energy demands

Single-family house

As in the case of the multifamily housing, the cooling demands of the single-family house with awnings are below the value of 15 kWh/m^2·year in all climatic zones, with slight differences between the different types of awnings.

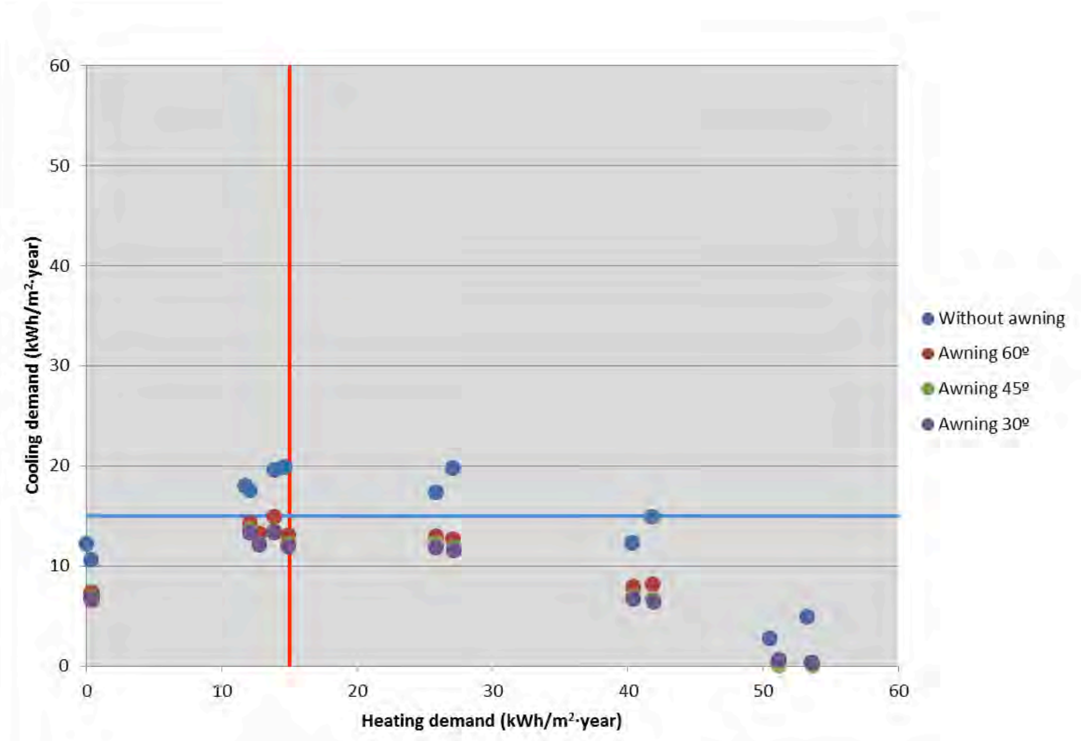

Figure 6. Single-family house energy demands

Semi-detached house

In the semi-detached house, as in the previous cases, the placement of awnings in windows causes the cooling demands to be less than 15 kWh/m^2·year, even in some of the simulated cases without awning, only with the solar protection of window glass.

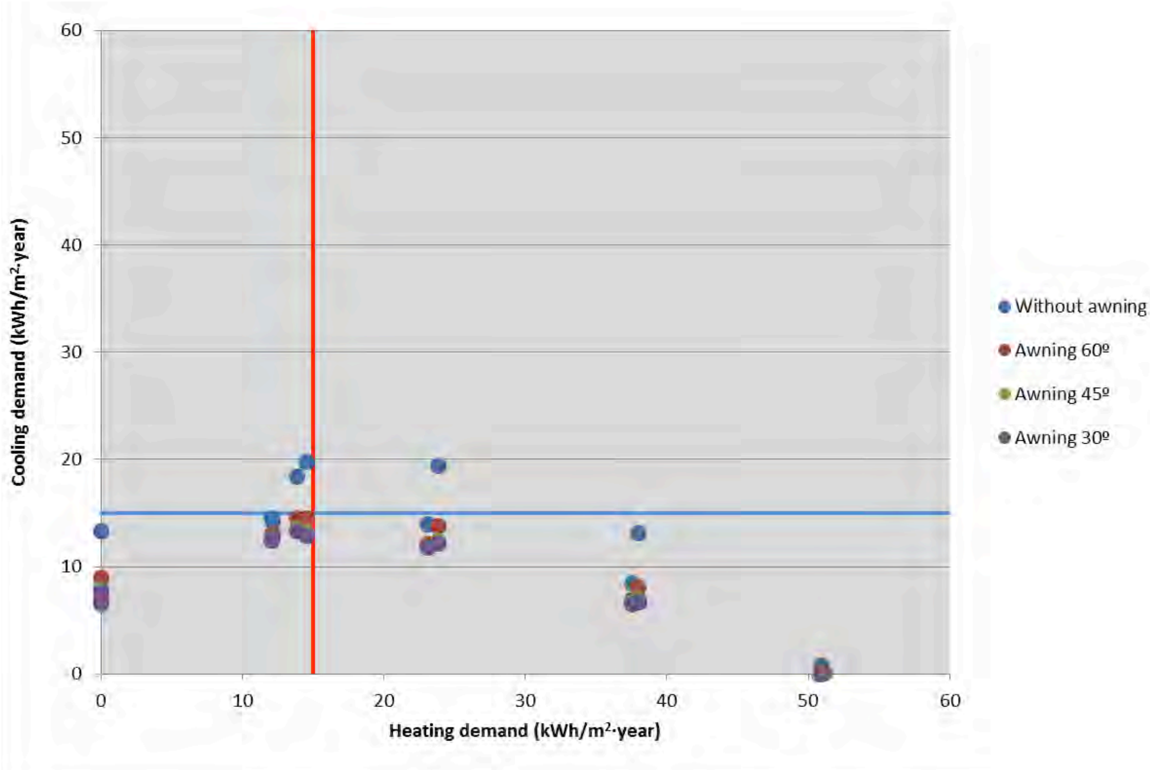

Figure 7. Semi-detached house energy demands

Discussion and conclusions

The provision of awnings in south, east and west windows orientations causes a significant decrease in the cooling demand. This reduction is already obtained with the awning at a higher inclination, 60 °, which makes less shading but sufficient to block the radiation that causes the increase of internal loads and the consequent increase of cooling demand.

The differences in cooling demands between the different inclinations of awnings is negligible, with the inclination of 30 ° being the one that provides the most shade and a lower value of cooling demand. In all cases, it is observed that with awnings at 60 ° the demands obtained are already less than 15 kWh/m^2·year, for all orientations and climatic zones considered.

It is also noted that in cold climatic zones, zones D3 and E1, the values of the cooling demands are zero or very low and less than 15 kW · h / m2 · year, so awnings becomes not so necessary, but recommended in D3 for the severe summer.

Recommendations for regulations

In view of the results, and taking into account the varied climate that we have in the Spanish peninsula, it is interesting to establish recommendations adapted to the climatic zone in which the building is located. The shading elements can be optional in cold climatic zones, such as zones E and D, mainly in combination with low summer weather severity, such as climates 1 or 2.

The rest of climates characterized by summers 3 and 4, must have shading elements in windows or façade hollows, with the possibility of adapting them to the time of year, in order to block solar radiation only in those months when we are not interested because of the high external temperatures.

Future lines

To adapt the required regulatory requirements to buildings in relation to their energy performance, it is necessary to update the climatic data with which to carry out the design and sizing. The climate change observed in recent years by higher temperatures compared to previous averages, makes it necessary to adapt the buildings to these new conditions, mainly in the warmer areas that occur in the climate of the Spanish peninsula.

Heat stress in hospital ward spaces: An investigation on a naturally ventilated hospital building in UK

R. Giridharan[1]

[1] Kent School of Architecture, University of Kent, Canterbury, United Kingdom.
email: G.Renganathan@kent.ac.uk

Abstract: In the context of climate change, there is increasing concern about the likelihood of overheating in hospitals in UK, especially in buildings which are not mechanically cooled. A number of studies have examined this issue in different hospitals in UK. On most occasions these studies have focused on overheating and evaluated the performance of the spaces using adaptive thermal comfort criteria. Adaptive criteria is not a good indicator of actual heat stress. Further, the adaptive criteria cannot be applied to spaces that have no operable windows. However, in hospital, substantial number of spaces are without windows, especially nurse stations. This paper will assess the heat stress in ward spaces using Wet Bulb Globe Temperature (WBGT) heat index in order to explain the occupant's vulnerability while looking at the potential of combining this index with adaptive thermal comfort criteria (BSEN15251). The paper will focus on naturally ventilated Runcie ward building at St Albans city hospital and assess its thermal performance for summer 2011. During summer 2011, the maximum WBGT varies between 21.5°C and 23.8°C while the minimum was between 13.6°C and 14.3°C. The paper proposes WBGT of 23°C as a heat stress threshold for sick and vulnerable.

Keywords: Adaptive comfort, Heat stress, Wet bulb globe temperature, monitoring, hospital.

Introduction

During periods of high ambient temperature, hospitals are expected to provide a safe environment for patients, especially during heat waves (NHS, 2011). On most occasions when temperatures are high that hospitals harbour the greatest concentration of vulnerable individuals. However, there is increasing concern about the likelihood of overheating in hospitals in UK, especially in buildings which are not mechanically cooled (Lomas and Giridharan; 2012). The maintenance of thermal comfort in such spaces is critically important and installing air-conditioning in response to climate change is expensive and potentially energy intensive. In this context, during the period 2009-12, the Design and Delivery of Robust Hospital Environments in a Changing Climate (DeDeRHECC) research project investigated the impact of summer overheating in hospital campuses operated by four National Health Service (NHS) Acute Trusts. Some of the findings and possible measures that could be adapted in the Addenbrooke's, Bradford and Glenfield hospital buildings to climate change have been presented elsewhere (Short et al., 2012, Short et al., 2015; Lomas et al., 2012: Giridharan et al., 2013). These papers examined the performance of ward spaces using the BSEN15251, CIBSE and HTM03.

DeDeRHECC research project shows that BSEN15251 is best suited to evaluate thermal performance of the ward spaces. However, the BSEN15251 can only be applied to naturally ventilated buildings with operable windows and mechanically ventilated building without conditioning the air. But, substantial part of hospital spaces do not have operable windows, for example, some nurse stations, internal corridors and consultation rooms. These important spaces cannot be assessed using BSEN15251. Further, although heating is turned off in most hospitals in summer, they tend to come into operation whenever there is cold period (Giridharan et al., 2013). For these days BSEN15251 cannot be applied. Therefore, alternative assessment criteria should be established that could be used to assess all types of spaces in the hospitals, considering that patients visit most of these areas and staffs in these areas also need to be in a comfortable environment to perform their services effectively. In this context, this paper will assess the heat stress in ward spaces using Wet Bulb Globe Temperature (WBGT) heat index in order to ascertain the occupant's vulnerability. The study will also compare the WBGT with the adaptive thermal comfort criteria (BSEN15251) results for the spaces where both criteria could be applied in order to establish the importance of using both systems to assess spaces. For this purpose, this paper focuses on 2011 summer conditions in the Runcie ward building at St Albans city hospital.

Premises for the investigation

The applications and limitations of CIBSE, HTM03 and BSEN15251 for the assessment of hospital spaces have been dealt in detail by Lomas and Ji (2009) and Lomas and Giridharan (2012). The summary of the above assessment criteria are presented in the Table 1.

Table 1: Criteria for assessing internal temperatures in naturally ventilated spaces [Short et al., 2012].

Assessment metric	Source	Criterion	Applicability	Comment
Total hours, dry-bulb temperature over 28°C.	HTM03-01 [2007]	Limiting value 50 hours.	All spaces and buildings.	Weather year to be used in simulations not stated.
Night time hours operative temperature over 26°C.	CIBSE Guide A [2015]	No more than 1% of hours above value.	Sleeping spaces only.	Value based on homes and not health care facilities.
Adaptive comfort Cat. I and Cat II envelopes. Thresholds of operative temperature vary with running mean of ambient temperature.	BSEN15251 [2008]	No more than 5% of hours outside envelope, in any day, week, month or year.	Naturally ventilated buildings with operable windows and mechanically ventilated building without conditioning the air.	Cat I is applicable to spaces with vulnerable individuals, such as wards, Cat II for 'normally' occupied spaces, such as offices, consulting rooms, etc.

Notes

1. The limiting value for a year is 50, 37 (assuming patient is at sleep the whole day) and 438 hours for HTM03-01, CIBSE and BSEN15251 respectively.
2. The*r*e could be few occasional hours where the room heaters could have been kept on based on individual preference. So the results should be viewed keeping this limitation.

Among the above said criteria, only BSEN15251 is based on adaptive principle. It is basically on the principle that people are sensitive to the environment and they make themselves comfortable by making adjustments to clothing, activity and posture (Nicol and Humphreys, 2007). Most importantly standard's scope includes hospital and advocates the application Cat I (fig. 1) band for 'spaces occupied by very sensitive and fragile persons with special requirements like, handicapped, sick, very young children and elderly persons (BSEN, 2008)'. As per the standard at a running mean of 30°C, the sick person is able to adapt an indoor temperature of 31°C. The author is of the opinion that this is not a practical limit. Therefore, within 'Cat I', there should be shorter range. However, what is best about adaptive criteria is that it is easy to use. The BSEN15251 requires hourly monitored indoor and outdoor temperature for the assessment. Monitoring hourly indoor temperature is relatively easy compared to complex parameters that one need to monitor to use other thermal comfort indexes. Therefore, BSEN15251 widely used for design and assessment of hospital spaces. Another drawback of this standard is that it cannot be applied to spaces that do not incorporate windows. However, in hospitals with deep plans there could substantial amount of such spaces. Further, one must also take into account that a person may continue to stay safe in a space that is considered to be as uncomfortable in terms of adaptive standard, as long as that person is not subjected to heat stress (Holmes et al., 2016). This could be true for a healthy person but not for a sick and a vulnerable person. However, it is still important to have an assessment criteria or index range that could be applied to all the spaces in hospital. In this purpose, this paper proposes Wet Bulb Globe Temperature (WBGT) heat stress index. This index was originally developed by the US military and subsequently applied to other work places (NEHC, 2007; OSHA, 2016).

The indoor WBGT (in ^{o}C) index (Eq-1) is a function of natural wet bulb temperature (T_{nwb} in ^{o}C) and black globe temperature ($T_{g\ in}$ ^{o}C) (Lemke and Kjellstrom, 2012). Measuring globe temperature in a functional ward is near impossible considering the clinical constraints one need to face. However, Lemke and Kjellstrom (2012) have validated a simplified equation (Eq-2) proposed by Bernard and Pourmoghani (1999) for the purpose of indoor assessment using psychrometric wet bulb temperature (T_{pwp} in ^{o}C), dry bulb temperature (T_a in ^{o}C) and air speed (V in m/s). This index assumes that occupants are healthy adults.

$$WBGT_{ind} = 0.7T_{nwb}+0.3T_g \qquad \text{Eq-1}$$

$$WBGT= 0.67T_{pwp} +0.33\ T_a-0.048\log_{10}V(T_a-T_{pwp}) \qquad \text{Eq-2}$$

According to Holmes et al., (2016) psychrometric wet bulb temperature could be generated using the equation proposed by Stull, (2011) i.e. T_{pwp} equal to T_w:

$$T_w= T_a\mathrm{atan}(0.151977(RH+8.313659)^{1/2})+\mathrm{atan}(T_a+RH)-\mathrm{atan}(RH-1.676331) + 0.00391838(RH)^{3/2}\,\mathrm{atan}(0.023101RH)-4.686035 \qquad \text{Eq-3}$$

The Eq-2 assumes indoor air temperature is equal to indoor radiant temperature. On most occasions, what is measured in a low air speed hospital environment is not air temperature, but indoor operative temperature i.e. combination of air and radiant. By and large, in low air speed hospital environments, this is influenced by radiant component. Lemke and Kjellstrom, (2012) have validated this equation (Eq-2) up to an air speed of 3m/s. However, this equation is not validated for hospital environments. This index advocates a threshold of 31^{o}C (figure 1) and is applicable for work places, more specifically, industrial work places, where healthy people are performing tasks. This 31^{o}C could be achieved with various combination of temperature and relative humidity (RH). This threshold value, at 100% RH, meets top of the BSEN15251 adaptive Cat II upper limit (figure 2). Therefore, this is not the appropriate threshold for sick. However, Holmes et al., (2016) are of the opinion 28^{o}C could be the threshold for below average healthy people (figure 1). But this has not been validated for a hospital environment. Further, there is big difference between below average healthy and a sick person. Therefore, the threshold needs to be brought down further. On the other hand, for outdoor, the threshold is 23^{o}C (NEHC, 2007) i.e. at this point hot weather practices will be activated. Although this is the initial warning point for outdoor, one could argue this as the threshold for sick and vulnerable by assuming that stress factor felt by healthy individual at WBGT of 23^{o}C (outdoor) will lead to severe health implications for sick person under naturally ventilated hospital (low air speed) indoor conditions. This paper will apply this proposed limit and assess critical ward spaces. The intention is not to validate WBGT of 23^{o}C, but to establish a starting point for further investigation. Further, successful validation could help to narrow down the adaptive comfort band to a range that is applicable for sick people.

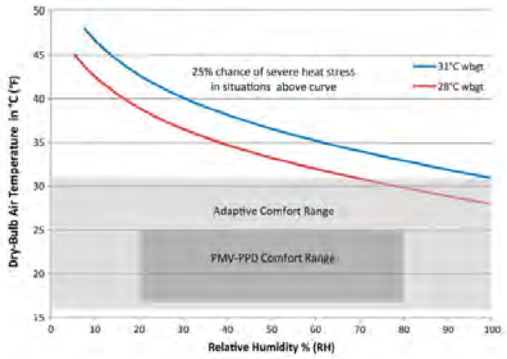

Figure 1: Indoor WBGT (0.3 m/s) and its relationship to BSEN 15251 adaptive threshold (source: Holmes et al., 2016)

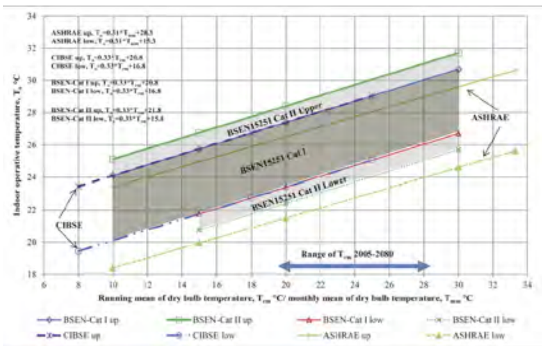

Figure 2: Comparison of adaptive thermal comfort standards (source: Lomas and Giridharan, 2012).

Case study description

The DeDeRHECC project monitored Runcie (wards), Moynahan (wards) and Gloucester wing (consultation) at St Albans city hospital between June 2010 and September 2011. This paper focuses on Runcie ward levels 1 and 3 (Figures 3 & 4) and limit its discussion to summer 2011. This is a three storeyed traditional masonry construction (102 mm brick work (outer leaf)-50 air gap- 50mm mineral fibre insulation-100 medium density block work) building with a concrete tiled pitched roof on timer trusses (with 100 mm mineral fibre insulation). Building is naturally ventilated with perimeter radiator heating. In the bed bay areas, especially in single bed rooms, it is possible to control the radiator through 'on/off' valves. The windows are made of timber frames. Level 1 houses the physiotherapy section while level 3 is elderly care section.

Although loggers are placed in 8 spaces, all the loggers did not measure both temperature and humidity. However, each space had at least one logger that measured both temperature and humidity. The paper will focus on these measurements since WBGT needs both temperature and humidity. So this paper will limit the discussion to loggers 2 (MB102) and 5 (NS) in level 1, and loggers 1(MB101), 4 (MB202), 5(CD01), 6 (SR01) and 7 (SB101) in level 3.

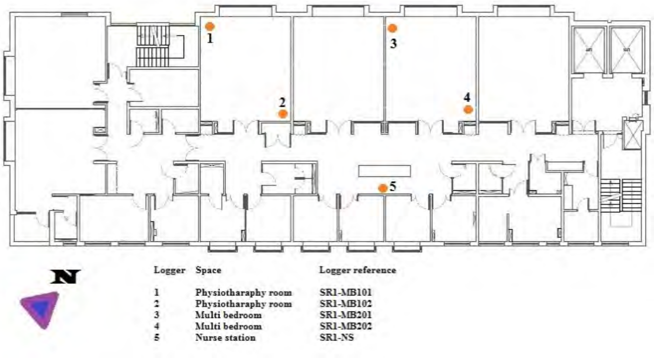

Figure 3: Logger locations in Runcie ward level 1

Figure 4: Logger location in Runcie ward level 3

Results and analysis

The summary of the performance during summer 2011 is presented in Table 2. The mean daytime temperature in the above mentioned spaces were between 22.5^{o}C and 24.0^{o}C. Maximum temperature of 29.0^{o}C was observed in the staff rest room. The maximum relative humidity in the observed spaces ranged between 68.3% and 76.6%. In both levels, circulation, and nurse station and related areas were warmer than bedrooms. MB202 was warmer than MB101. This could be attributed to the air flow i.e. M101 is closer to the window while MB202 is located at the inner most area. However, this change of location did not have an impact on the night time mean temperature since windows were shut. But in terms of CIBSE night time sleeping criteria MB202 exceedance was more (double) than MB101. Therefore, window had an impact in terms of duration of exceedance. Overall, only MB202 marginally exceed the CIBSE night time criteria but all the spaces were within the BSEN15251 Cat I threshold. In terms of HTM03 all the spaces, including nurse station, corridor and staff rest room were within the threshold.

The WBGT values for the spaces were calculated using Eq-2 considering an air speed of 0.1 m/s. The study assumes a low air speed, considering the HTM55 recommendation of 100mm window opening. In the past, during the hospital modelling work, author has observed 0 to 22 ach for summer period in naturally ventilated ward spaces with100mm window opening, however on most occasions it is less than 3ach. Considering the size of the window openings in wards, air speed on most occasion will be less than 0.3 m/s. This value is in line with the air speed recommended for Ultra Clean Ventilation i.e. 0.2 to 0.3 m/s (HTM03, 2007). Further, differences in WBGT for the air speeds of 0.1 m/s and 0.3 m/s is very marginal.

Table 2: Comparison of internal temperatures measured between 1st May and 30th September, 2011, with BSEN15251, CIBSE and HTM03 overheating criteria and Wet Bulb Globe Temperature (WBGT): Runcie Ward Building, St Albans City Hospital.

Space	Maximum $WBGT_{ind-av0.1\ m/s}$ °C	Minimum $WBGT_{ind-av0.1\ m/s}$ °C	Maximum temp °C (24 hours)	Minimum temp °C (24 hours)	Mean daytime temp °C (7:00 to 20:00)	Mean night time temp °C (21:00 to 6:00)	Maximum diurnal range (K)	Maximum relative humidity %	Minimum relative humidity %	H HTM03: Hours over 28 °C (24 hours)	CIBSE: Hours over 24/26 °C (21:00 to 6:00)	BSEN15251:Hours over Cat I / Cat II upper
Level 1												
Multi bedroom (SR1-MB102)	21.5	14.3	25.5	20.1	22.5	22.3	3.3	69.6	21.7	0	29/0	2/0
Nurse station (SR1-NS)	23.0	15.3	27.7	21.8	23.7	23.6	4.2	71.0	19.8	0	NA	NA
Level 3												
Single bedroom (SR3-SB101)	22.9	14.9	28.0	20.5	23.9	23.2	4.1	76.6	17.3	1	256/15	105/09
Multi bedroom (SR3-MB101)	22.6	14.9	27.5	21.2	23.7	23.5	2.9	68.3	19.9	0	365/17	41/05
Multi bedroom (SR3-MB202)	23.1	14.0	28.0	20.0	23.6	23.5	3.7	69.4	22.0	2	360/38	97/18
Corridor (SR3-CD01)	23.0	14.5	28.3	21.2	24.0	23.8	2.8	70.2	20.1	7	NA	NA
Staff restroom (SR3-SR01)	23.8	13.6	29.1	20.0	23.9	23.2	5.1	76.6	17.3	21	NA	186/50

Notes (Table 2):

1. Total number of hours: 3672. Total number of night time (21:00 to 6:00) hours: 1530
2. The study assumes that all the overheating takes place during May to September. Therefore, limiting overheating values for the monitored period are: HTM03, 50 hours over 28 °C; BSEN15251, 438 hours above category upper threshold and CIBSE, 37 night time hours over 26°C.
3. Levels 1 and 3 are physiotherapy and elderly care respectively.

The maximum WBGT varies between 21.5°C and 23.8°C while the minimum was between 13.6°C and 14.3°C. The spaces NS, MB202, CD01 and SR01 have crossed the proposed WBGT threshold of 23.0°C. The spaces SB101 and MB101 are marginally below the proposed threshold. MB202 and CD01 have one hour above WBGT of 23.0°C for daytime while NS has one hour for night time. SR01 has 9 daytime hours above WBGT of 23.0°C. Overall, 99% of the time, spaces were below WBGT of 23.0°C.

However, it should be noted that there were 9, 5, 18 and 50 hours above BSEN15251 Cat II for SB101, MB101, MB202 and SR01 respectively (Table 2). BSEN15251 says that 5% of occupied time the space could be above the category threshold, however it does not clearly state whether this exceedance could cross the next category i.e. can the Cat I exceedance cross Cat II? In the case of MB202 and SR01 there were few hours above Cat III (Figures 5 & 6). In principle, this is very critical for sick people. However, the author is of the opinion that exceedance is acceptable if it does not cause heat stress. The exceedance above Cat II in

MB202 and SR01 take place around WBGT of 23.0^{o}C. Similar trend was found in SB101 and MB101. Therefore, these exceedances were acceptable. At the same time, some may consider this as a conservative figure in terms of energy savings and carbon reduction, and speculate another 1 or 2 degrees higher as suitable value. But, definitely WBGT of 28.0^{o}C will be an extreme point for sick people. Therefore, further in depth research is required to validate an appropriate WBGT heat index for patients. However, from above findings it is clear there could be occasions, especially in the future, where there will be periods within or above Cat I but under severe heat stress conditions. Such scenarios could take place when the running mean temperature exceeds 22.0^{o} C (refer figures 1, 5 & 6 together). Similarly, one needs to look at the lower limit as well i.e. the cold stress. In essence, future research should establish heat and cold stress boundaries for sick people within the BSEN15251 Cat I adaptive band.

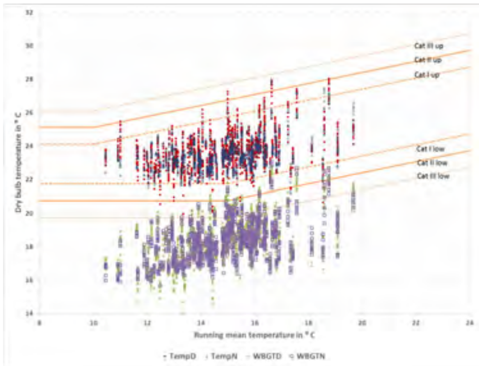

Figure 5: Internal temperature measured in MB202 is compared to BSEN15251 categories. The WBGT is also potted against corresponding running mean temperature for the purpose of comparison.

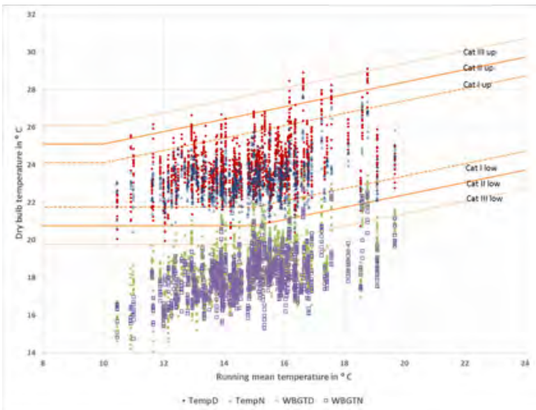

Figure 6: Internal temperature measured in SR01 is compared to BSEN15251 categories. The WBGT is also potted against corresponding running mean temperature for the purpose of comparison.

Conclusion

The study assesses the thermal performance of Runcie ward building at St Alban city hospital by applying BSEN15251 adaptive criteria and WBGT heat index. During summer 2011, the spaces were within the threshold of BSEN15251 Cat I. Overall, maximum WBGT of all the spaces were between 21.5^{o}C and 23.8^{o}C. The paper outlines the convince of using BSEN 15251 for hospital environmental performance analysis while highlighting the importance of combining WBGT heat stress index into the analysis.

In principle, the spaces should not be considered comfortable for patients if the temperature exceedance hours are within BSEN15251 threshold but the temperature values lead to maximum heat stress. This study proposes WBGT of 23.0^{o}C as the maximum heat stress for patients and establishes a case for validation of this through in depth research in the future.

The Inadvertent Consequences of a Bright Idea: An Experimental Study of Reflective Roofing

Elizabeth Grant[1], Stephen Werre[2] and Kenneth Black[1]

[1] Center for High Performance Environments, School of Architecture + Design, Virginia Polytechnic Institute and State University, Blacksburg, USA, elizabeth@vt.edu;
[2] Research & Graduate Studies, Virginia-Maryland College of Veterinary Medicine, Blacksburg, USA

Abstract: There is presently a conversation in the roofing design community about the potentially adverse effects of broadly implementing reflective white roofing on projects irrespective of climate, microclimate, or building-specific geometry. These effects include the winter heating penalty, difficulty with drying of wetted roof assemblies, and the potential for overheating of building elements atop and adjacent to white roof surfaces. The research described in this paper contributes to the literature documenting the effects of roof surface reflectivity on air temperatures above roofs and on mechanical and electrical equipment components located above them. It also documents the potential thermal consequences of installing white roofs adjacent to south- and west-facing opaque and glazed facades. An experiment was undertaken to determine the different thermal effects induced by black ethylene propylene diene monomer (EPDM) and white thermoplastic polyolefin (TPO) single-ply roof membranes in a low-slope roof application in ASHRAE Climate Zone 4. This paper presents statistically-analyzed findings from data collected on two sunny days in September and October of 2016 and compares them to results from a previous data set collected in March, May, and August of 2016. Conclusions are offered regarding the implications of these findings for architects and other designers.

Keywords: roof reflectance, cool roofs, single-ply roof membrane, building envelope, roof design

Introduction

White, reflective roofs have gained a great deal of popularity in recent years. These "cool" roofs, which are characterized by both high solar reflectance and high thermal emittance (Akbari & Konopacki, 2005), purport to reflect heat upwards and away from buildings, preventing them from overheating. They, along with vegetated roofs, have been named by green building rating systems such as the US Green Building Council's Leadership in Energy and Environmental Design (LEED) program as a preferred strategy to mitigate the urban heat island effect. Many jurisdictions have gone so far as to legislate them on new buildings and retrofit projects through adoption of ASHRAE Standard 90.1 (2013).

Within this context of widespread approval, several groups have challenged the assumption that white reflective roofs are appropriate for all building types and locations. While cool roofs are known to provide energy benefits during the cooling season, there has been debate about the extent of their negative effect in the winter months, called the "heating penalty", which is explored with tools such as the Roof Savings Calculator (Miller, New, Huang, & Erdem, 2010). Ibrahim (2013) has also argued that cool roofs may not be appropriate for colder climates because of concerns relating to condensation risk and associated biological growth. A paper by Jacobson and Ten Hoeve (2012) widely cited in roofing circles suggests through a simulation that if all existing roofs were replaced with cool roofs, there would actually be a net increase in global temperature.

Three studies have focused on the building-scale impacts of cool roofs. Ibrahim (2013) found that that air temperatures were typically higher above white TPO roofs than black EPDM roofs. Dupuis (2013) reported that air temperatures were higher above white TPO roofs versus above black EPDM roofs at a height of 30 cm, with differences negligible above that height. Lindsey et al. (2006) found that metallic conduits within 2.5 cm of a roof surface were hotter above a black roof, but above that height were hotter above a white roof.

The present study builds on previous work by the authors (Grant, Black, & Werre, 2017) and seeks to answer the following questions:

(1) What is the effect of roof membrane reflectivity on air temperatures at various heights above the roof surface?

(2) What is the effect of roof membrane reflectivity on temperatures of electrical metallic tubing (EMT) at various heights above the roof surface?

(3) What is the effect of roof membrane reflectivity on temperatures of opaque wall surfaces adjacent and perpendicular to the roof surface?

(4) What is the effect of roof membrane reflectivity on exterior and interior temperatures of glazed wall surfaces adjacent and perpendicular to the roof surface?

Methodology

An experimental study was conducted atop the roof of the Virginia-Maryland College of Veterinary Medicine in Blacksburg, Virginia, adjacent to a west-southwest-facing opaque wall and a south-southwest-facing glazed wall. 12m by 6m overlays of TPO and EPDM were adhered to the existing EPDM membrane near the opaque wall, and 6m by 6m overlays were installed next to the glazed wall. Beginning on September 30, 2015, 102 Onset S-TMB-M006 smart temperature sensors along with a weather station were installed in the study area (Figure 1). Temperature sensors were positioned inside specialized M-RSA radiation shields in the air above the membranes, and affixed to conduits above the membranes at 8, 14, 23 and 86 cm at locations marked T1. Sensors were also adhered to precast concrete wall panels and double-glazed aluminum-framed windows at 56, 86, 132 and 162 cm above the roof at locations marked T2. Three replications of temperature measurements were taken at all study locations.

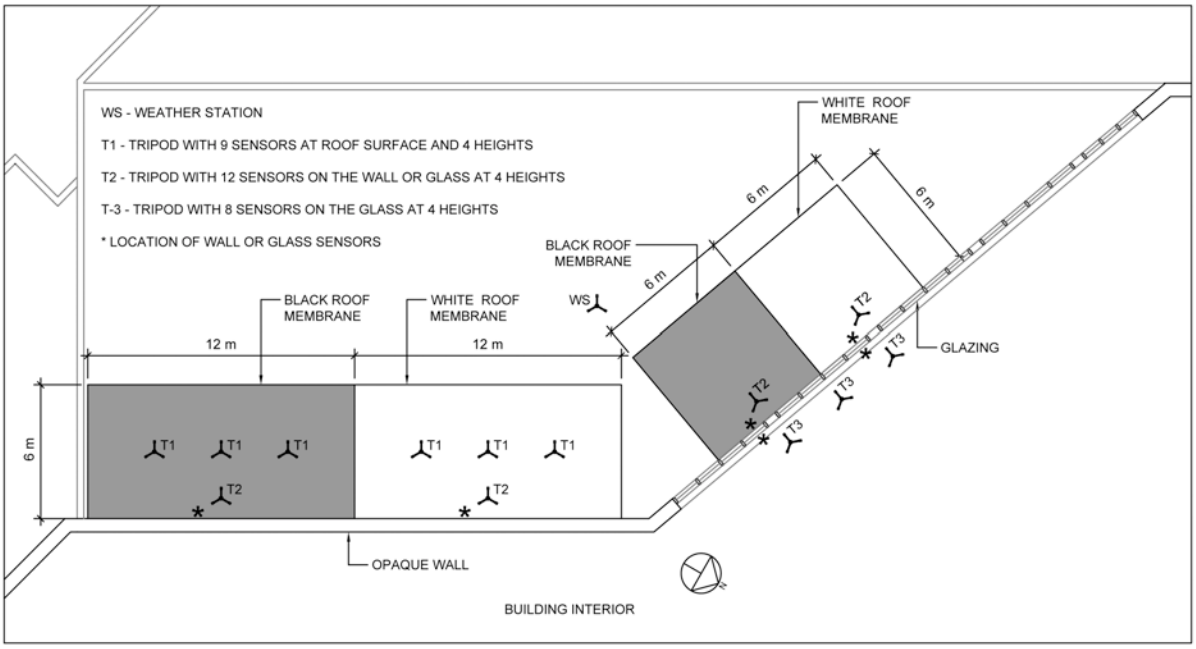

Figure 1. Diagram of experimental setup

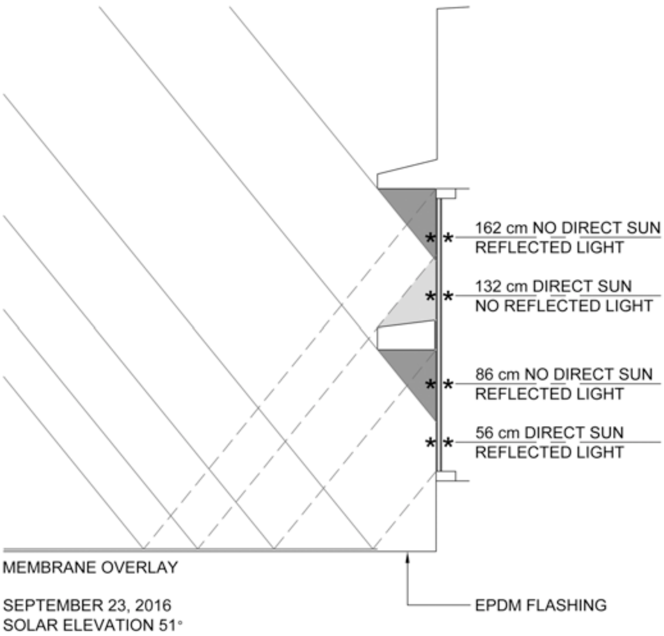

Figure 2. Geometry of direct and reflected sunlight at glazed wall sensors on September 23, 2016 at 14:00 EDT. The solar elevation on October 21 was 43 degrees.

On July 7, 2016, additional sensors were placed on the inside of the glazing to determine the effects of the two types of adjacent roof surface on glass temperatures without the potential interference of the wind. These sensors were linked to three remote data loggers shown at locations marked T3. Because the glass is protected from both direct sun and reflected light off the adjacent roof by two solar shades, and because high-angle sunlight bounces off the existing EPDM flashing rather than the membrane overlays, temperature measurements were only collected on study dates between the autumnal and vernal equinoxes when solar elevations were sufficiently low (Figure 2). Data collected from the sensors at 132 cm were not used as a solar shade blocks reflected light at this location.

Results and Discussion

Data were collected on selected dates while all mechanical equipment in the area was shut down, avoiding the potential interference of an exhaust vent discharging onto the roof near the study area. Thirty-minute temperature averages were centered on the moment when the solar azimuth was perpendicular to the opaque wall or the glazed wall as appropriate.

Table 1. Weather characteristics at times of data analysis for air, EMT and opaque wall surface temperatures, and glazing surface temperatures (highlighted in gray)

Date	Time Range	Avg. Ambient Temperature (°C)	Avg. Relative Humidity (%)	Avg. Solar Radiation (W/m^2)	Avg. Wind Speed (m/s)	Solar Azimuth (°)	Solar Elevation (°)
September 23, 2016	16:30-17:00 EDT	30	40	418	0.34	245	28
October 12, 2016	16:30-17:00 EDT	22	47	338	0.12	240	22
September 23, 2016	13:45-14:15 EDT	29	45	777	0.37	198	51
October 12, 2016	13:45-14:15 EDT	19	53	700	0.12	198	43

Statistical analysis

Normal probability plots showed that temperatures (the primary outcome) followed an approximately normal distribution. Subsequently data were summarized as means or least squares means. To test the effects of type of roof membrane at different heights in the air, at the EMT, on the opaque wall or on the glazed wall, data were analysed using mixed model analysis of variance. Type of roof and height were the fixed effects in the model for each set of analyses. Sensor within type of roof was specified as the random effect. Statistical significance was set to $P < 0.05$. All analyses were performed using SAS version 9.4 (Cary, NC, USA).

Results from September 23, 2016 are shown in Figures 3 through 6. Outcomes from October 12, 2016 are not shown due to space constraints, but will be mentioned in conjunction with the September results. Throughout, the discussion is limited to statistically significant results and rounded to the closest degree. Air temperature measurements on September 23 (Figure 3) were 1°C warmer above the EPDM membrane than the TPO at heights of 8 and 14 cm, but 1°C warmer above the TPO than the EPDM at 86 cm. On October 12, the air above the EPDM was 1°C warmer at 8 cm.

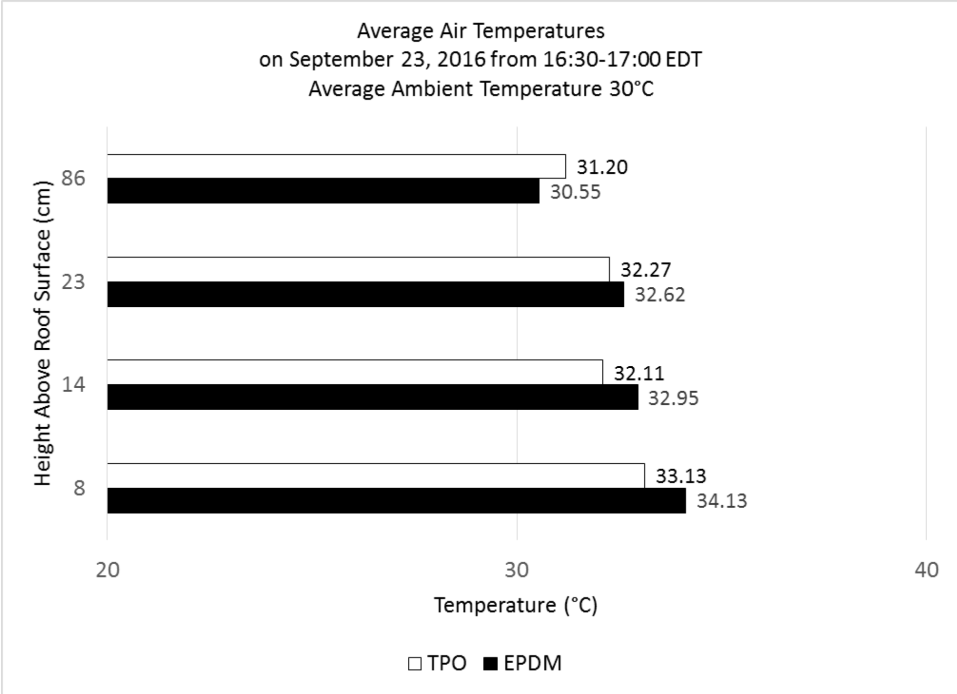

Figure 3. Average air temperatures on September 23, 2016. Differences are statistically significant at 8, 14, and 86 cm.

On September 23, the EMT was an average of 2°C warmer above the TPO surface at 8 cm (Figure 4). No significant differences were observed on October 12 at the EMT.

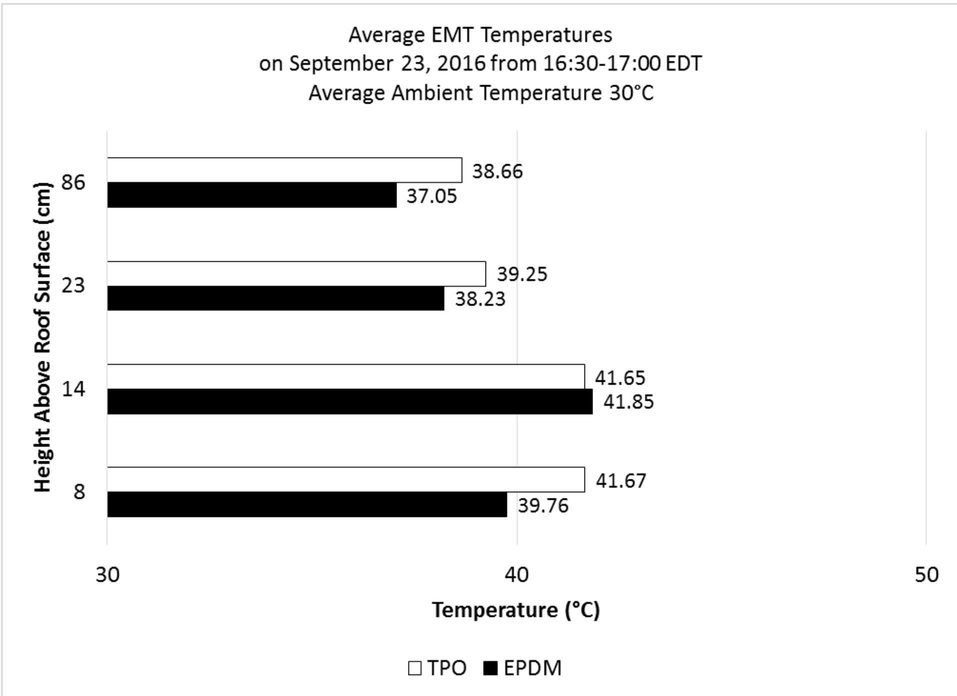

Figure 4. Average EMT temperatures on September 23, 2016. The difference is statistically significant at 8 cm.

On September 23, the opaque wall was 3°C warmer adjacent to the TPO surface than to the EPDM surface at 132 cm, and 4°C warmer at 162 cm (Figure 5). On October 12, the TPO was again warmer by 3°C at 132 cm, and by 5°C at 162 cm.

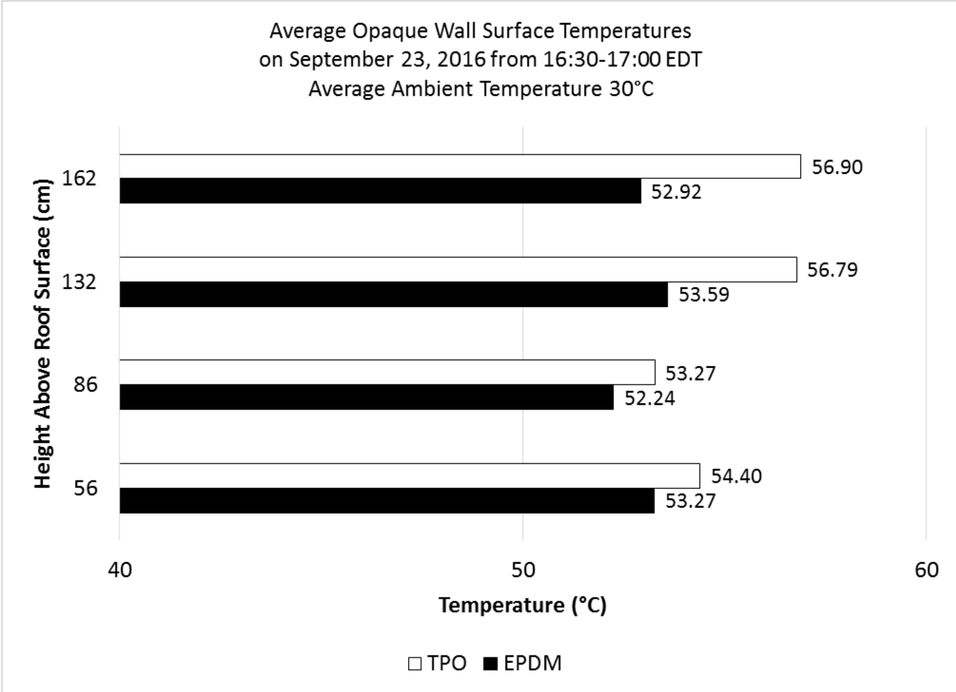

Figure 5. Average opaque wall surface temperatures on September 23, 2016. Differences are statistically significant at 132 and 162 cm.

Results at the glazing were mixed on both study days, both inside and outside the glass, with no differences deemed statistically significant on either day (Figure 6).

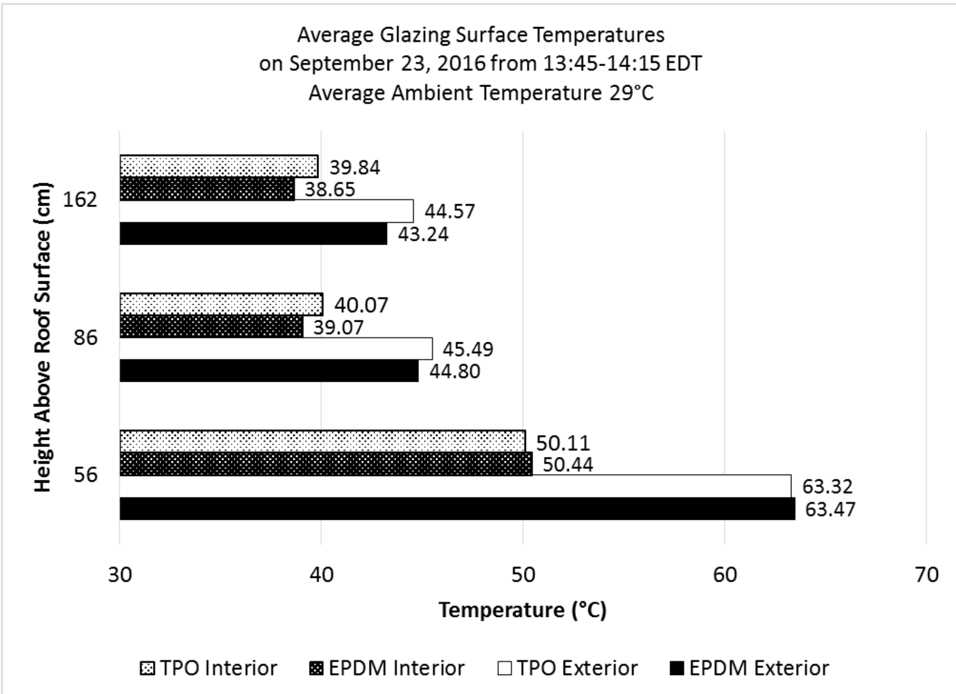

Figure 6. Average glazing surface temperatures on September 23, 2016. Differences are not statistically significant.

Conclusions

Proceeding in the order of the four research questions, conclusions are drawn with respect to the data collected on September 23 and October 12, 2016, and related to previous findings from data collected on March 8, May 24 and August 12, 2016 (Grant, Black, & Werre, 2017).

In September, air temperatures were 1°C warmer above the EPDM roof at 8 cm and 14 cm, while in October air temperatures were 1°C warmer above the EPDM roof at 8 cm. Similarly, in May and August, air temperatures were 2°C warmer above the EPDM roof at 8 cm and 14 cm. This greater difference may be due to the higher solar elevation angles (63° and 55° in May and August, respectively, versus 28° and 22° in September and October, respectively) and the higher average solar radiation during the spring and summer data collection periods (788 W/m^2 on May 24 and 811 W/m^2 on August 12) versus in the fall (418 W/m^2 on September 23 and 338 W/m^2 on October 12). The present study found that, in September, air above the TPO roof was hotter than that above the EPDM roof by 1°C at 86 cm. No other significant results were found at other heights on any of the four days tested. These findings point to the general conclusion that air above EPDM roofs is slightly warmer than air above TPO roofs in close proximity to the roof surface, but that otherwise, air temperature differences between the two are essentially negligible.

EMT temperatures were an average of 2°C warmer above the TPO surface at 8 cm on September 23. The same temperature differential was previously found at 8, 23 and 86 cm in May and at 8 cm and 86 cm in August. This replication of findings indicates that electrical metallic tubing is likely to be hotter above a TPO membrane than an EPDM membrane, and again, the weaker solar radiation in October may explain the absence of significant temperature differences on that day.

Temperatures at the opaque wall were found to be from 3°C to 5°C higher adjacent to the TPO membrane at 132 and 162 cm in September and October, which generally aligned with findings from May and August. The new data corroborate the previous conclusion that the greater reflectivity of the TPO contributed to greater warming of precast concrete panel walls.

Roof reflectivity did not have a significant effect on adjacent exterior or interior glass temperatures in the present study. On March 8, 2016, when glazing surface temperatures were previously measured at the exterior only, they were 2°C hotter adjacent to the TPO membrane. Solar altitude angles were similar on all three dates (46° in March, 51° in September and 43° in October), as were solar radiation levels (737 W/m^2 on March 8, 777 W/m^2 on September 23, and 700 W/m^2 on October 12). The wind was calm on all three dates, and the average air temperature on March 8 was 22°C, which was similar to the temperature on October 12 and much cooler than on September 23 (Table 1). The average relative humidity was only 29% on March 8 while it was 45% in September and 53% in October. While the interaction of weather variables with temperature outcomes was not statistically examined in this study, these interactions may help to explain the differing results. Additionally, while it was not studied quantitatively, it is interesting to note that the average temperature differences between roof membrane treatments found at sensors both outside and inside the glass were qualitatively similar (Figure 6), though exterior temperatures were higher at all heights, and all temperatures were highest at 56 cm where sensors were in the direct sun. These observations suggest that the exterior sensors, at least during calm wind conditions, served as adequate predictors of interior temperature differentials.

Outcomes of the study as a whole point to the need to consider the effects of light bounced off of low-slope reflective roofs toward adjacent building components, namely electrical and mechanical equipment and perpendicular vertical building surfaces. For the most part, these effects are strongest in the months when solar radiation and solar altitude are at their peaks, and the impacts of unwanted heat energy are most problematic. Architects and roof designers need to be cognizant of the influence of their roofing system selections on the environments surrounding roofs. Doing so is necessary to protect the interests of building owners and their neighbors, and, more broadly, to minimize negative impacts on climate at both the micro and macro scales.

Design to Thrive

Assessing the occurrence of summertime overheating in occupied and unoccupied low energy homes

Rajat Gupta[1], Matt Gregg[1] and Adorkor Bruce-Konuah[1]

email: rgupta@brookes.ac.uk, mgregg@brookes.ac.uk, nbruce-konuah@brookes.ac.uk

Abstract: This paper presents an empirical study to assess the occurrence and possible causes of summertime overheating in three occupied and two unoccupied low energy dwellings in the UK. All five dwellings are identical in terms of construction and location, but have different occupancy profiles and household compositions in the three occupied dwellings. An interdisciplinary approach is adopted, drawing from building science and social science methods, including monitoring of interior environmental conditions, thermal comfort diaries and interviews with residents. Temperature data from bedrooms and living rooms from the case study homes were analysed for overheating using both static and adaptive thermal comfort analyses methods. The findings suggest that summertime overheating is prevalent across both occupied and unoccupied case study dwellings, although overheating assessment using static criteria found a much higher proportion of the rooms to be overheated than the adaptive criteria. In the dwellings a common finding was that bedrooms were found to be more prone to overheating than living rooms. Since it is likely that methods used to assess overheating will be incorporated into regulations in future affecting the design of housing, it is necessary to deploy passive design strategies to prevent the overheating risk in low energy homes.

Keywords: overheating, code for sustainable homes, post occupancy evaluation, adaptive thermal comfort

Introduction

Despite the relatively mild climate of the UK, concern has increased about summertime temperatures in air-tight low energy houses due to the effects of high temperatures on occupant health (Armstrong et al., 2010). There is in fact growing evidence of overheating in homes, particularly in newer homes built to satisfy more demanding standards of energy efficiency (ZCH, no date). The term overheating is used to describe when temperatures make building occupants uncomfortable or heat stressed. With consecutive days of hot weather (including warmer than average nights), internal temperatures in some homes, particularly newer efficient homes, can start to exceed external temperatures and may no longer provide protection from the heat. These conditions can cause discomfort and heat-related effects on health (Armstrong et al., 2010, Hajat et al., 2014).

Overheating can occur in homes as a result of a number of causes acting alone or in combination. These can include heat gain from high external temperatures, direct solar gain on the exterior surface or penetrating glazing, and internal heat gains. Home characteristics such as dark surface materials, rooms in the roof, skylights, inability to ventilate due to location, predominately dark hard surface surroundings, single aspect flats on upper floors, and orientation that allows late solar gain in windows can all contribute to overheating (Gupta and Gregg, 2012). For more vulnerable occupants, such as infants, the elderly or sick, the risk of severe heat stress, including potentially fatal heat stroke, is greater. To make matters worse, these people are typically at home for most of the day and exposed to peak day temperatures, unlike those who go out to work. The cause of overheating is complex and not a simple measure of maximum temperatures; therefore, long continuous periods of above-average indoor temperatures in homes are used to evaluate this condition.

Much research has set out to establish the risk of overheating by simulating the current and future risk in older dwellings (Gupta and Gregg, 2013) and in newer dwellings (McLeod et al., 2013). A number of studies have also demonstrated present-day monitored overheating or summer 'discomfort' in existing dwellings and newly built dwellings (Sameni et al., 2015) in the UK and abroad, in Denmark (Larsen and Jensen, 2011), Sweden (Ruud et al., 2005) and Estonia (Maivel et al., 2015). Within these studies the propensity to overheat is much greater in newer dwellings, e.g. passivhaus designed dwellings, and particularly in flats. It is important to note that overheating is defined slightly differently from region to region, however, there is roughly an agreement that surpassing hours at 26-27^{o}C is problematic.

To contribute to this body of knowledge, the objective of this study is to investigate the extent of overheating in both occupied and unoccupied dwellings in York, England. The homes are newly-built within the past few years and are built to the highest energy efficiency levels under the UK standards current at the time, i.e. Code for Sustainable Homes Level 4. An interdisciplinary approach is adopted, drawing from building science and social science methods, including monitoring of temperature and relative humidity in the living room and principal bedrooms over August and September 2016, dwelling surveys, thermal comfort diaries and interviews with residents.

Methodology

The study involved five dwellings, three occupied dwellings (H1 – H3) and two unoccupied dwellings which are show-homes for the development (SH1 & SH2). All five dwellings are identical in terms of construction and location, but have different orientations and the three occupied dwellings have different occupancy compositions. Table 1 lists some dwelling characteristics for the homes.

Table 1. Summary of characteristics of the case study dwellings
(N/A indicates where some data were unavailable; EPC = Energy Performance Certificate)

	H1	H2	H3	SH1	SH2
Built form	Detached	Mid-terrace	Semi-detached	Detached	Mid-terrace
Front orientation	East (slightly N)	North (slightly E)	South (slightly W)	East (slightly N)	South (slightly E)
Total floor area	84 m^2	118 m^2	93 m^2	N/A	N/A
Occupants	1 adult	2 adults, 1 child	2 adults, 2 children	No occupants	No occupants
EPC rating	B (81)	B (85)	B (83)	B	B
Air permeability	3.8 $m^3/h.m^2$	3.7 $m^3/h.m^2$	3.8 $m^3/h.m^2$	N/A	N/A

Overheating assessment methods

For the overheating assessment, two methodologies were used. These are the *static method* and the *adaptive method*. The static method defines overheating as when in living areas, 1% of occupied hours is >28°C and in bedrooms, 1% of occupied hours >26°C

(Humphreys and Nicol, 2006). The adaptive method is a dynamic threshold based on changes in external temperature which also includes levels of occupant sensitivity. The adaptive method defines overheating as when two of the following three criteria are failed: 1) hours of exceedance, 2) daily weighted exceedance, and 3) upper limit temperature (Nicol and Spires, 2013).

Quantitative data collection and assumptions

The evaluation of overheating risk employed internal and external temperature readings on a quarter-hourly basis using internal and external Onset HOBOs and occupancy hours of the monitored spaces. The monitoring of living rooms and bedrooms of all dwellings took place from August 11th – November 24th 2016. This provided partial data on overheating for the summer; specifically, from August 11th – September 30th. In addition to interior spaces, two exterior data loggers were placed outside of H1 and SH1. The exterior (micro-climate) data were found to follow the same pattern; however, a mean was taken between the two loggers to represent the external condition. Actual occupancy details were not collected, however, assumed occupancy schedules are applied for analysis. Consistency across all dwellings in this way assists in comparing the unoccupied dwellings with the occupied dwellings. It is likely; however, that because there is a very young child living in H2, the occupancy varies from this general assumption. The occupancy hours used were 6:00 – 8:00 and 18:00 – 22:00 for the living rooms and 22:00 – 6:00 for the bedrooms.

Qualitative data collection

For H1 & H2, household surveys, interviews and a thermal comfort diary (H2 only) were employed to collect information on occupants' comfort perception, lifestyle, behaviour, use of windows, appliances, etc.

Table 2. Interview summary

	H1	H2
Comfort in summer	Summer is comfortable	Hot throughout the house, main bedroom most uncomfortable
Most occupied space	Living room	No comment
Method to keep cool	Open windows at about 25°C (uses digital thermostat to observe interior temperature), shorts and t-shirt, cool drinks	Open windows and trickle vents to cool down the space
Window behaviour	Open windows in all rooms daily when home / do not leave them open when away from home, window trickle vents left open in summer	Windows opened whenever necessary in all rooms; however, living room and second bedroom windows are closed overnight
Ventilation or fans	No ventilation units or fans	No ventilation units or fans
Interior doors	Always left open	Always left open
Blinds	Occasionally used	Occasionally used

Results

Table 3 shows the overall findings with relation to the overheating in the dwellings. All dwellings have some level of overheating according to the static method; however, there were no temperature readings >28°C. No dwellings overheat according to the adaptive method (which requires two criteria to fail). It is important to consider that the adaptive method has been developed in and for non-domestic buildings, though this does not explain its lower sensitivity. However, it is useful to evaluate as it considers more variables and theorises an adaptive response from occupants. Only some bedrooms overheated during (expected) occupied hours of the bedrooms. In the occupied dwellings, only the second bedroom overheats in all three cases. In the show-homes both bedrooms overheat. It is theorised that bedroom 1 in the occupied dwellings do not overheat because the adult(s) (prime occupant) control the windows to alleviate overheating in the space. The antithesis of this is potentially why only the second bedrooms overheat. As the show-homes are not occupied during bedroom occupancy hours, windows are not open; this is why overheating occurs in both bedrooms of two of the show-homes.

Table 3. Overheating results from 11 August – 30 September
(N = north, E = east, W = west, S = south, +sky = skylight, OH = overheating)

	Room	Window orientation	Static method	Adaptive method (failed)	Occupied hours between 26 – 28°C
H1	Living room	NE / SW	0%	-	0%
	Bedroom 1	NE	0%	-	0%
	Bedroom 2	**SW**	**4% - OH**	-	**7%**
H2	Living room	S	0%	-	**3%**
	Bedroom 1	N / S +sky	0%	-	0%
	Bedroom 2	**S**	**2% - OH**	-	**4%**
H3	Living room	SW / NE	0%	-	0%
	Bedroom 1	NE	0%	-	**1%**
	Bedroom 2	**SW**	**3% - OH**	-	**4%**
SH1	Living room	E / W	0%	-	0%
	Bedroom 1	**W**	**6% - OH**	Criterion 2	**8%**
	Bedroom 2	**E**	**14% - OH**	Criterion 2	**13%**
SH2	Living room	N	0%	-	0%
	Bedroom 1	**S / N +sky**	**2% - OH**	-	**7%**
	Bedroom 2	**S**	**4% - OH**	-	**2%**

The H1 occupant considers the summer conditions in the house comfortable and overheating results reflect this. As there is only one occupant in H1, it is probable that the occupant does not use the 2nd bedroom or experience the overheating in that space. In contrast, the responses from H2 show that the occupant finds it hot throughout the house with the main bedroom, as most uncomfortable. Interestingly, it is the main bedroom which has the highest proportion of lower temperatures than the other rooms; this however, could be the perception before opening windows to ventilate, wherein the measurements show the impact of opened windows. Survey responses may also indicate the thermal comfort opinion of the occupants between these two homes, whereas: H1 begins the heating season in October with a heating set-point of 21-22°C and H2 begins the heating season in November with a heating set-point of 18°C. These findings may suggest that the occupant of H2 has a lower tolerance for higher temperatures.

Thermal comfort diary assessment

Thermal comfort diaries were only completed by H2. The results for the actual mean vote (AMV) and predicted mean vote (PMV) corroborate the previous assumption, that the occupant of H2 may be more sensitive to warmer temperatures than other occupants. This can be seen in figure 1, where the AMV is essentially a two point shift above the PMV.

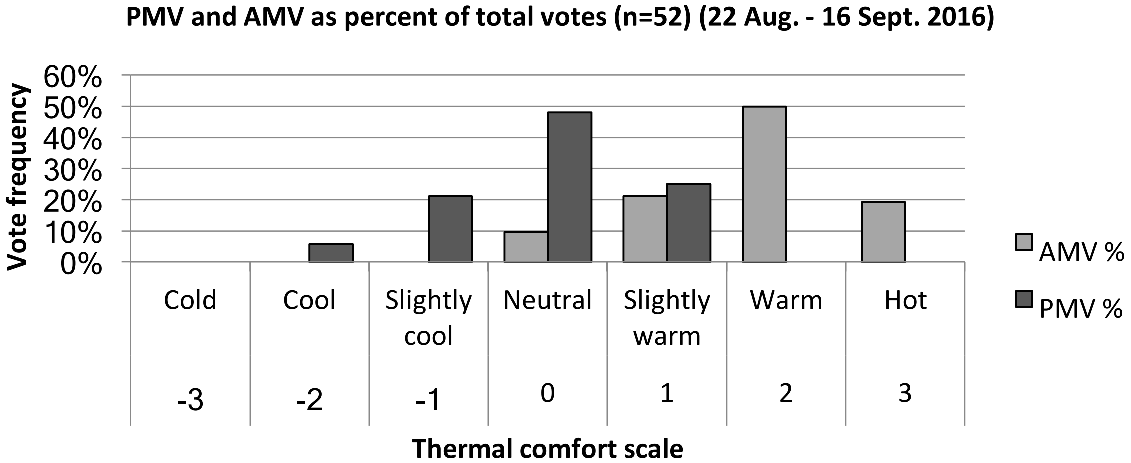

Figure 1. PMV and AMV percentage votes.

Overheating factors

Occupied vs. unoccupied

Neither dwelling type overheats in an overall sense more than the other purely due to occupancy status. This can be seen by comparing SH2 to the occupied dwellings; however, the lack of active ventilating in the SHs is apparent in the bedrooms. Figure 2 focuses on the evening hours to further investigate the difference between the occupied and unoccupied houses. The intent is to observe the dwellings during the 7pm – 7am period, when it is theorised that the show-homes are sealed and unoccupied. As expected, the show homes demonstrate steadier temperature readings due to lack of occupants. A difference between occupied and unoccupied dwellings is difficult to see in the living room, as most dwellings appear to retain similar temperatures and patterns of change during the periods of focus. The bedrooms during this period indicate a different pattern. The occupied dwellings for the most part, appear to be ventilating at night as the temperatures are 1-3°C lower than the show-homes. The tendency for H2 is to exhibit sharp peaks of overheating in response to high temperatures. These sharp peaks were most likely not experienced in the bedrooms as they tend to happen during mid-day when external temperatures were highest and bedrooms are not occupied. According to the interviews, though windows were often used to cool down spaces, windows were not left open when rooms (or the dwelling) were not occupied. SH1, in contrast, retained a steady higher internal temperature though without the sharpness of the peaks. The consistency of the higher temperatures is likely due to the lack of window opening in the show home, particularly in the evening. The remaining dwellings whether occupied or not, appeared to demonstrate a lower level of sensitivity to the external temperature spikes. This may be due to orientation or different space management. Though the dwellings demonstrated the same responsive patterns, overall the temperatures for all dwellings were roughly 2°C cooler in the living rooms than in the bedrooms.

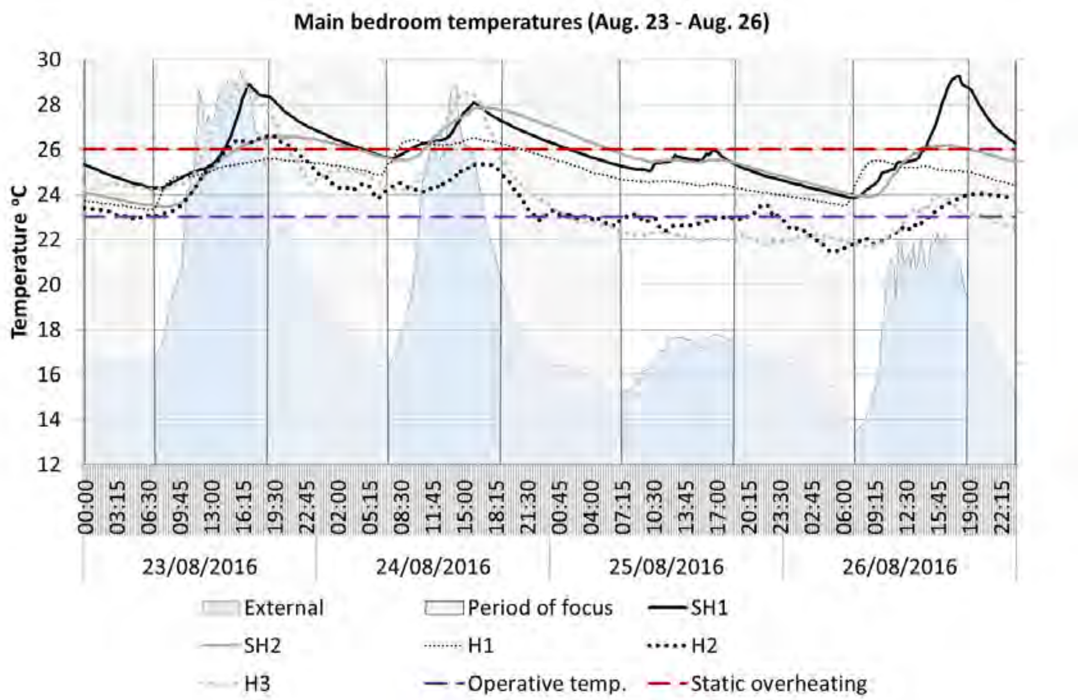

Figure 2. Occupied vs. unoccupied dwelling temperatures in bedroom 1

Orientation

Considering the orientation of the rooms, table 3 demonstrates the following. There is greater tendency to overheat in south, west and east facing rooms. Excluding the influence of occupants, it might be concluded that dwellings with E/W orientation (e.g. SH1) have a much greater tendency to overheat than N/S.

Different occupancy hours

Those most vulnerable to overheating, such as the elderly or sick, are more likely to occupy their homes during daytime, when the heat is most intense. Whereas in the preceding analysis, occupied hours are assumed to be generalized, the following explores a scenario where the dwellings are occupied full time. Figure 3 shows a side-by-side comparison of total hours and occupied hours (the hours assumed in the methodology above).

At first, it is expected that in most cases, total hours will show greater overheating than the occupied hours due to the higher daytime temperature and direct solar gain. This does appear to be true for a majority of the spaces, especially the 2nd bedroom in H2 and the 1st bedroom in the SH1. Interestingly however, bedroom 2 in H3 has a higher level of overheating during the generalized occupied hours as opposed to the total hours. The fact that this space is southwest orientated could help to explain this; that is, most of the overheating occurs in the late afternoon / evening hours, as the sun sets, closer to occupancy time of the bedroom. Also in reality, actual presence of people (H3 has most occupants) in the space can add to the internal heat gain of the room, thereby, increasing the actual measured temperature of the space during assumed occupancy hours.

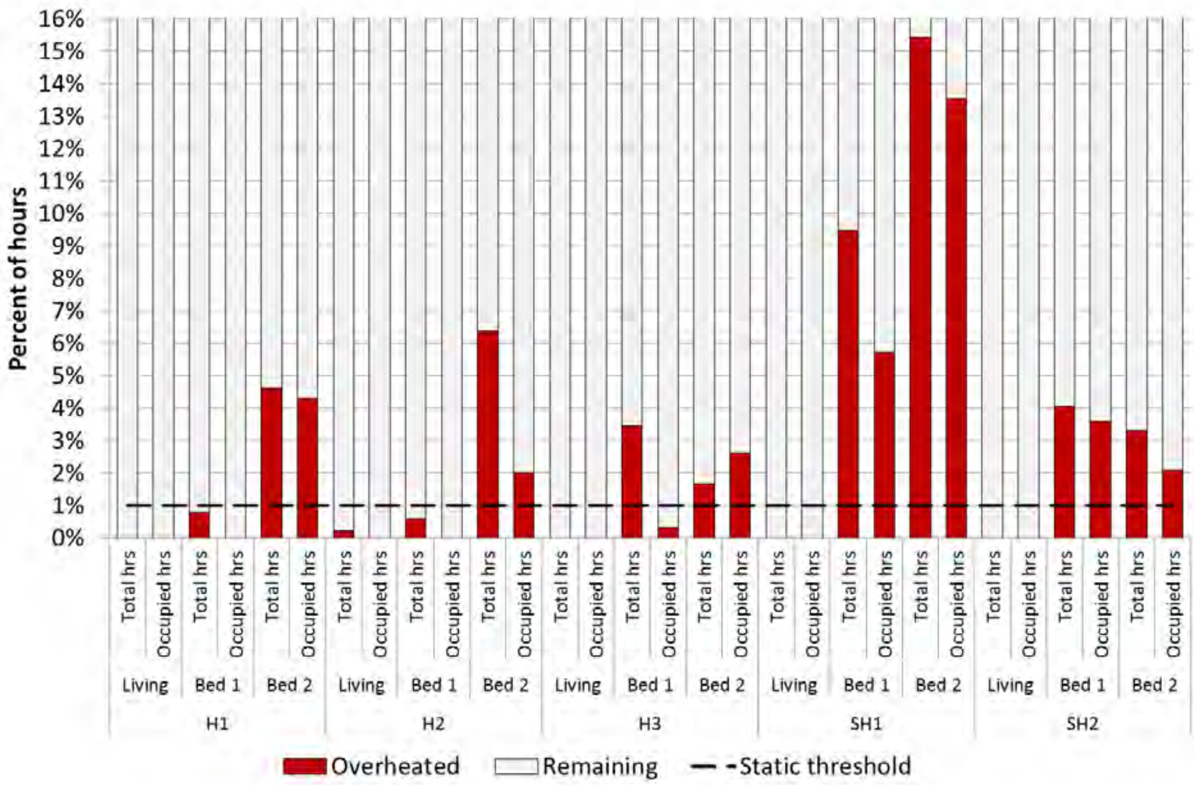

Figure **3**. Percent of hours overheated for all rooms

Concluding discussion

This study is based on data collected between August and November 2016 in five dwellings located in a new low-energy development in York, England. Analysis of the results showed that in general, overheating is prevalent in both occupied and un-occupied homes. Bedrooms, particularly those facing south, east or west, more specifically the upper levels of the dwellings, are more prone to overheating than living rooms. The living rooms in contrast, are large, open, and can be cross-ventilated and potentially well managed to avoid the risk of overheating. One contributing attribute is the open plan where the living room (or 'lounge') is shared with other spaces. In addition, in the two dwellings interviewed, the normal practice was to always leave the door open from the living space to the hall and stairs. This allows heat to move more freely and to not remain trapped in the living area. The movement of heat into the upper levels may also contribute to the higher propensity of overheating in the upper level rooms. It is also expected that this openness of all doors is prominent in the show-homes to give visitors a welcoming feeling.

SH1, an unoccupied dwelling, exhibited significant overheating results. The presence of occupancy appears to most obviously affect the overheating potential in bedrooms, where window ventilation is essential to alleviating or reducing overheating potential. No ventilation or fans were found among the interviewed occupants; however, the frequent use of windows in these dwellings has helped mitigate overheating to some degree in the monitored spaces. In most cases, where rooms are occupied all day, the overheating potential is higher. One exception to this is in southwest orientated bedrooms. These bedrooms tend to have overheating hours concentrated in the evening and at night.

It important to note that design has a heavy influence on overheating and given the findings, adaptive measures would definitely have their place in current new-build. Passive design strategies such as designed in shading and light coloured surfaces, etc., evaluated elsewhere (Porritt et al., 2012, Gupta and Gregg, 2013, McLeod et al., 2013), continually prove effective when tested in the literature. It is however, also vital to engage with occupant about managing heat during hot weather. Occupant behaviour is highly important when affecting the level of overheating. This is apparent in the assessment of both unoccupied homes and in second bedrooms of occupied homes where there is less or no occupant use of windows. Though SH1's temperature profile follows that of SH2, the internal temperatures are consistently 2^{o}C higher in the bedrooms in the summer. The greater level of overheating in SH1 cannot be explained without further investigation into management of the space.

Abstract: Heat-related morbidity and mortality is anticipated to increase as climatic change induced overheating become increasingly common. The development of building-specific predictive models has the potential to alert occupants and emergency services to the severity of impending risks. This research aims to evaluate the implementation of a newly developed time series model for overheating prediction. Since risk forecasting is contingent upon the accuracy of the model at different future time steps, the sensitivity of model outputs to the uncertainty in the data inputs needs to be understood. Internal and external climatic variables were monitored in an unoccupied domestic dwelling in order to evaluate the empirical model's predictive accuracy. The uncertainty related to the proximity of external weather stations was evaluated using data taken from four nearby weather stations and further bespoke data sets derived by interpolation. The results confirmed the overall accuracy of the newly developed time series predictive model, whilst highlighting the benefits of climatic data interpolation in reducing predictive uncertainties. The empirically derived modelling approach showed a low variance to the actual temperature evolution over a seven-day predictive period, pointing to its validity as a robust model for the prediction of future overheating risks.

Keywords: Overheating, Time Series Analysis Method, Uncertainty, Meteorological data, Spatial interpolation

Introduction

Context

Time series data, spanning more than a century, illustrates that the most populous regions on Earth are experiencing progressively hotter annual temperatures (NASA & GISS, 2017). Warmer than average summers coupled with an increased frequency of extreme heat wave events (Jenkins et al., 2008) pose obvious risk factors in relation to overheating in the built environment. Events such as the 2003 heat wave, which is reported to have resulted in over 2000 heat-related deaths in the UK, are predicted to become increasingly common (Armstrong et al., 2011; Hajat et al., 2006; Rooney et al., 1998; Wright et al., 2005).

Active cooling systems remain relatively uncommon in UK homes but their uptake is projected to increase rapidly (Pathan et al., 2008). O'Neill et al. (2005) point out that unless extensively subsidised however, the ownership of cooling systems is likely to reflect socioeconomic inequalities thereby rendering disadvantaged households more vulnerable. Furthermore widespread power outages in North America and Australia during heat waves have highlighted the risks associated with reliance upon active cooling systems at times of grid overload (Ostro et al., 2010).

Despite strong epidemiological correlations between elevated external temperatures and increased risks of heat-related morbidity and mortality (Armstrong et al., 2011; Vardoulakis & Heaviside, 2012) relatively little is known about internal temperature evolution under these conditions. Real-time predictive overheating models are needed in order to understand when critical thresholds are likely to be breached in specific buildings and to warn occupants and facility managers when health-endangering environmental conditions are anticipated to occur.

Background – the development of time series models and indoor temperature prediction

Studies related to overheating in dwellings, conducted in recent years, can be broadly categorised as: those that involved measuring internal temperatures in order to identify and quantify the risk of overheating (Beizaee et al., 2013; McLeod and Swainson, 2017; Pathan et al., 2017), those that involved dynamic thermal simulation modelling to assess the current and future risk of overheating in dwellings (McLeod et at., 2013; Mavrogianni et al., 2012); and those that have used empirical data to construct predictive models in order to assess overheating both spatially and temporally (Mlakar & Strancar, 2011; Mirzaei et al., 2012). Modelling methods that make use of measurements to explain the variation in the data present advantages over other modelling methods that typically entail large numbers of assumptions and thereby elevate the level of uncertainty in the results. The Time Series Analysis Method (TSAM) has been successfully used in diverse fields such as economics, geophysics, control engineering and meteorology to describe, explain, predict and control processes (Chatfield, 1996). Here the descriptive TSAM is applied to room temperature data. The advantage of TSAM over other black box approaches (such as artificial neural networks, autoregressive models, multiple linear regression models, distributed lag models, transfer functions etc.) is that it is an exploratory technique that allows a clear understanding of the causality of internal temperatures.

Methodology

An empirical TSAM model was used to predict the hourly internal temperature evolution in the test house, in relation to different sources of meteorological data. The data measured on-site were compared with the meteorological data and the modelling predictions in order to assess the effects of the proximity of weather stations and interpolation of weather data on the models' predictive accuracy.

Time series model

This paper utilises a newly developed Internal Trend and Cyclical Component (ITCC) Model, which is based on the descriptive TSAM approach. The principle aim of the descriptive TSAM is to decompose the variation in the series into individual components (Trend, Cyclical variation) that can be described and modelled independently (Fleming & Nellis, 1994). The definition of these components is specific to the dataset used in the analysis. In this work, the components *trend* and *cyclical variation* are defined in relation to the internal air temperature profiles in homes. The *trend* represents the changes in the series from day to day over the (52 days) monitoring period which encompasses the daily variation. Whilst the *cyclical variation* encompasses the diurnal fluctuations of internal temperatures (the variation within a 24h period). These concepts have their origins in the formative work of Chatfield (Chatfield, 1996) and Kendal & Ord (1990).

The detailed methodology describing the ITCC model can be found in Oraiopoulos et al. (2017). The ITCC model is the result of joining the *trend* and the *cyclical* component models together and is given below:

$$\boldsymbol{\theta'_{in,t} = i + g \times \left[(1-\alpha) \times \left(\overline{\theta}_{ex,d} + \alpha\,\overline{\theta}_{ex,d-1} + .. + \alpha^{m}\,\overline{\theta}_{ex,d-m}\right)\right] + A \times C_{ex,\varphi_e} + B \times C_{s,\varphi_s} - \gamma}$$

Where:

$\theta'_{in,t}$	hourly modelled internal air temperature
i	y-axis intercept of the line of best fit for the correlation between the daily mean internal temperature and the exponentially weighted moving average of the daily means external air temperatures
g	gradient of the line of best fit for the correlation between the daily mean internal air temperature and the exponentially weighted moving average of the daily means of the external air temperatures
α	constant between 0.00 and 1.00 (BS EN 15251, 2007)
$\overline{\theta}_{ex,d}$	daily mean of the external air temperature of the current day
$\overline{\theta}_{ex,d-1}$	daily mean of the external air temperature of the previous day
m	total number of previous days used in the formula for the exponentially weighted moving average of the daily mean of the external air temperature
$\overline{\theta}_{ex,d-m}$	daily mean of the external air temperature of the m^{th} previous day
A	numerical coefficient of the cyclical component of the external air temperature
C_{ex,φ_e}	cyclical component of the external air temperature
φ_e	phase of the cyclical component of the external air temperature
B	numerical coefficient of the cyclical component of the solar irradiation
C_{s,φ_s}	cyclical component of the solar irradiation
φ_s	phase of the cyclical component of the solar irradiation
γ	Constant

Test house and empirical data monitoring

The data used in this study was collected from one of two unoccupied, semi-detached test houses located in Mountsorrel, Leicestershire. The experiment was undertaken, and all the data collected, by other researchers as part of a different research project (see acknowledgements), during the summer of 2016. The houses are typical, solid brick walled, family homes dating from the 1910s which have subsequently undergone some refurbishment.

Figure 1. Front elevation (facing S-SE) of the test houses (the left hand house was used in this study).

Weather and environmental data

Internal monitored data

Internal temperature data was collected in the test house from 9 June to 31 July (2016) using a U-type thermistor (accuracy = ±0.2°C) installed in the middle of each room (with an aluminium foil shielding to mitigate radiant heat influences). Logging was carried out at five-minute intervals. During the tests, the windows remained closed, with blinds and trickle vents open. Synthetic occupancy was created, simulating the occupancy profile and appliance usage of an elderly couple (staying at home the whole day): living room (occupied from 08:30 to 23:00) and bedroom (occupied from 23:00 to 07:30).

External weather data – measured on site

External temperatures were monitored on site during the monitoring period (from 9 June to 31 July) using a shielded U-type thermistor (accuracy = ±0.2°C). The sensor was mounted in a shaded location on the North side of the house. The data was logged at the same interval as the internal sensors (five-minute intervals).

External weather data – third party sources

Hourly weather data was gathered from two different sources: Loughborough University (LU) meteorological station and the Centre for Environmental Data Analysis (CEDA, n.d.). Through the CEDA platform, it was possible to access data from the Met Office Integrated Data Archive System (MIDAS): UK Hourly Weather Observation Data. Three MIDAS stations in the proximity of the test house were selected for this study: Sutton Bonington (SB), Coundon Coventry (CC) and Wittering (WIT). The locations of the test house, meteorological stations and their distances from the site are shown on the map in Figure 2.

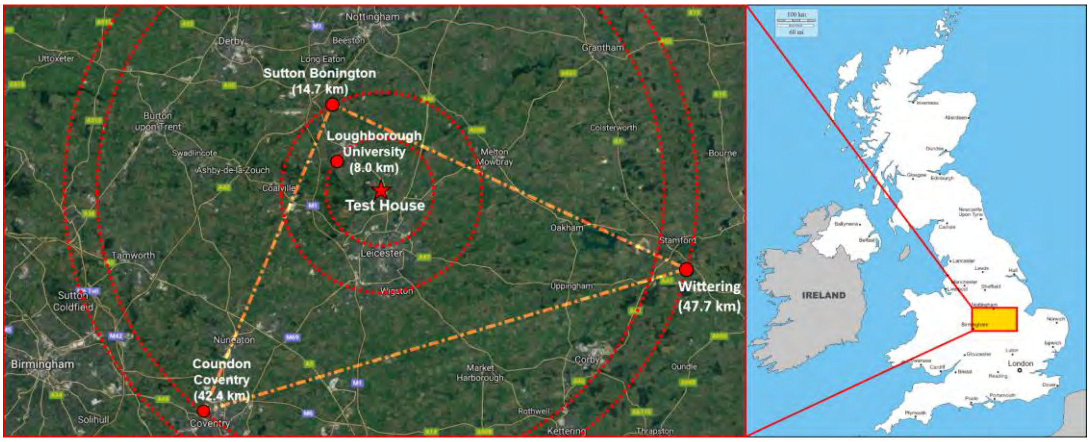

Figure 2. Locations of the test house (star) and meteorological stations (circles) on the map.

External weather data – spatial interpolation

For the spatial interpolation of meteorological data, the method adopted by the Joint Research Centre (JRC) of the European Commission was selected (Voet, Diepen, & Voshaar, 1994). This method was chosen due to its proven reliability and ease of application. Voet et al. (1994) demonstrated that with the averaging of data from optimally sited meteorological stations it is possible to obtain satisfactory results without the use of weighting coefficients or other more complex interpolation methods such as splines, kriging etc. (Franchello, 2005; Hofstra et al., 2008). Although the JRC method was originally developed for interpolating daily meteorological data, in this study the same criteria were adopted for spatial interpolation at an hourly resolution. As suggested by Voet et al. (1994), the optimal number of three weather stations for interpolation was used in this study. The results of interpolation using two meteorological stations are also shown for reference. In this case study, no algorithm was adopted for their selection, but the three closest meteorological stations (triangulating the site) with complete hourly temperature and solar radiation data were chosen. The JRC method foresees that in order to improve the accuracy of the data, the air temperature and has to be corrected to take into account the altitude difference. For every 100m increase in altitude (relative to the site) the temperature was reduced by 0.6°C. To interpolate the data, the corrected station data was then simply averaged.

Overheating

Various criteria have been developed to assess when rooms in a dwelling might be considered as overheated. These include CIBSE static criteria which suggest that the operative temperature (OT) in living rooms should not exceed 28^{o}C for more than 1% of occupied hours in the year, for bedrooms the criterion is 1% of hours over 26^{o}C (CIBSE, 2006). More recently a move towards the use of adaptive overheating thresholds, which vary according to the outdoor temperature, have gained popularity for the assessment of risks in free running (i.e. naturally ventilated) buildings (CIBSE, 2013). In terms of legislation The Health and Safety Rating System (HHSRS) Operating Guidance states that when temperatures exceed 25°C there is a significant increase in the risk of strokes and mortality (HHSRS, 2004). Currently the HHSRS provides the only statutory definition of 'overheating' risks in relation to morbidity and mortality in UK residential properties (McLeod and Swainson, 2017).

Uncertainties analysis

As stated by Hopfe et al (2013), "in the assessment of the performance of a building, it is imprudent to take deterministic values for the input parameters". Moreover, to generate robust predictions, analysis of the measurement uncertainties is required (Buswell, 2013). In order to take measurement uncertainties into account, they were evaluated in accordance with good practice guidance developed by the National Physics Laboratory (Bell, 2001). Using type A (repeated readings) and type B (manufacturer specifications – accuracy) uncertainties for the air temperature measurements were calculated to be ±0.10°C and ±0.12°C respectively, producing a combined standard uncertainty of ±0.15°C. Considering a coverage factor of k=2, the resulting extended standard uncertainty is ±0.30°C, with a confidence interval of 95%.

Model evaluation

The ITCC time series model was trained from 9 June to 16 July, and produced hourly predictions from 17 to 31 July. Since the external air temperature was also monitored on-site, in order to assess the data from the various meteorological stations and the interpolated data, the RMSE between the measured and adopted meteorological data was used as a dispersion metric, as used for example by (Voet et al., 1994). The RMSE was also used to evaluate the errors between predicted and measured internal temperatures in the living room and bedroom. To check the influence that measurement uncertainty has on the results, the RMSE and R^2 were also calculated on the measurement uncertainty limits as an adjunct to using the deterministic values. These values represent the minimum errors and the maximum explanatory power of the model (respectively), which could be achieved when considering the uncertainty in the measurements. Since the model was predicting reliably for the period up to seven days, the errors between the predicted and modelled data were evaluated only for the first week of predictions.

Results and Analysis

Modelling inputs – weather data

As shown in figure 3, when the meteorological data is taken from a single station, the RMSE ranges between 0.93 and 1.32°C, compared to the site values. The RMSE is significant also for the meteorological stations that are very close to the test house. It has to be mentioned that the errors for the MIDAS stations are at certain hours very large, suggesting that the air temperatures are varying more quickly than at the analysed site. This can be easily explained due to the locations of the MIDAS stations, which are usually located in open field, whilst the test house is located in the middle of a small town. However, when the meteorological data is interpolated, the RMSE drops significantly. The best results were obtained using triangulation (interpolation of three meteorological stations), with the RMSE ranging between 0.47 and 0.8°C. This indicates that using triangulation it is possible to improve the input data by 14-64% relative to using a single 'near neighbour' weather station.

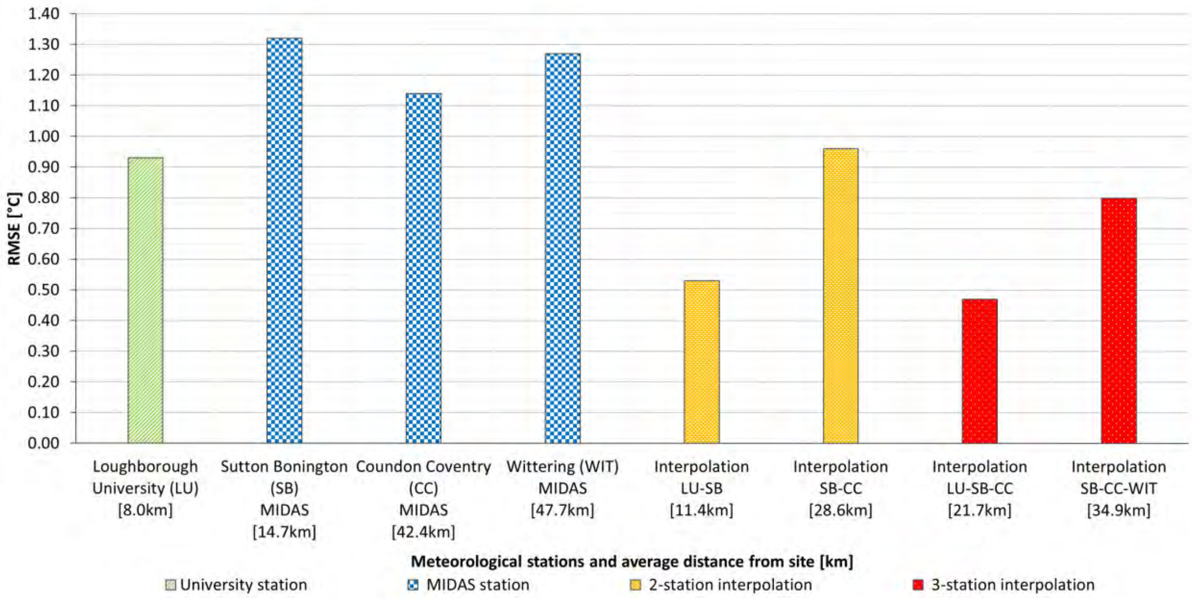

Figure 3. RMSE of the meteorological data against the external temperatures measured on site.

Modelling outputs – hourly predictions

Figure 4 illustrates how the model was trained on 38 days of data to predict the internal temperature evolution for the following 14 days. Due to the increasing inaccuracy of forecasts after day 7, only the first week of predictions was considered in this study.

Overall, the model showed an excellent explanatory power for the first week of predictions for all the meteorological data, with an R2 of 0.876-0.896 for the living room (LR), and 0.943-0.952 for the bedroom (BR). Considering the measurement uncertainty, the explanatory power might be even higher with the potential maximum of 0.937-0.951 (LR) and 0.951-0.960 (BR). As shown in figure 5, taking the data from the closest meteorological station does not guarantee that the most accurate prediction will be achieved. Indeed, in this case, the predicted data showed that while the largest RMSE was obtained from the two closest stations (LU and SB), the lowest RMSE (CC and WIT) was obtained from the two furthest stations. Whilst the interpolation did not show significant reductions in the RMSE of predictions, it is evident that with its use the errors show a greatly reduced variability (Figures 3 and 5), thereby reducing the uncertainty of the data that are used for the model.

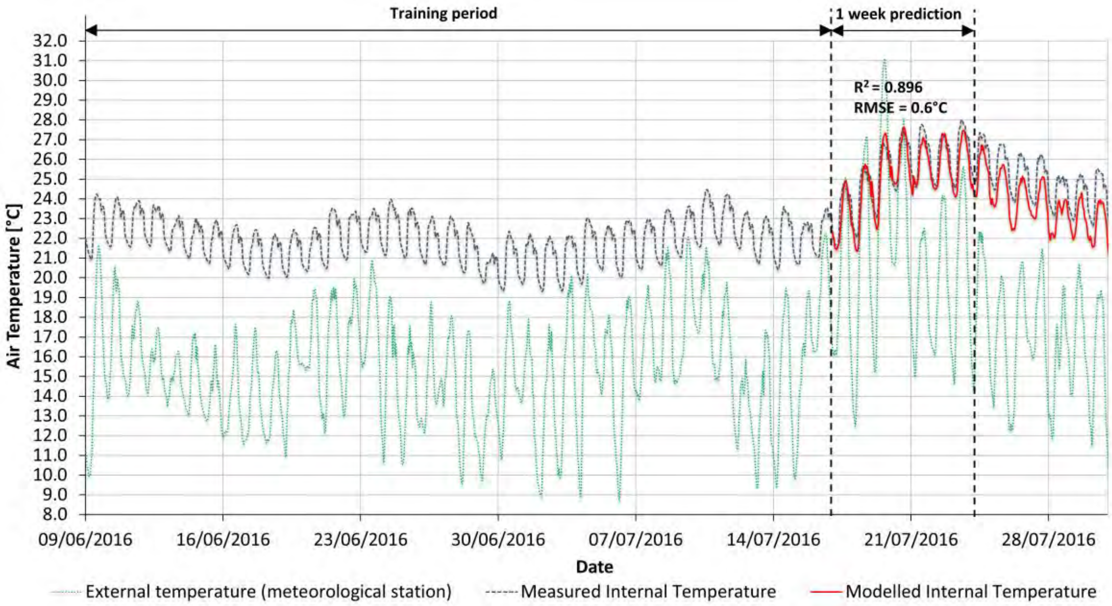

Figure 4. Measured and modelled temperatures – Example showing model dry bulb temperature predictions for the living room using meteorological interpolation (SB-CC-WIT)

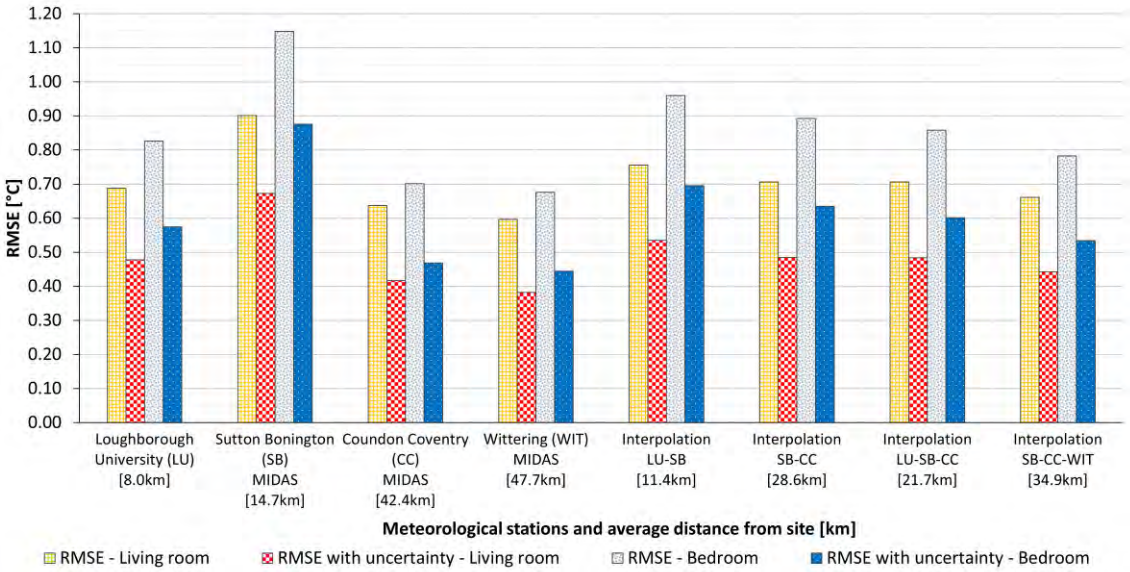

Figure 5. RMSE of the predictions in the LR and BR, with and without considering the uncertainty range.

Conclusions and recommendations

This study has shown that the newly developed ITCC empirical TSAM model is able to accurately predict the internal temperature evolution of a dwelling, for a period up to 7 days in the living room and bedroom of this test house. It also highlights the inaccuracies that are introduced to the model when data from 'near neighbour' meteorological stations are used. Triangulation of the weather data inputs improved the model's predictive accuracy whilst reducing the variability and uncertainties associated with the results. For more robust and prolonged predictions, further model development is needed in order to further improve predictive accuracy during sudden spikes in the external temperatures.

Acknowledgments

This research was made possible by EPSRC support for the London-Loughborough CDT in Energy Demand (grants EP/L01517X/1 and EP/H009612/1). The authors would like to thank

Effect of thermal diffusivity of insulating materials on room free-float temperature with façade external insulation

Emanuele Habib[1], Marta Cianfrini[2]

[1] DIAEE – Sapienza Università di Roma, Italy, emanuele.habib@uniroma1.it
[2] DIMI – Università degli Studi Roma Tre, Italy

Abstract: External insulation of building façade is widely used to reduce heating energy demand in buildings. Usually, its design concerns only thermal transmittance, while transient thermal behaviour is commonly addressed only as dumping factor or time lag of outdoor heat wave. During summer, in many mild climates, outdoor daily mean temperature is close to comfort temperature. Yet, even though mean heat transfer through building envelope is null, heating during daytime may lead to positive cooling loads or discomfort temperatures in non-conditioned rooms. In residential buildings internal loads are usually very low, so the most relevant loads are heat transfer though outer facades. Moreover, where there is no cooling, wall dumping factor is not meaningful to evaluate the thermal performance of wall insulation, as it is referred to constant indoor temperature. In this framework, a model of a room with a single outer wall has been developed to study the effect of insulating material on free-float temperature. Transient heat transfer through the envelope as well as through inner walls is considered to model indoor air temperature. Different localities in Italy and commonly used insulating materials are considered.

Keywords: Overheating, Thermal comfort, Night cooling, Dynamic effect of thermal insulation, multi-layered walls

Introduction

External insulation of building façade is widely used to reduce heating energy demand in buildings. Actually, in conventional buildings, heating energy demand is mostly due to heat transfer through the building envelope. So, increasing thermal resistance of outer walls by applying thermal insulation reduces heat transfer rate. In order to avoid interstitial moisture condensation and to reduce thermal bridges, insulating panels are often applied outside.

Besides, in many parts of Europe, in summer, climate is quite mild so that heat transfer is from inside to outside during the night as outdoor temperature decreases under indoor comfort temperature. Moreover, in non cooled rooms, indoor temperature fluctuates as a result of inner loads, solar loads and heat transfer through building envelope. So, even during daytime, heat transfer is often from inside to outside. Therefore, insulation of outer walls reduces outgoing heat transfer through building envelope, leading to an increase of indoor temperature.

The risk of overheating in highly insulated dwellings have been pointed out in a number of reports concerning different European Countries (Isaksson & Karlson, 2006; Schmitt et al., 2007; Janson, 2010; Larsen & Jensen, 2011; McLeod et al., 2013). These finding suggests that the thermal insulation of outer walls reduces heating energy demand but may provoke an increase in cooling demand, urging the application of cooling systems.

Anyhow, even in this case, the new cooling energy demand is usually quite low, so yearly energy balance is positive.

As stated, during summer heat transfer through an outer wall may be either inwards or outwards, changing direction during the same day. Thus, transient behaviour of each layer is relevant for indoor temperature behaviour, including insulating layer.

In this framework, different materials, commonly used in outer insulation of building envelope, are analyzed in order to highlight their effect on indoor temperature, presuming there is no cooling. A standard apartment bedroom is considered.

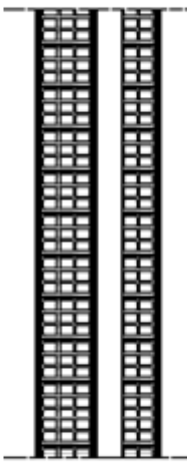
Mathematical Formulation and Computational Procedure

The room is considered to be 5 m wide and 4 m deep with a 3 m height. Only one wall is outfacing in which there is a 1.25 m^2 window. Other walls, the roof and the floor are supposed to adjoin rooms that are almost at the same temperature, so that heat transfer through them may be neglected. In order to evaluate their contribution to indoor heat capacity they are modelled assuming that the midplane is adiabatic.

The outer wall is the type known as “a cassetta”, made of two layers in bricks and a wide hollow-space, that is the most common one among reinforced concrete skeleton buildings built between the end of WWII and the arising of the energy crisis in mid '70s. The composition of the wall is sketched in fig. 1. In the cavity, heat transfer occurs by natural convection and radiation at the same time. As radiation heat transfer is prevalent and its thermal capacity per unit volume is much lower than other layers, for calculation purpose it may be treated as a homogeneous layer made of an opaque material with an equivalent conductivity evaluated from eq. 1:

$$k_{eq} = h \cdot s_{cavity} \tag{1}$$

where , *k* stands for thermal conductivity, *h* for combined convection and radiation heat transfer coefficient in the cavity, *s* for thickness.



Material	Thickness mm	Thermal conductivity W/m·K	Density kg/m^3	Specific heat capacity J/kg·K
Plaster	15	0.9	1800	1000
Bricks	120	0.4	750	836
Cavity	60	0.3	1.2	1000
Bricks	80	0.4	750	836
Plaster	15	0.8	1400	1000

Figure 1. Outer wall composition. Data are outside to inside

The window is made of two glass layers with low emissivity inside coating (0.1 emissivity), Argon filling, and is assumed to be completely shaded from direct sunlight.

An energy renewal intervention by application of 60 mm thick insulating panel on the outer face is considered. Expanded polystyrene (EPS), Expanded polyurethane (EPU), and a double density Mineral wool panel (MWP) are considered, with properties stated in table 1, together with insulated wall thermal transmittance.

Table 1. Properties of insulating materials

Material		**Thickness** mm	**Thermal conductivity** W/m·K	**Density** kg/m^3	**Specific heat capacity** J/kg·K	**Thermal diffusivity** m^2/s x10^6	**Thermal transmittance** W/m^2·K
EPS		60	0.036	18	1450	1.38	0.39
EPU		60	0.028	35	1464	0.55	0.33
MWP	outer layer	20	0.031	120	1030	0.25	0.37
	bulk layer	40	0.035	70	1030	0.49	

Thermal field equation in each wall layer is described by a Cartesian one-dimensional Fourier's equation for conducting fields:

$$\frac{\partial^2 T}{\partial x^2} = \frac{1}{\alpha} \times \frac{\partial T}{\partial \tau} \tag{2}$$

where, T for temperature, α for thermal diffusivity, and τ for time. At layer junction, heat flux conservation is given by:

$$k_a \frac{\partial T}{\partial x}\bigg|_a = k_b \frac{\partial T}{\partial x}\bigg|_b \tag{3}$$

where subscripts a and b stand for the two neighbour layers. Outdoor boundary condition is combined convection and radiation heat transfer coefficient:

$$h_o \cdot (T_{outdoor} - T) + a \cdot W = -k \frac{\partial T}{\partial x} \tag{4}$$

where h_o is outdoor heat transfer coefficient, a is absorption coefficient of solar radiation, and W is solar radiation specific power. Indoor boundary condition is convection heat transfer to room air, and radiation heat transfer to the other surfaces of the room, evaluated through its mean radiant temperature:

$$-k \frac{\partial T}{\partial x} = h_i \cdot (T - T_{room}) + h_r \cdot (T - T_{mr}) \tag{5}$$

where h_i is indoor convection heat transfer coefficient, h_r is indoor radiation heat transfer coefficient, T_{room} is room air temperature, and T_{mr} is mean radiant temperature, defined from eq. 6:

$$T_{mr} = \frac{A_o \cdot T_o + A_i \cdot T_i + A_w \cdot T_w}{A_o + A_i + A_w} \tag{6}$$

where subscripts o, i and w stand for outer wall, inner wall and window, respectively. Room air temperature is assumed to be uniform and calculated through energy equation:

$$\begin{aligned} V \cdot \rho_a \cdot c_{p_a} \frac{dT_{room}}{d\tau} &= \\ &= h_i \cdot A_i \cdot (T_i - T_{room}) + h_i \cdot A_o \cdot (T_o - T_{room}) + h_i \cdot A_w \cdot (T_w - T_{room}) + \dot{Q}_i + \dot{Q}_V \end{aligned} \tag{7}$$

where V is room volume, ρ_a is room air density, c_{pa} is room air isobaric specific heat, $\dot{Q}_i$ *is* inner loads due to people, lighting and appliances, and $\dot{Q}_V$ is ventilation heat transfer, given by eq. 8:

$$\dot{Q}_V = n \times V \times \rho_a \times c_{p_a} \times (T_{outdoor} - T_{room}) \tag{8}$$

where subscripts n is room ventilation rate (air changes per unit time). In the window, conduction heat transfer is neglected, assuming each glass to be isothermal.

Governing equation, along with boundary and initial conditions stated above, are solved through a control-volume formulation of the finite-difference method. A second-order backward scheme is used for time stepping. Auxiliary temperature nodes at materials interfaces are used. The discretized equations lead to a linear system that has been solved with Thomas algorithm with a specifically developed Matlab code.

The code was checked against reference simple analytic solutions found in (Carslaw & Jaeger, 1959) to get the optimal mesh-size and time step. In order to assure that the error to the analytic solution is less than 10^{-3}, 30 s time step with an x-wise step given from eq. 9 has been found to be a good balance between calculation time and solution accuracy.

$$\Delta x = s\sqrt{\frac{1.5}{\alpha \times \Delta\tau}} \tag{9}$$

Results and discussion

Simulations with typical year outer climate in different cities in Italy with usual ventilation and inner loads, as well as with 24 hours sinusoidal solicitation response are performed. While the former simulations provide data close to effective use conditions, the latter are useful to understand the phenomenon. All simulations are performed assuming 0.3 vol/h continuous air change rate.

Sinusoidal solicitation - 24 hours period

A 24 hours long sinusoidal variation of outdoor temperature is considered with 24°C minimum and 34°C maximum. No sunlight nor inner loads are introduced in the calculation. Simulation is reiterated up to periodic regime with a maximum variation of any temperature lower than 10^{-3} K. Periodic regime is reached after 15 to 25 periods.

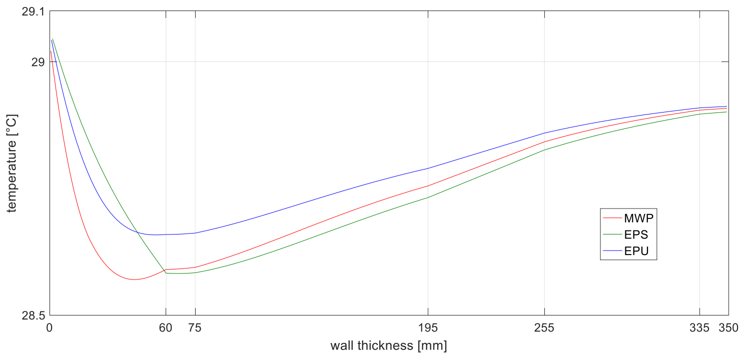


Figure 2. Temperature fields within the outer wall at solicitation beginning (outdoor temperature 29°C)

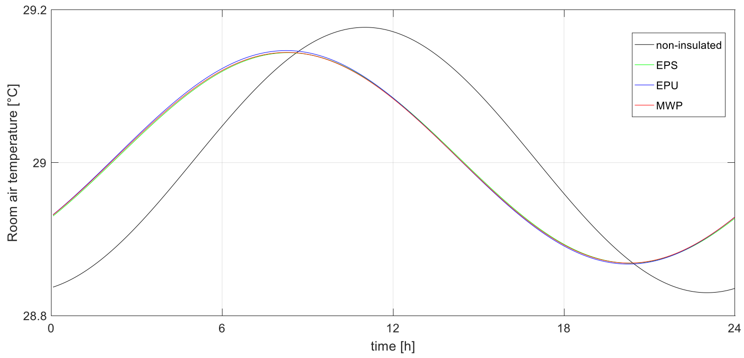

Figure 3. Room air temperature during a full period

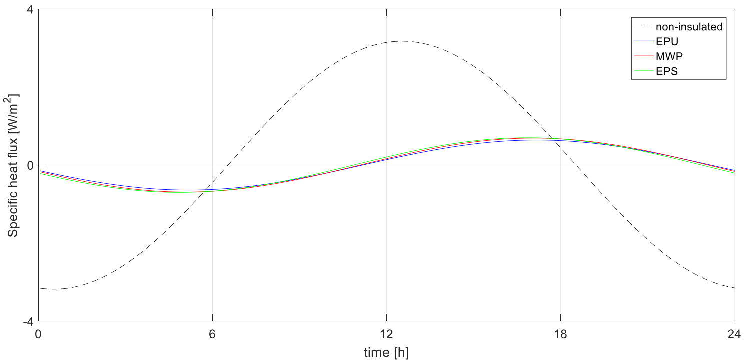

Figure 4. Heat transfer through outer wall during a full period

Temperature fields with the three different insulating materials after 4 minutes from solicitation beginning, when outdoor temperature is equal to the mean 29°C, is shown in fig. 2. Temperature fields in the bricks show a lower gradient in EPU than in the other two. This is clearly due to the higher thermal resistance introduced by this insulating material that is due to its lower thermal conductivity. Besides, MWP show a thermal inertia that lead to a delay in heat wave crossing, so that it is still cooling the outer bricks, while in EPU and EPS panels heat transfer direction is already fully inverted.

As far as the effect on indoor air temperature is considered, the differences between insulating materials smooth down, almost vanishing as shown in fig. 3. All insulating materials share almost the same behaviour. It might be surprising that insulating the outer wall leads to a reduction in heat wave time lag with respect to non-insulated outer wall. It must be considered that room air temperature is due to the combined effect of heat transfer through the outer wall altogether with heat transfer through the window and by ventilation. Insulating the wall reduces its contribution to room temperature, so the effect

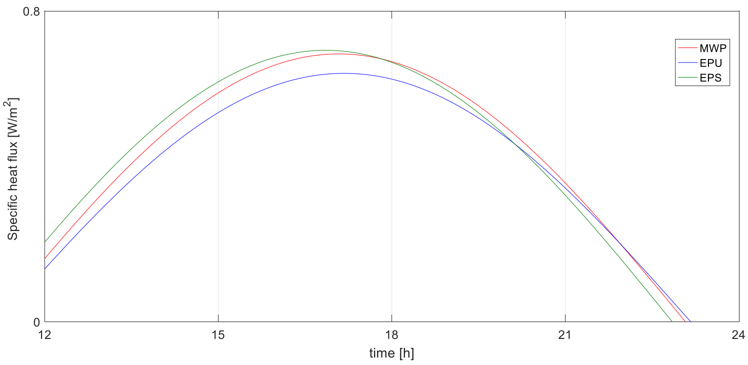

Figure 5. Highlight of peak heat transfer through outer wall for different insulating materials

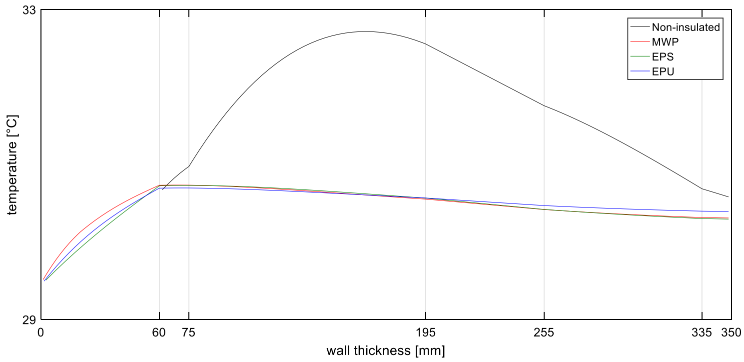

Figure 6. Temperature fields within the outer wall on the hottest day in Rome at 8 p.m.

of the other two heat transfer modes, that share a negligible time lag, take effect earlier, bringing forward the temperature maximum.

Considering solely heat transfer through the outer wall, as shown in fig. 4, the effect of outside insulation is highlighted. Outer wall contribution to heat transfer is strongly reduced, increasing its time lag from almost 7 hours to almost 11 hours. Focusing on the behaviour of different materials it may be seen from fig. 5 that while MWP and EPU share the same time lag, while EPS time lag is one hour shorter.

Data show quite clearly that insulating materials contribution to time lag is mainly due to their thermal resistance. Yet, using materials with lower thermal diffusivity (like MWP) increases time lag further.

Typical year climate

Summer period in a typical year is considered for Milan, Rome, Naples and Palermo, whose mean outdoor temperatures in July and August are given in table 2. The outer wall is assumed to be South facing. Inner loads are assumed to be equal to 150 W from 10 p.m. till 7 a.m. Simulations are performed from 1st May till 30th September to simulate the whole summer period.

Table **2**. Monthly mean temperatures

	Milan	Rome	Naples	Palermo
July	22.3°C	24.1°C	24.6°C	25.6°C
August	21.8°C	24.4°C	24.4°C	26.2°C

Temperature fields in the outer wall for different insulating materials on the hottest day in Rome at 8 p.m. show a decrease in inwards heat transfer rate with some residual thermal inertia in MWP insulating, as shown in fig. 6.

In order to compare the influence of insulation and differences between insulating materials, cumulative indoor temperature distributions are generated, as shown in fig. 7, illustrating the cumulative time in which it is higher than the temperature on the abscissa. It is evident that insulating the outer wall increases indoor temperature as in non air conditioned rooms mean heat transfer direction is outwards. Thus, wall insulation implicates a higher indoor temperature to restore heat transfer rate.

The influence of climate on performance of different insulating materials may be highlighted by comparing cumulative time in which indoor temperature is higher than 28°C,

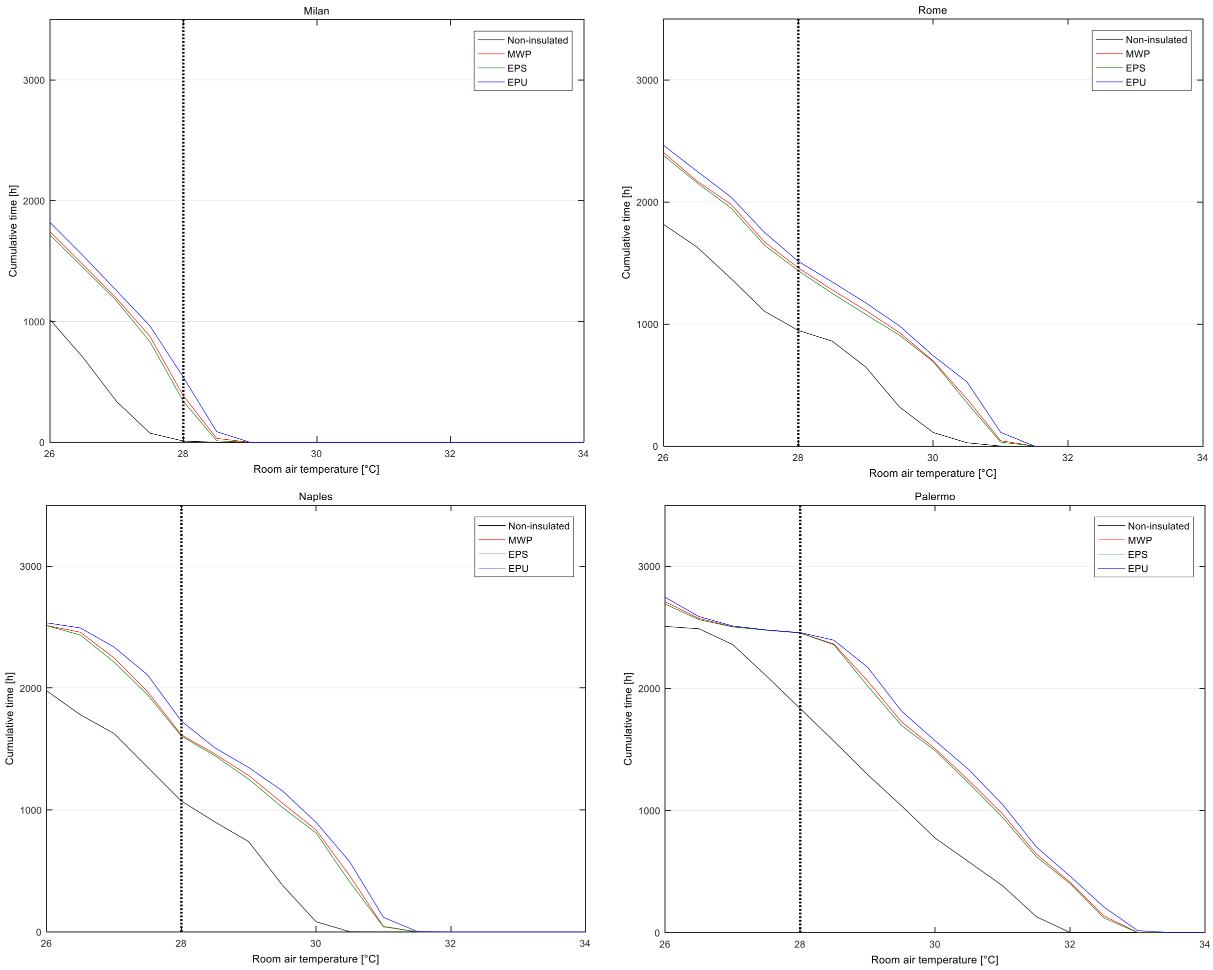

Figure 7. Outer cumulative indoor temperature distributions

that may be chosen as indoor distinctive temperatures for summer, as depicted in fig. 8. It is evident that in Palermo all insulating materials perform in the same way with a 33% increase in cumulative hours with indoor temperature higher than 28°C. As Palermo has a quite hot climate in summer, heat transfer through the outer wall is less relevant on overall behaviour. In Rome and Naples, that have milder summer climate, the higher insulation provided by EPU increases room overheating, especially in Naples in which July is even hotter than August. The overheating due to MWP and EPS, slightly lower in Naples than in Rome, suggests that their effect may be more relevant on a peak period of outdoor temperature rather than on a high mean value.

Conclusions

Simulations of temperature fields and indoor air temperature for a sample room has been performed with a finite difference formulation of heat transfer equations.

Sinusoidal solicitation show that outer insulation modifies indoor temperature evolution reducing room temperature time lag as heat transfer due to ventilation and windows become more relevant. Yet all insulating materials provide almost the same increase in wall time lag, slightly lower for EPS insulation. Mineral wool shows a higher thermal inertia, although it is not enough to change wall behaviour, it may compensate a slightly lower thermal resistance.

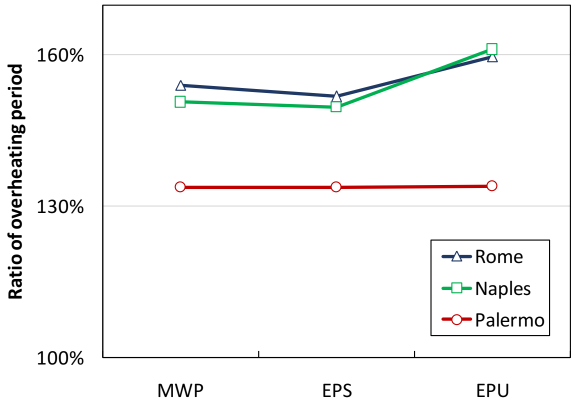

Figure 8. Cumulative time in which indoor temperature is higher than 28°C, ratio to non-insulated wall

Typical year simulations for different climates in Italy with common inner loads show a pronounced overheating, especially in the least hot climate. In Naples and Rome, although monthly mean temperatures are similar, the effect of different insulating materials is not the same. The higher thermal resistance provided by EPU lead to a longer overheating, while MWP and EPS provide a longer overheating in Rome than in Naples, although July monthly mean temperature is lower.

Abstract: Solar radiation entering through windows can contribute a significant amount of heat into the building, which is a liability when cooling is needed during overheated periods. In warm climates it is important to control solar radiation, especially through windows, with properly designed shading systems that also allow daylight during the whole year. There are several manual and digital tools to design shading systems, however, manual methods are typically based on rules of thumb and simplifications that do not provide the accuracy needed to design the high performance buildings that we need today. Digital methods are accurate when done correctly, but also require more time, that is not always available, and a more sophisticated knowledge of certain tools. This paper discusses a process to design static shading systems for buildings that provides accuracy and speed. The process follows four general steps: a) climate analysis b) solar study c) shade design, e) performance evaluation. After this process the shade might be redesigned or adjusted if required. Examples from practice and academia will be included in the presentation.

Keywords: Shading, building simulation, building overheating, low energy design, design for warm climates

Introduction

Uncontrolled amounts of glass in buildings, though attractive, can lead to overheating and glare, forcing occupants to close the blinds, which then usually stay closed, blocking views and daylight, negating the purpose of the window. However, solar radiation can be controlled during the overheated period with properly designed shading systems that also provide daylight and views during the whole year.

Heat is exchanged through a window by conduction, convection, and radiation. Depending on the size, orientation, and quality of the window, this heat can be a large percentage of total heat gains and losses in a building. Gains should be reduced in the summer and shade is one of the most effective strategies to reduce these heat gains. A well designed shade should reduce solar gains during the overheated period while maybe allowing them during the under-heated period. In an air conditioned building shade reduces cooling energy and GHG emissions, while in a naturally ventilated building it reduces overheating. Shade can also improve comfort in outdoor spaces during the overheated period.

From earliest history, all buildings in warm climates have tried to protect themselves from the sun. Socrates, more than 2400 years ago stated “is it not pleasant to have the house cool in the summer and warm in the winter?” “Now in houses with southern orientation the sun’s rays penetrate into the porticoes, but in summer the path of the sun is right over our heads and above the roof so we have shade….To put it succinctly, the house in which the owner can find a pleasant retreat in all seasons is at once the most useful and the most beautiful.” (cited from Perlin, 2013). Le Corbusier, with his brise soleil was one of the first contemporary proponents of shading in buildings, and examples include the Ministry of Education and health in Brazil in 1936 and the Unité d'habitation in Marseille in 1952. The Olgyay brothers (1957, 1963) rigorously studied shading systems, proposing responses that responded to orientations, and a method to design them based on the relationship between external climate and a comfort zone of 21.1 °C, using shadow masks plotted in a sun path diagram.

Givoni continued developing the shadow masks and studied the effect of fixed shading devices in different orientations (Givoni, 1976). For a location in Israel at a latitude of 32 N he stated that a horizontal shade works better on the south (equatorial facing façade); a vertical fin on the west side of the windows was better to block summer afternoon sun on the north façade; and that east and west were better shaded by a horizontal element combined with a vertical oblique to the south. Givoni also stated several now commonly accepted guidelines regarding shading devices (Givoni, 1998):

- External shading is much more effective than internal shading.
- The performance difference between external and internal shading increases with darker shade material.
- The efficiency of external shading increases with darker colours. However, these can overheat and radiate longer wave radiation to the interior when the window is open.
- The performance of internal shading increases with lighter colours.
- Efficient external shading can eliminate about 90% of solar radiation
- With inefficient shading, such as dark internal devices, the solar gain inside the space will still be 70-80% of the striking radiation.

Ed Mazria included in his book (Mazria, 1979) shading calculators, a method to plot the skyline, and a calculator to estimate the amount of solar radiation falling on surfaces with different inclinations, from vertical to horizontal at 30 degree intervals.

The effects of shade combined with thermal mass and night ventilation have also been quantified and the performance of night ventilation increases significantly with shade, either fixed or automatic (La Roche, Milne 2004) (La Roche, Milne 2005).

Andrew Marsh (Marsh, 2005) provided a quick and easy way to calculate shadow masks inside the Ecotect software environment. A shadow mask is a graphical mechanism to record which parts of the sky are visible from a particular point in the building model. For any given set of obstructions, this information can be overlaid on a sun-path diagram indicating shade over a given point at any time of the year. To improve the precision of the numerical analysis and increase computational speed, Marsh divided the sky into discrete segments, storing shading values for each one, and implemented algorithms to calculate the effect of diffuse, direct and reflected solar radiation on surfaces. He overlay this information on the sun-path diagram, providing additional data, beyond simply unshaded or shaded.

As weather files with solar radiation data have become more common, the implementation of software for solar and shadow studies continued developing. A prototype tool that evaluated solar radiation on complex building envelopes using Maya, a three dimensional modeling and animation software was developed at UCLA (Da Veiga, La Roche 2003). In this program, a fitness function rated the individual and overall performance of the proposed building envelope as a function of solar radiation levels. The goal was to design a tool that would generate the most effective form that would respond to specific solar geometry and solar radiation. Shade design tools such as Shaderade (2011, Sargent, J., et al) based on Rhinoceros® and EnergyPlus have been developed to assess the thermal desirability of solar transmittance through any potential shading volume or surface. Linking parametric design software, energy simulation tools, and optimization algorithms allows for the customization of shading devices to reduce anticipated energy use (Glassman E., Reinhart C., 2013).

In a warming world, overheating is becoming more important at all latitudes and locations, even in areas which traditionally did not have this problem. Studies in a prototype tested across different climates in Europe indicate that overheating is already a problem (Brotas, L., Nicol, F., 2015), (Brotas, L., Nicol, F., 2016). This is further exacerbated under climatic predictions for 2030, 50 and 80. Brotas and Nicol propose several low carbon and economically viable solutions such as night cooling, cross ventilation, and shading to reduce the danger of overheating. They state that "shading systems are fundamental to mitigate solar access to the building on hot periods and where possible should be positioned externally to minimize heat entering the space." (Brotas, L., Nicol, F., 2016). They tested several models and results showed that a building that complies with current standards and adopts passive strategies (e.g. natural ventilation and shading, especially external shading), is likely to cope with overheating in line with climate predictions. External shading had the highest impact in preventing overheating.

Research by Gupta el al, (2016) also suggests a mismatch between overheating risk predicted using climate modelling and the actual occurrence of overheating. His study focused in facilities for the care of elderly individuals which have an increased heat-related mortality and morbidity and health related risks. While climate modeling suggests that overheating is not a significant risk in the UK until 2080s, measured data indicated that there is a current risk of overheating in care facilities for the elderly, especially during short heat waves (lasting two to four days).

Design Method

Shade must be designed appropriately, considering both climate and building type. There are two major approaches for the design of shading systems: a) manual methods based on rules of thumb and b) parametric design methods that link software with energy simulation tools. Methods based on rules of thumb are usually found in existing literature and websites and followed by many designers. Due to simplifications they are not sufficient to design the high performance buildings that we need today and in some cases might even provide incorrect guidance. On the other hand parametric design methods linked with energy simulation tools can provide very accurate results but require more time and knowledge to implement. This approach can lead to very interesting designs but also to erroneous results if assumptions are incorrect during the process. Because the method uses sophisticated tools the designer might think that a shade system is very accurately designed while in reality there are major flaws in it.

Shading Devices can be fixed and operable and internal and external. This paper will discuss the process of designing fixed external shading devices for buildings. The method can also be used for the design of shade in outdoor spaces with some variations. The process uses analogue and digital tools, following several steps: a) climate analysis and determination of overheated and under-heated periods; b) solar analysis; c) shading design; d) performance evaluation; e) redesign/adjustment (Fig 1).

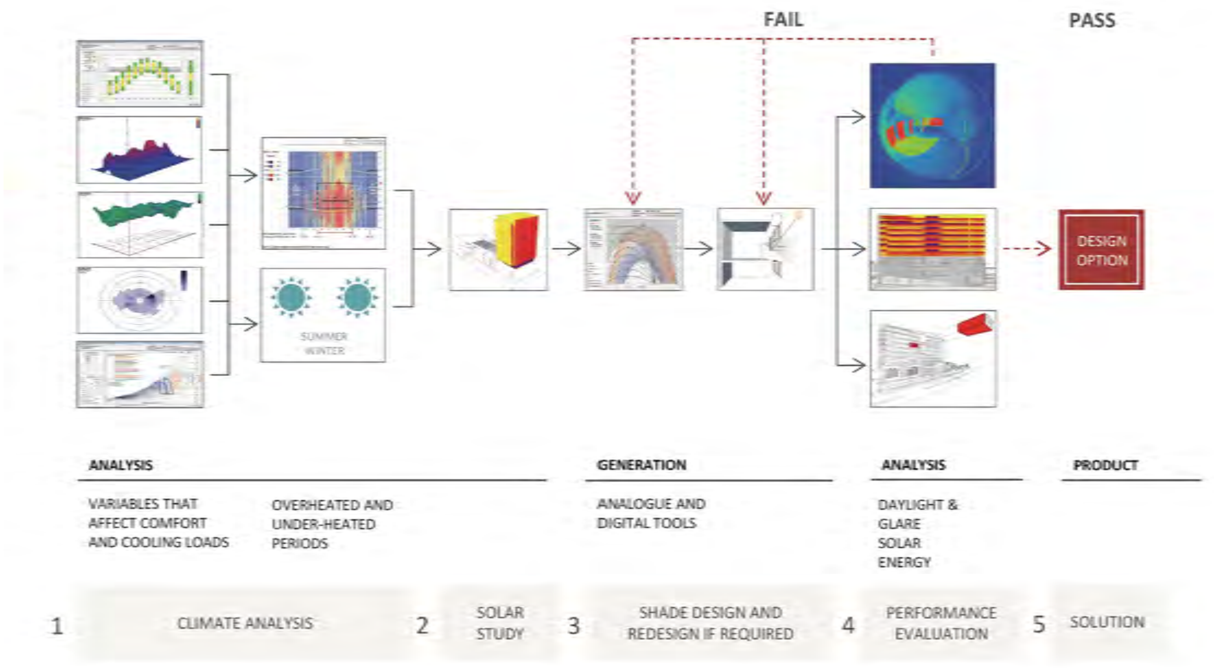

Figure 1. Design Process for Fixed Shading Devices

Climate Analysis

The process begins with a climate analysis. The most important factors to analyse in climate are those that affect thermal comfort, energy consumption and GHG emissions in buildings. Typically temperature, direct and diffuse solar radiation, relative humidity, and wind speed and direction are studied using a weather file. EPW weather files can be obtained from several sources including the U.S. Department of Energy at https://energyplus.net/weather. Temperature and solar radiation (direct and diffuse) are critical to accurately determine cooling and heating seasons and when solar radiation should be promoted or blocked. For analysis there are several free tools. Climate Consultant from the University of California Los Angeles, is very easy to use and also provides design advice based on the climate, now linking to the 2030 Palette with examples of strategies for buildings in different climates (http://2030palette.org/). A tool developed at MIT allows for visualization of EPW files https://mdahlhausen.github.io/epwvis/. Grasshopper with Ladybug provide a relatively easy to use option to visualize weather data.

Climate data helps to determine the overheated and under heated periods, which are used for summer and winter insolation analysis, self-shading studies, determination of critical façades, and the design of shading options for windows. Overheated and under heated periods are calculated differently for outdoor spaces or buildings. Non-building outdoor shade requirements are better defined by the environmental variables that affect thermal comfort or thermal stress (temperature, radiation, air velocity, relative humidity), while the building shade period is better defined by the cooling requirements of the building or by indoor thermal comfort. These are also affected by environmental variables, but regulated by the building. Outdoor spaces might have similar but not exactly the same shading periods.

There are several methods to determine the overheated period in buildings. Reinhart (2014) describes a solstice method, a degree day method, and a thermal balance method. The authors use similar methods but use an outdoor temperature method instead of a solstice method. The goal of all of these is to predict the shade period to reduce solar gains, reducing cooling loads and overheating. This period will be defined by a start and end date and a start and an end hour. The timetable plot of bioclimatic needs proposed by Olgyay can be used to show these in one chart. Static devices will always be symmetrical around the summer solstice but unfortunately, temperature will not. This means that a static shade will probably provide excessive or insufficient shade during some part of the year. The following paragraphs describe some of the methods used by the author to determine the overheated period.

Exterior temperature method

In this method the overheated and under-heated periods are determined using the outdoor dry bulb temperature and its relationship to a reference temperature, which is usually linked to the balance point temperature. The balance point is the temperature at which a building needs neither heating nor cooling for comfort because the internal gains equal the losses. The assumption is that when outdoor temperature is above the reference temperature the building will overheat and need air conditioning to maintain comfort. Shade during this period would reduce cooling loads in mechanically conditioned buildings and improve comfort in naturally ventilated buildings. This method is very easy to implement but it does not consider different types of buildings with differing envelopes and heat capacities, or different schedules and internal loads. Thus, this method is more effective when implemented on light weight buildings.

The Olgyay brothers proposed a reference balance point of 21.1°C in temperate areas, and higher in buildings closer to the equator (Olgyay, 1963). They plotted this overheated period in a matrix divided in hours and months, which they called the timetable plot of bioclimatic needs. The balance point in current buildings is now much lower than 21 °C due to buildings with better envelopes. The method however, can still be implemented using a different value and Climate Consultant provides an option to implement it changing the value of comfort low to the balance point temperature and using the sun shading chart. This chart shows every hour of the year divided in two six month periods, from December 21 to June 21 and from June 21 to December 21. It provides the position of the sun and shade requirements for every hour of the year based on outdoor temperature divided into one of three options, warm/hot (shade needed), comfort (shade helps), and cool/cold (sun needed) according to the comfort model selected. It is possible to use this sun shading chart to define the months and the hours during which shade is required based.

Degree day method

This methods uses heating and cooling degree days to determine the overheated period. Heating and cooling degree days are based on balance point temperatures and provide an estimation of heating and cooling requirements in a specific climate. Heating degree days (HDDs) describe the average daily temperatures below a base temperature and cooling degree days (CDDs) for a specified base temperature describe the average daily temperatures above a base temperature. The base temperature for Heating Degree Day calculations is typically the lower limit of the balance point temperature and the base temperature for Cooling Degree Day calculations is typically the upper limit. When the outdoor temperature is between these two values, the building will typically not need mechanical heating or cooling. Monthly heating and cooling degree days are plotted for the whole year using degree day tables, or online sources of data. In climates that need both heating and cooling there will be one or more months in the spring and fall in which there will be both heating and cooling. The overheated period starts when cooling degree hours appear in spring and ends when they disappear in the fall. During this period there might be overlapping of HDD and CDD, so the designer must select when there is sufficient need for cooling to require shading, which could be when the difference between them reaches a predetermined value. The designer may decide to define a shorter shade period based on other considerations such as daylight, unequal distribution of CDDs around the solstices, adding interior operable blinds, or costs. Climates with high CDDs all year also require shading during the whole year.

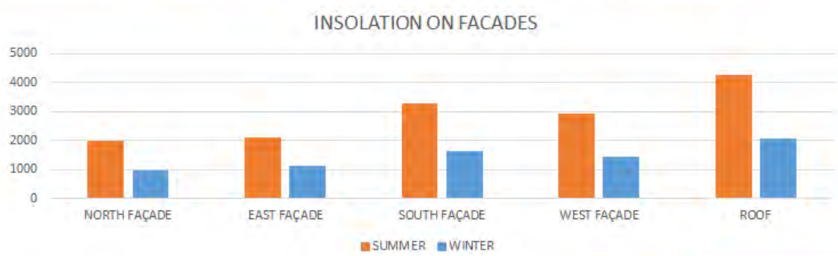
The Energy Model method

This method is more precise but requires energy modelling software to determine cooling and heating loads. It provides more precision than the balance point method because it accounts for the specific properties of the building being analysed that are not accounted for in the degree day method. Annual building analysis using a local weather file and a simplified building design, with envelope and internal loads similar to the project will provide a monthly breakdown of heating and cooling energy to determine cut off months for the shading system. These values can also be converted to carbon emissions using appropriate factors, allowing to compare effects from different sources in a common unit of measure, CO2e.

Solar Study

Façade solar studies, permit to quickly determine critical orientations that require more solar protection. Solar studies should be done for the previously defined overheated period using one of the methods previously described. Values can be expressed as average daily per unit of area or total values for the analysis period. There are several software that perform solar studies such as IESve and DIVA. Fig 2 shows some views of a solar study and bar charts with winter and summer average daily solar radiation (Fig 3).

Figure 2. Example of solar Studies on Building Surfaces



Summer:
Roof receives most solar radiation. Most critical facade is south followed by west.

Winter:
Heat gain on the facades averages 50% of summer values. Highest value is also on the roof but followed very closely by the south and then the west facades. Solar heat gain in the winter could be beneficial depending on internal loads. Glare should be controlled.

AVG. DAILY RADIATION (Wh/m²)		
SURFACE	SUMMER	WINTER
NORTH FAÇADE	1988	940
EAST FAÇADE	2090	1095
SOUTH FAÇADE	3271	1622
WEST FAÇADE	2896	1413
ROOF	4238	2030

Figure 3. Example of data from solar studies on building surfaces in Fig 2

Shade Design

The next step is to design the shade component(s) based on orientation and dimensions of the surfaces requiring shade and seasonal requirements. Vertical and horizontal shadow angles should be calculated using one of several methods. Shadow masks are useful because they show annual shading for a whole year in one figure. Climate Consultant permits to test vertical and horizontal shadow angles using outdoor temperature. Multiple options can then be designed and dimensioned using proposed vertical and horizontal shade angles. It is also useful at this moment to propose shading design goals, for example percentage reduction over a given period. Dimensions of shade components are then designed as a function of the dimension of the window (or element to be shaded) and the vertical or horizontal shadow angle. For example, to calculate a horizontal shade element:

$$OP = HP/\tan VSA$$

Where OP is the horizontal overhang projection and HP is the distance of the horizontal overhang from the shading element to the bottom of the window and VSA is the vertical shadow angle.

To calculate a vertical shade element:

$$FP = WW/\tan HSA$$

Where FP is the fin projection, or fin size, and WW is the width of the window that must be protected by the shadow of the fin and HSA is the horizontal shadow angle.

Alternatively, visual trial and error with a 3d modelling tool or a parametric method can be used to determine optimum dimensions.

Performance Evaluation

Shading options should be tested for overall energy consumption, illuminance and luminance levels. A simple shoebox modelling tool like COMFEN is a quick and easy way to do this as are other energy modelling tools. A physical model can also be used for daylight studies and a heliodon for shadow studies in analogue models. If there are no tools available to calculate energy use and daylight, a comparison of the solar gains on the façade with and without shade is useful. The façade with the least amount of incident radiation on the envelope during the overheated period is the most effective option. This number can be described as a percentage reduction (Fig 4). The percentage reduction at peak cooling loads is also helpful.

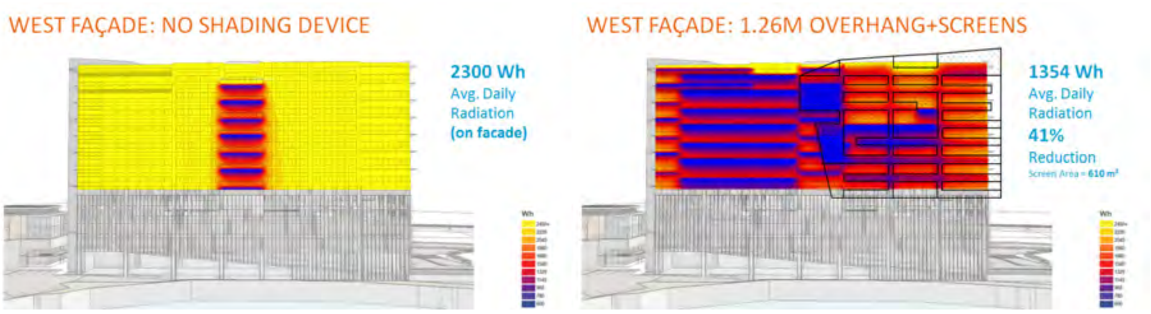


Figure 4. Solar Studies Comparison of Design Options

Final Solution or Return to Adjustment

If the design provides either insufficient shade or too much shade, it must be redesigned and re-evaluated, returning to step 3, assuming the overheated period is correctly calculated.

Conclusion

Shade is an effective strategy to reduce solar gains. It is clear that climate change will require buildings that are better shaded to reduce GHG emissions and increase indoor comfort. However, shade components cannot be too large so that they block winter gain and must also be right sized for good daylight. The method described in this paper is not prescriptive, instead it is a guide in which different tools can be plugged in and out following the indicated steps. Following this process will produce lower carbon buildings which can still have transparency in their façades providing occupants with good daylight and views.

Experimental study of the roof thermal performance influence over the mean radiant interior temperature of an industrial building

Jefferson Torres[1], Helena Coch[1], Isabel Crespo[1] and Antonio Isalgué[2]

[1] Architecture & Energy, School of Architecture, Polytechnic University of Catalonia, Barcelona, Spain, Av. Diagonal, 649, 7th floor. 08028;

Abstract: Industrial building rehabilitation is one the latest trends within the field of sustainable development. However, these interventions often disregard the issue of user comfort, despite being the most important factor of energy efficiency. This work deals with the assessment of the indoor thermal conditions of a restored industrial building, considering not only air temperature but also mean radiant interior temperature. The research focuses in the influence of the radiative performance of the saw tooth roof of this building regarding these conditions. Results show that the analysed thermal parameters depend directly on the roof thermal behaviour. In fact, the glazed area of this type of roof is responsible for the 60% of the increase of the mean radiant temperature over air temperature. This result is a consequence of the high interior temperature reached by the glass panels, 47°C max, despite their northern orientation. These temperatures are a result of the diffuse radiation action and, particularly, the heat flux emitted by the opaque part of the saw tooth-roof, which significantly reduces the radiative cooling capacity of the glazed surface.

Keywords: Industrial building, mNACTEC, Mean radiant temperature, Saw-tooth roof.

Introduction

The industrial revolution, being one of the most significant changes in the history of humankind (Andrei, 2012), brought as a consequence the development of a new building typology. Large manufacturing spaces with proper lighting-spatial conditions for the implementation of productive activities were needed.

Some of these buildings have left their mark on contemporary cities through some examples of technological and aesthetic value (Fernández et al, 2016). Furthermore industrial heritage has impacted not only tangible aspects, but intangible factors too like the collective memory and identity of a place (Sutestad et al, 2016). These buildings accumulate materials, energy, and the human effort that made them possible. Their conservation and recycling for new uses is nowadays a challenge (Romeo et al, 2015).

Vapor Aymerich, Amat i Jover, designed by architect L. Muncunill, was built in 1908 in Terrassa (Spain) to operate as a textile industry, being a case of industrial architecture. This building has been restored in 1992 and converted to the Catalonia Science and Technology Museum (mNACTEC). It had a production area around 11,000 m2 which has become the principal exhibition hall of the Museum after its rehabilitation. Due to its initial purpose, the elaboration of fine textiles, this space was provided with a roof in saw-tooth. This type of roof, with its glass panels facing north, provides a large amount of natural light, and avoids the access of direct solar radiation to the interior. However, after the rehabilitation and used as Museum, the thermal indoor conditions are considered too hot in summer by visitors and workers, in spite of the scarce of sunlight entering.

The preservation of industrial buildings is considered a sustainable approach. However, the mNACTEC rehabilitation disregards its new museum's use and this could became a contradiction in terms of energy efficiency. Industrial buildings should be rehabilitated in order to be adapted to their new uses with the purpose to improve their conditions adapted to the current standards and requirements (Blagojević et al, 2016).

Even energy saving is one of the main aim in building sector, the user indoor conditions should be considered in any construction (Kalmár et al, 2011). The most important variables in regards of thermal comfort conditions are: air temperature, relative humidity, wind velocity and the mean radiant temperature (Givoni, 1994) (Walikewitz et al, 2015). Several researches have studied the influence of hot air temperatures in the interior comfort conditions on residential buildings (Beizaee et al, 2013)(Mirzaei et al, 2012). Other studies approach this issue focusing in the mean radiant temperature, assessing issues like its influence on the indoor thermal environment (d'Ambrosio et al, 2013), the interrelation with the room geometry (Kalmár et al, 2012) or the comfort limits for heated ceilings (Fanger et al, 1980). Likewise, Atmaca argues that the mean radiant temperature is a very significant factor especially in buildings whose envelopes are exposed to a strong solar radiation (Atmaca et al, 2007), like is the case of the mNACTEC roof.

In this sense, due to the proportion that the roof represents with respect to the indoor space and the singularity of its own geometry, a detailed analysis of the radiative performance of this element will be recommended.

This work addresses the issue of the interior thermal conditions, considering the possible influence of the mean radiant temperature. The specific aim of this research is to assess the influence of the radiative performance of the building saw-tooth roof, evaluating the thermal repercussions of the opaque and glass envelope surfaces.

Methodology

The methodology is based on an experimental work carried out in the mNACTEC during a period in the hottest period of summer 2015. The building is located in Terrassa-Spain, at 2°00´E, 41°33´N and 286 masl, which lies in the Mediterranean climatic zone.

The building has a main exhibition hall, 11000 m2, with 161 Catalonians vaults arranged in a grid of 7 modules in the East-West direction and by 23 modules in the North-South direction covered by a saw-tooth roof. Every module of the roof is composed by two parts: an opaque and a glass surface. The opaque surface is a semi-vault defined by a double bent built in brick. It has a 0.33m thickness composed by various layers of bricks with an air gap in the middle as shown in Figure 1c. The glass surface, oriented almost to the North (19° to the West), is formed by two simple glass panels separate by an air gap.

The experimental work of analysis of the roof radiative performance influence on the mean radiant indoor temperature has been divided in two parts. The first part focuses on the roof thermal behaviour and the second part on the thermal interior conditions. The roof measurements had the purpose to assess its thermal response to the climatic conditions to which it is exposed. Due to the singularity of its geometry the two surfaces, opaque and glazed, had been analysed separately. Solar radiation (SR), long-wave radiation (LW) and surface temperatures Ts of the opaque and glass parts (Ts.op, Ts.g) were measured, outside and inside, on this two elements that comprise the roof. The second part addresses the ambient interior conditions in order to match these results with the roof thermal behaviour. The parameters considered in this part were the mean radiant interior temperature (Tmrt) and indoor air temperature (Tai). It has been analysed the independent influence of the glass and opaque surface over the mean radiant temperature through calculations.

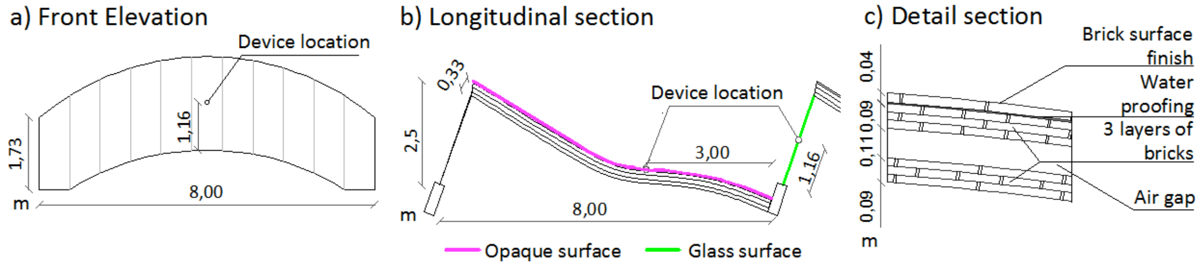

Figure 1. Construction specifications a) Front elevation b) longitudinal section and c) detail section.

The module selected from the grid to be measured was the tenth from North, and the third from West. The data of the glass surface, SR and LW was collected from June 23th to June 30th, and the outdoor surface temperature from July 1st to July 8th. The three same parameters were measured on the opaque surface from July 1st to July 8th. The data are always referred to solar time (UTC). The equipment used was: for SR a pyranometer MS-020VM with a spectral range from 350nm to 1100nm, for LW a pyrgeometer IR02 with a spectral range from 4.5 µm to 40 µm and a field view angle of 150° connected to a data logger CR800, and for the surface temperatures an external thermocouple K-type connect to a multifunctional meter TESTO 435. The first two instruments were set to collect data in 5 min and the last in 20 min intervals. Due to the difficulty of measuring the indoor temperature of the glass and opaque surfaces, an infrared thermometer was used, spectral range 8-14 µm, and emissivity calibrated at 0.90. In order to make a proper diagnostic of the radiative roof behaviour, due to the complexity of its geometry, measurements in 9 different points over glass an opaque surface were done. The measurements were done outside and inside on both surfaces, on July 9th from 09:00h to 18:00h every 30 min. This procedure was supported through thermal images with the use of a thermo-graphic-camera FLIR I7. These measurements of radiant temperatures were validated comparing the outside surface temperatures measured with the infrared thermometer and the K-type thermocouples, and the average differences were less than 0.7°C.

In regards to the ambient indoor measurements, all parameters considered in this part were collected from July 9th to July 13th. In order to assess Tmrt under indoor conditions, a frequent method validated in several studies was used (Thorsson et al, 2007) (d'Ambrosio et al, 2013) which involved the globe temperature, air temperature and air velocity. The globe and air temperature were measured using a globe thermometer WB 20SD; for the air velocity an anemometer HIBOK AM8901 range from 0.4-35 m/sec. All the equipment was placed at 2.10 m height, out of visitors' reach. The data was collected at 10 min and 60 min intervals respectively.

Finally, outdoor air temperature data was gathered from the database of the nearest Weather Station from the Museum ID: ITERRASS3, located at 300m from the building at 2°00´48´´E, 41°33´59´´N and 307 masl. The information was collected in 20 min intervals.

The data were collected in 3 different periods but with the aim to make a comparable analysis, 1 day from each period with similar climatic conditions has been chosen, June 29th, July 1st and July 9th. All these days had clear sky conditions, with mean temperatures and SR of 28.8ºC, 360 W/m2; 28.6ºC, 330 W/m2; and 27.5ºC and 332 W/m2.

Results and discussion: Roof.

Figure 2 shows the results of the radiation heat flux data on the opaque surface (a) and glazed surface (b). Regarding to the results for opaque surface, it shows a SR curve with no interruptions, which reflected 0% obstructions, and completely clear sky conditions throughout the whole day. This radiation appears at 04:30h, it rises until its peak 1000 W/m^2 at 12:00h, and then it starts to fall down until disappearing at 19:30h. In regards to the LW at night periods from 00:00 h to 04:30 h and 19:30 h to 24:00 h the roof is emitting a flux quite constant, -87 W/m^2. While the SR appears the heat losses start to rise up until reaching its peak -192 W/m^2, around the same time with the SR peak. After this, its heat losses diminishes until the SR disappears and comes back to its constant behaviour at night.

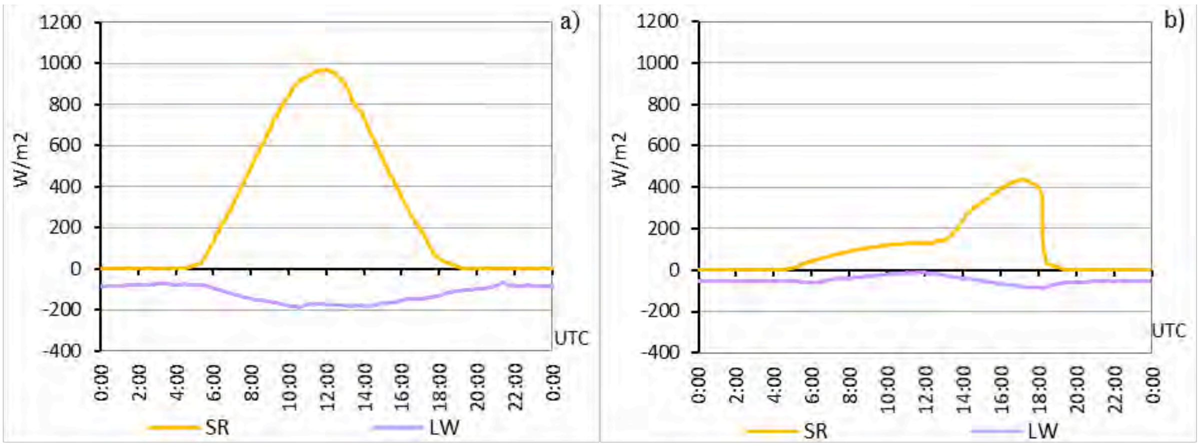

Figure 2. Solar and long wave radiation measured a) on the opaque surface and b) on the glass surface.

There is a relationship among the values of the SR and LW. However, this behaviour gets complicated on the glazed surface due to the roof geometry. The results on the glass surface, Figure 2b, show a SR curve with two different ascending slope. In the morning, the curve keeps a low ascending slope until midday, from 0 to 130 W/m^2. These values reveal the presence of the diffuse-reflect radiation, due to the fact that the glass panels oriented to the North avoid the penetration of the whole direct radiation in this period. After this, SR curve starts to rise with a higher slope until its peak 430 W/m^2, reflecting the incidence of the direct radiation. This behaviour can be observed in Figure 3b, which shows the incidence of the direct radiation only in the afternoon due to the building orientation, 19° to West.

With respect to the LW results, the heat flux is quite constant in the night time periods but with a lower value, -55 W/m^2, than the opaque surface. However in the daytime it displays a totally different behaviour. When solar radiation appears, specifically the diffuse-reflect component, heat losses decrease until -10 W/m^2, around midday. Then, this flux increases until its peak, -87 W/m^2. This responds to direct radiation incidence.

As mentioned, the relationship seen on the opaque part between the SR and LW is not the same in glazed surface results. This behaviour support that the heat losses do not only depend on the amount of the solar radiation received, but also on the heat exchange with its environment. In reference to this, the portion of sky seen by the glass is lower than the one seen by the opaque surface, 55-75% respectively, in terms of Sky View Factor (SVF). Furthermore, the portion of opaque surface seen by the glass has great influence on its heat losses performance due to the high amount of heat flux emitted by the opaque surface, as consequence of the high temperatures it reaches.

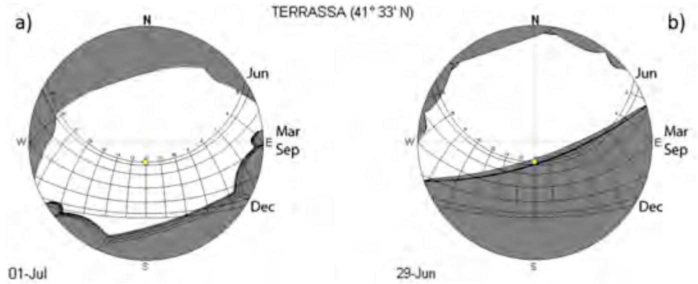

Figure 3. Obstructions of the sun paths in a stereographic projection from the same point of the pyranometer location on the opaque (a) and glass (b) surface. Graphics obtained by Heliodon (Beckers et al, 2003).

In order to analyse the whole heat radiation exchange, the exterior glass and opaque surface temperatures had been measured, Figure 4. At night time periods, these temperatures clearly only depend on heat losses by LW. This is reflected in the temperatures of both surfaces, which keep under the outdoor air temperature due to the high levels of LW emitted to the sky. Moreover, these results shows the influence of the lesser portion of sky seen by the glass compared to opaque part over its surface temperature, which impacts in an average of 2°C higher.

In daytime period, the temperature performance of these two surfaces are conditioned by both radiations: SR and LW. In regards to the opaque part results, these values show a behaviour quite corresponding to their radiation exchange, Figure 2a. In the same way, the results of glass surface temperature show the same pattern seen in the measurements of SR, a curve with two ascending slopes. Nevertheless, these two slopes do not have the large difference seen on radiation results, Figure 2b. With the purpose to analyse this behaviour, it has divided daytime in two periods, morning and afternoon. The average of SR received in the afternoon period is 3 times (255 W/m^2) higher than the one received in the morning (85 W/m^2). Meanwhile the average difference between surface and air temperature, comparing the same periods is 2.5 times, (5°C to 2°C). This behaviour responds to the scarcity of net LW flux emitted in the morning period, which impact in a higher temperature, and transparency of glass to SW.

Regarding the interior surface temperatures results, Figure 4b, the maximum value on both surfaces is around 17:00h. In the case of the opaque surface, it shows a delay of 5 hours and a reduction of 20°C, between the exterior and interior maximum. Meanwhile, in the glass part, the transmission occurs almost immediately, and it displays an increase of its temperature of 7°C. Moreover, the peak on the glass surface temperature is 10°C higher than the one of the opaque part.

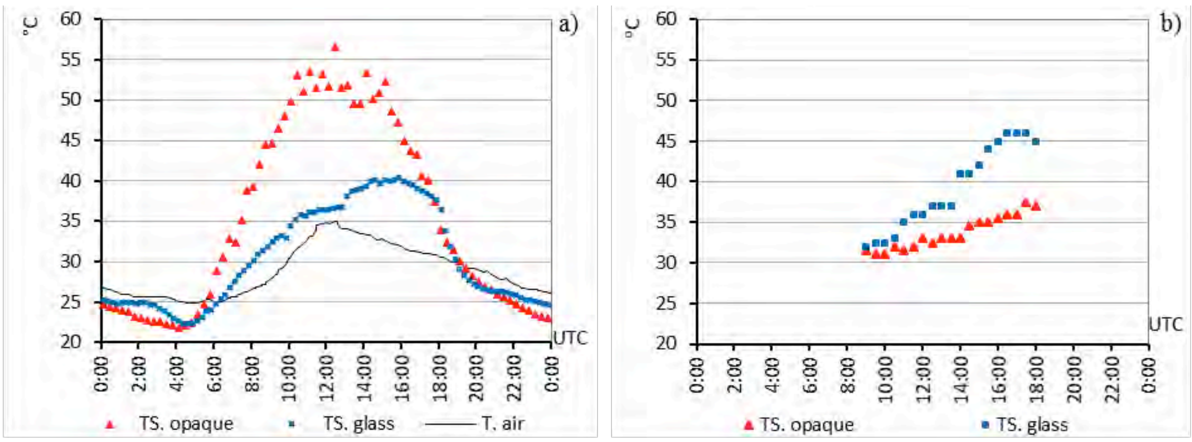

Figure 4. Glass and Opaque Surface temperatures a) exterior and b) interior

Results and discussion: Indoor.

Due to the air velocity measurements obtained (<0.4 m/s), the mean radiant temperature values are considered the same than the globe temperature values (Thorsson et al, 2007). Also, according to these air velocity values the operative temperature is equal to the globe temperature (ASHRAE, 2001).

Figure 5a, shows the indoor results of the air temperature (Tai) and the mean radiant temperature (Tmrt). Neither of these two parameters go under 30°C and their maximums are around 40°C. The indoor temperatures are higher than the outdoor air near the whole day. The average difference between inside and outside is 5°C. Moreover, Tmrt and Tai have the same behaviour and almost the same values in the entire period measured; the highest difference is in their peak time. Figure 5b displays the difference between the Tmrt and Tai (ΔTmrt-Tai). It is observed the range of difference goes from -0.4°C, very constant in night periods, to 1.53°C, in the peak time. Their maximums are around 17:00h, which coincide with the interior temperatures peak of the glass and opaque surfaces, Figure 4b. This reflect the large influence of these surfaces over Tmrt and the influence of this over Tai.

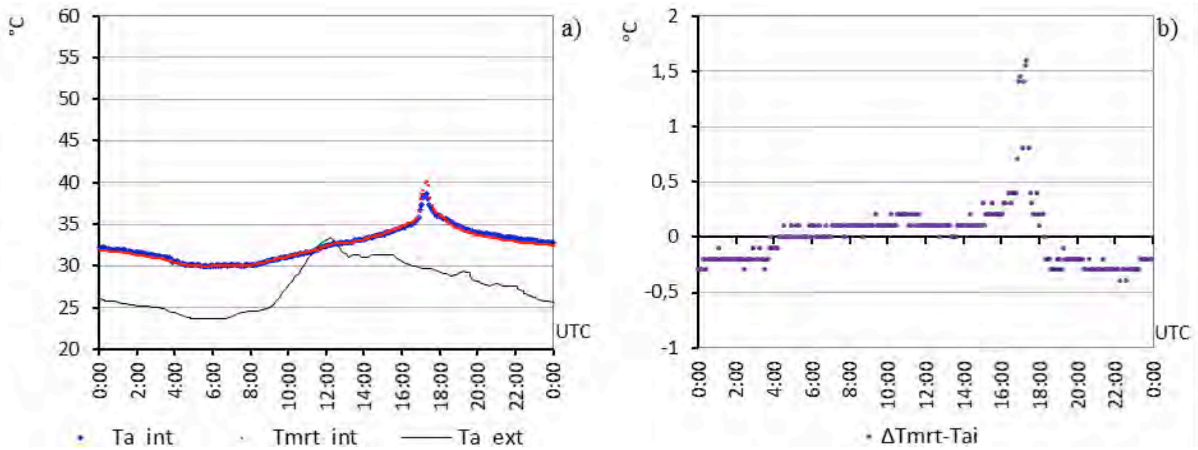

Figure 5. Indoor air temperature and mean radiant indoor temperature (a), and Difference between mean radiant temperature and air temperature (b)

In order to determine the independent impact of the roof surfaces over the interior ambient, it has been calculated the influence of surrounding surfaces over Tmrt. This parameter was calculated based on measured values of the envelope surface temperatures, and their positions respect to the chosen point, shape factor (SF) (Kabre, 2010) obtained from the software Heliodon (Beckers et al, 2003). Equation (1) was used for this purpose:

$$T_{mrt}^4 = \sum_{i=1} T_{si}^4 \, . \, F_{pi} \qquad (1)$$

Where, T_{mrt} = mean radiant temperature, in K, T_{si} temperature of surface N, in K, F_{pi} angle factor between a point and a surface N. If we refer to the specific case analysed, then the equation can be written as:

$$T_{mrt}^4 = T_{s.op}^4 \, .F_{p.op} + T_{s.g}^4 \, .F_{p.g} + T_{s.w}^4 \, .F_{p.w} + T_{s.f}^4 \, .F_{p.f} \qquad (2)$$

It has simplified the impact of the all surrounding surfaces to one interior point, in 4 surfaces, op = opaque surface, g = glass surface, w = walls, f = floor. Regarding the radiant temperatures, according to the thermal images, Figure 6, the floor and walls have almost the same values than Tai measured, while roof surfaces have higher temperatures. Thus, only roof surfaces are considered in the analysis of the influence over Tmrt. To obtain Ts.g.

and Ts.op. it has been averaged the 9 different points measured over each part. With respect to shape factor parameter, it has been simulated the angle factor between these 4 surfaces and one interior point with the same location of the globe thermometer.

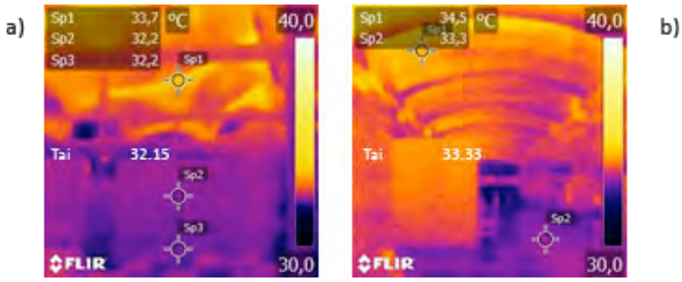

Figure 6 . Interior thermal image 10h00 UTC (a), and 14h00 UTC (b).

Figure 7 shows the difference between the global mean radiant temperature and the mean air temperature (ΔTmrt-Tai), depending on the different values of surrounding temperatures and their shape factors. In the axis X, the range of the surfaces shape factor values, from 0 to 0.5, since 0.5 SF will be the maximum angle factor between the roof and the point analysed. In the axis Y, the values of the difference between surface temperature and air temperature (ΔTs - Tai).

It has been analysed the influence of the Ts.g. and Ts.op. on Tmrt at two different heights: P1: 2.4 m which simulate the same location of globe thermometer, and P2: 4.8 m, a point located in a second floor. The analysis corresponds to temperature peak time, 17:00 h.

According to these results, the glass part has a higher influence over ΔTmrt-Tai than the opaque part on both points analysed. On P1, the influence of the glazed part is 0.84°C and the opaque part is 0.56°C, 60–40% respectively. Meanwhile on P2, the influence, in the same order, are 1.09°C and 0.57°C, 66-34% respectively. It can be observed that when the analysed point gets closer to the roof, the influence of both surfaces over ΔTmrt-Tai becomes higher. However the glass part increases its influence 0.25°C, while the opaque part 0.01°C.

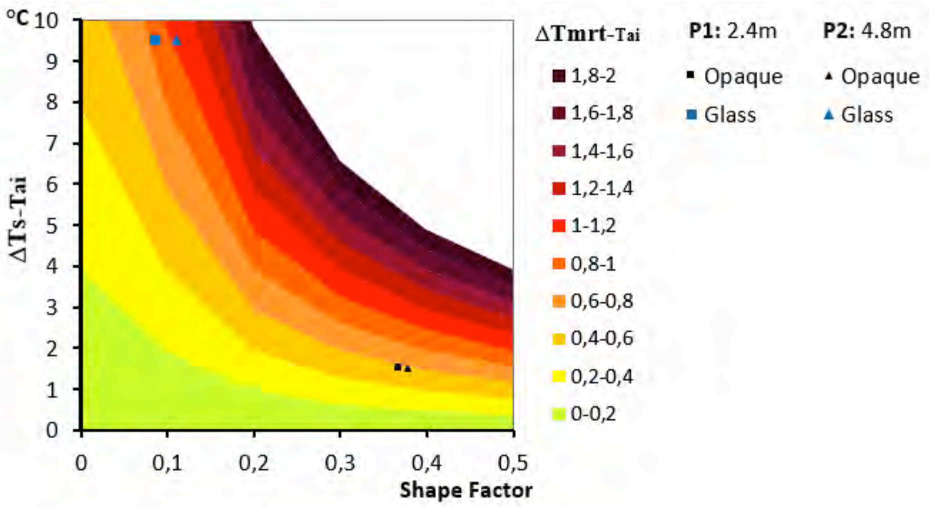

Figure 7. Shape Factor and ΔTs-Ta influence of the surrounding surfaces over Tmrt

Conclusions.

This research approach the analysis of the rehabilitated industrial building interior ambient conditions, focusing in the envelope radiative performance and its impact on the users.

The parameters analysed in this study, Tai and Tmrt, have a strong dependency on the roof thermal behaviour. Considering the whole building volume the highest heat exchange is with the roof surfaces, while the heat flux with the walls and the floor is negligible. In this sense, this analysis supports that the glass surface has the highest repercussion, between the all surfaces of the envelope, over Tmrt. The glass impact represents the 60-66% of the entire long wave radiation flux. This behaviour responds to the high temperatures reached by this surface, 47°C (maximum) although this surface is oriented to the North. These temperatures are determined by the constant action of the diffuse component throughout the whole day, and particularly to the heat radiation emitted by the opaque part, which diminishes the heat losses of this surface.

PLEA 2017 EDINBURGH
Design to Thrive

Development of simulation program that helps designers find potential overheating in houses

Yuko Tsukiyama

Architectural Technology Dept., Asahi Kasei Homes Corporation, Tokyo, Japan,
S-TEC Building 24-1, Nishi-shinjyuku 1-chome, Shinjyuku-ku, Tokyo 160-8345, Japan
tsukiyama.yb@gmail.com

Abstract: This study aimed to reveal the effect of solar radiation heat through windows and provided a simulation program to mitigate overheating in houses. First, we measured the amount acquisition of solar radiation heat through windows using a full-scale model house to reveal the effect of room direction. Second, we identified cases wherein house occupants felt uncomfortable because of overheating during summer and collected their house plans to check the typical feature of overheating. Using these existing house plans we determined the relation between the amount of solar radiation trough windows and occupants' uncomfortableness. Third, we adjusted the parameters in the analysis to calculate the solar radiation heat, examined the results of the simulation and then set the threshold to determine whether the room had the possibility of overheating in summer. Finally, we developed a simulation program that alerts designers of overheating at the stage of planning a house and it could help designers choose the most suitable solution for the overheating easily.

Keywords: overheating during summer, simulation program, experimental measurement, analysis of questionnaire

Introduction

Overheating, which is caused by both global warming and high insulation, has become a serious problem in recent years. In Japan, the main cause of overheating originates from solar radiation heat through windows, the size of which is relatively large in typical Japanese houses. The best way to confirm whether a room would be overheated is to calculate the room temperature using technical thermal simulation program. However, using such a simulation program is difficult for designers because of its complexity. When we simulate an indoor thermal environment, we must consider various effects such as heat capacity of the structure and absorption of solar heat into walls. Moreover, evaluating the phenomenon of overheating in detail is time consuming.

In this study, we aimed to provide a solution for mitigating overheating in houses more easily for designers. As only a few studies have been conducted on solar radiation heat through windows and overheating of houses, we constructed an experimental house to measure the relation between the acquisition of solar radiation heat thorough windows and the thermal indoor environment and analysed questionnaires about comfort during summer to develop a simulation program for overheating.

We already developed an original simulation program for indoor environments, called ARIOS. ARIOS can calculate and display the effects of the estimated sunshine hours on the floor and indoor natural ventilation routes (Figure 1). We considered adding the prediction function for the possibility of overheating to this program. The existing simulation program uses the Expanded AMeDAS Weather Data. Therefore, the new simulation for overheating should use the same weather data for convenience in calculating.

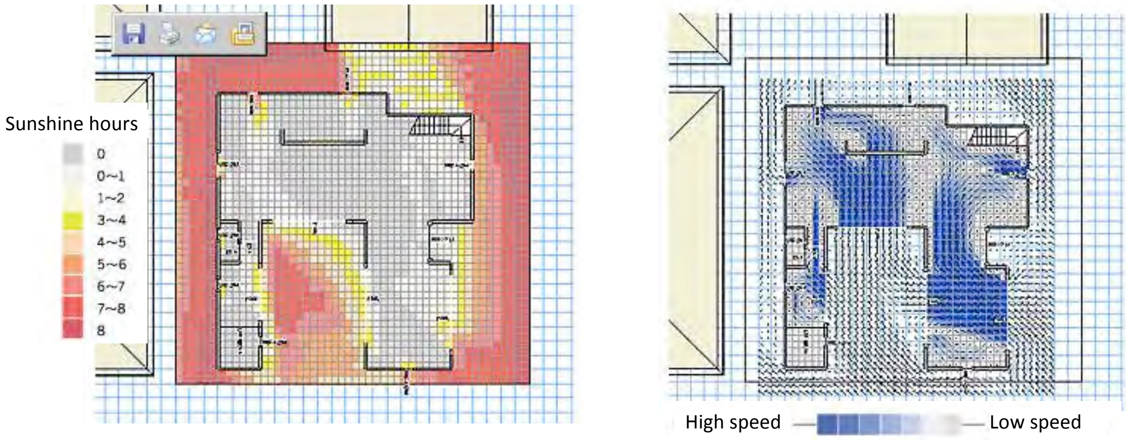

Figure 1. Display example of ARIOS: Diagram on the left represents the sunshine hours and that on the right illustrates the natural ventilation routes

Taking into consideration the factors mentioned above, we decided to use the acquisition of solar radiation heat to predict the possibility of overheating in rooms.

Measurements of a full-scale model house

Experimental methodology

The experimental house was constructed in Itabash-ku, Tokyo, Japan. The test rooms were located on the second floor to avoid sunlight blockage by nearby buildings. Two symmetrical rooms were used with openings in either the south and east or the south and west walls to compare the indoor thermal environment through different solar directions and their effects. Each room had a floor space of 13.4 m^2, a ceiling height of 2.4 m and openings consisting of double-glazed low-e glass with an aluminium sash. The main structure comprised a steel frame with autoclaved, aerated light weight concrete panels. Wall insulation consisted of high-performance phenolic foam 25 mm in thickness in the exterior walls, rock wool 100 mm in thickness in the ceiling chamber and rock wool 55 mm in thickness in the party walls. These features were the standard insulation used in Japan in 2004. All measurements were performed during the summer of 2004 using T-type thermocouples, globe thermometers and pyranometers placed approximately 1 m above the floor level in the locations shown in Figures 2 and 3.

As shown in Table 1, the five experimental modes were as follows: Mode-1 with solar radiation through all windows without (Mode-1a) and with (Mode-1b) air-conditioning (a/c) and Mode-2 with solar radiation heat through the southern window only without (Mode-2a) and with (Mode-2b) outer solar shading devices as well as changing the glass type to reduce heat from the sun (Mode-2c).

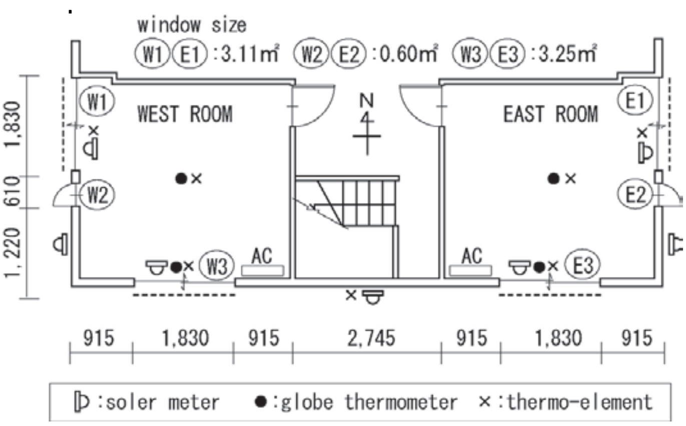

Figure 2. Floor plan and measurement point

Figure 3. West room interior

Mode	Type of glass		Solar shading		Air conditioning	Measurement day
	South	East or West	South	East or West		
Mode-1a	Double glazed low-e	Double glazed low-e	without	without	—	2nd-7th/July
Mode-1b	Double glazed low-e	Double glazed low-e	without	without	ON at 27 °C	11th-19th/August
Mode-2a	Double glazed low-e	—	without	—	—	7th-13th/July
Mode-2b	Double glazed low-e	—	with	—	—	14th-20th/July
Mode-2c	Double glazed low-e (to reduce heat from the sun)	—	without	—	—	21st-29th/July

Table 1. Experimental modes

Experimental results

Figure 4 shows the air temperature 1 m above the floor in the middle of the room (hereinafter called 'room temperature') and the inside vertical insolation and Table 2 presents the integrated value of insolation per typical day in Mode-1a (no a/c).

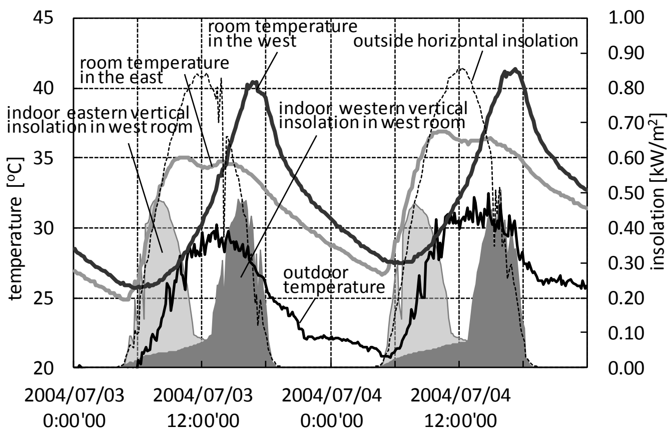

Figure 4. Temperature and insolation patterns in Mode-1a

Table 2. Integrated value of insolation per typical day in Mode-1a

Outdoor [MJ/m^2]				Indoor [MJ/m^2]	
Horizontal	Vertical			East	West
	South	East	West		
24.61	8.39	12.35	11.23	39.34	39.37

In Mode-1a (no a/c), room temperature in the east increased rapidly with the increase of outdoor temperature, reached a peak temperature of 35 °C at 10:00, remained stable at a high level until 13:40 and thereafter began to decrease gradually. In contrast, room temperature in the west showed a bell-shaped curve, and it reached the peak room temperature of 40.4 °C at 16:40. As shown in Table 2, the integrated values of the inside vertical insolation of both rooms were almost the same. Therefore, the difference in room temperature between the room in the east and that in the west was caused by the onset of the solar radiation heat through the windows in each room. The room in the east received solar radiation heat through the windows during the mid-morning hours when the room and outdoor temperatures had not increased yet, whereas the room in the west gained the solar radiation heat through the windows in the afternoon when the room temperature had already increased because of the increased outdoor temperature and heat of transmission through the walls and the roof. Therefore, we should consider the effects of heat gain which the room has already received in addition to solar radiation through windows in examining the room temperature in rooms facing west.

Figure 5 shows the room temperature and the inside vertical insolation, and Figure 6 illustrates the vertical temperature distribution of a typical day in Mode-1b (with a/c). As shown in Figure 5, the room temperature in both the rooms was stable at the a/c setting of 26 °C throughout the measurements. Figure 6 indicates the different trends of the vertical temperature distribution. In particular, the temperature close to the ceiling and the floor of the room in the west at 16:00 was over 30 °C, thus making difficult to maintain a comfortable indoor environment in the afternoon even though a/c was turned on.

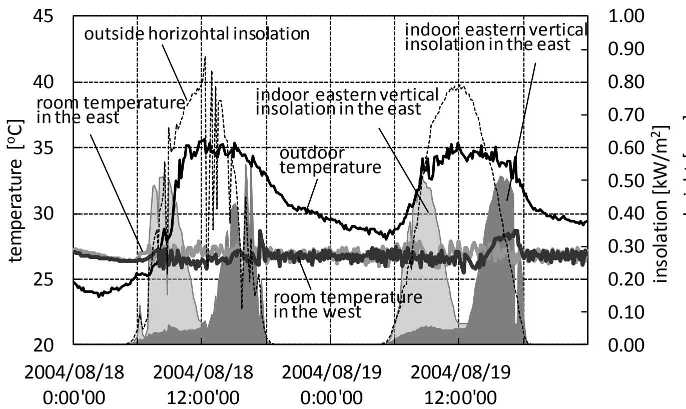

Figure 5. Temperature and Insolation patterns in Mode-1

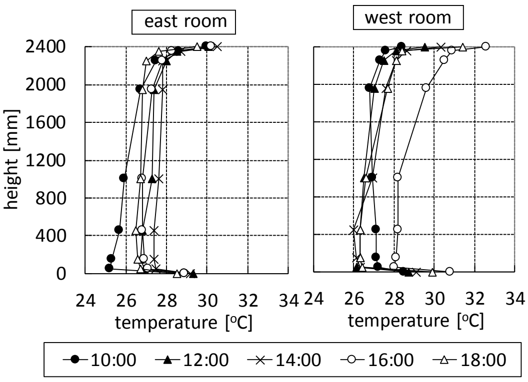

Figure 6. Vertical temperature distribution in Mode-1b

The solar radiation heat acquisition ratio calculated by the results of Mode-2 (southern window only) and the outside view of the opening are illustrated in Figures 7 and 8, respectively. In Figure 8, the image on the right shows the opening covered with an outer solar shading device. This removable outer shading device is made of polyester finished with resin. The solar radiation heat acquisition ratio was estimated as a relative value of the outside vertical insolation on the south wall by the amount of indoor vertical insolation in a typical day in each experimental mode, and it was similar to that of the outside environment.

Then calculated solar radiation heat acquisition ratios in Mode-2a (double-glazed low-e glass), Mode-2b (double-glazed low-e glass with outer solar shading device) and Mode-2c (double-glazed low-e glass that reduces heat from the sun) were approximately 40%, 25% and 30% respectively. This result reveals that the most effective solar shading method is installing an outer shading device. Each design value was 62%, 18% and 40% respectively, and the calculated value of glass was smaller than that of design value due to the high altitude of the sun in the measurement term.

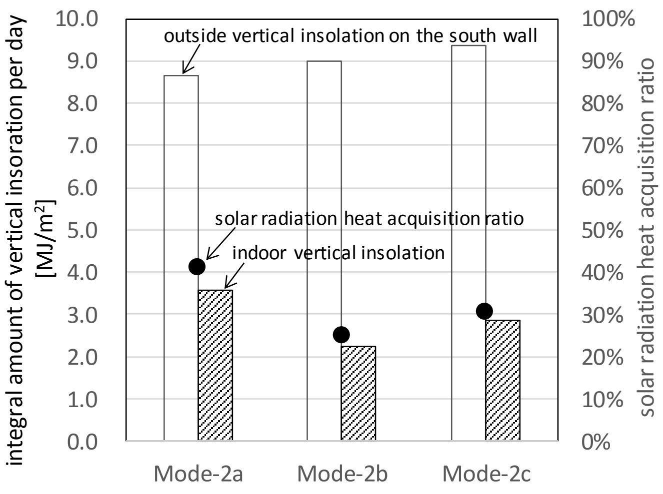

Figure 7. Solar radiation heat ratio in Mode-2

Figure 8. Outside view of the southern window (right: with outer solar shading device

Analysis of existing houses and the threshold setting

Extracting case studies on overheating

We identified cases wherein house occupants felt uncomfortable because of overheating during summer by examining the results of general questionnaires conducted by us regularly. The target subjects of the questionnaires were those who lived in the houses we built for more than one year. We extracted 87 case studies. Examples of the answers about overheating were ‘My room on the first floor is too hot during summer’, ‘My room facing west gains too much solar heat’. Simultaneously, we collected the subjects’ floor plans. We found similar features that could likely cause overheating such as large windows or no shading devices. Furthermore, the occupants revealed that small rooms, such as the kitchen or toilet, with windows on the western wall were too hot. To investigate the possibility of overheating of these houses, we conducted a simulation on the acquisition of solar radiation heat using the original simulation program called ACHIEVE which was developed based on the SMASH multizone dynamic thermal simulation program.

Customisation of parameters

The simulation aimed to determine which houses were likely to suffer from overheating in summer. Thus, we used a different approach from the usual thermal simulation: we customised the parameters. First, we redefined ‘simulation period’ to ‘July to September’ to be more specific. Furthermore, we extracted only the dates with a horizontal quantity of total solar radiation per day of over 14 MJ/m^2, and these dates were predicted sunny days.

Second, we calculated the outside temperature to adjust the calculated acquisition of solar radiation heat of the room facing west. Because we confirmed that the occupants were prone to feeling uncomfortable in the room facing west even if the acquisition of solar radiation heat through windows in the room facing west was similar to that in the room facing east in both the measurements results and the questionnaires. In particular, we added ‘outdoor temperature / 25 °C’ to the outdoor temperature when the outdoor temperature had been over 25 °C. By adjustment of this parameter, we could evaluate the effect of the direction.

Third, the solar radiation heat acquisition ratio of glass was specified in more detail. This ratio of glass could vary depending on the altitude of the sun but we used a fixed value for the thermal simulation program because of convenience of calculation. We set the different solar radiation heat acquisition ratios of glass at different solar altitudes to accurately calculate the acquisition of solar radiation heat through windows.

Results of the simulation

Figure 9 shows the results of the simulation of the 87 existing houses using the abovementioned customisation of parameters. The simulation used weather data of the place where the existing houses were built. The calculated acquisition of solar radiation heat is called the comparable acquisition of solar radiation heat (CASRH) to distinguish the value from the physical quantity of solar radiation heat. We set the unit of the calculated acquisition of solar radiation heat of the rooms to [kJ/m^2·mat]. Mat denotes the size of 1 tatami mat of 1.67 m^2, which is the standard unit to describe the size of rooms in Japanese houses. We chose this unit because it enabled us to compare the possibility of overheating in rooms with different sizes such as living room, kitchen and toilet.

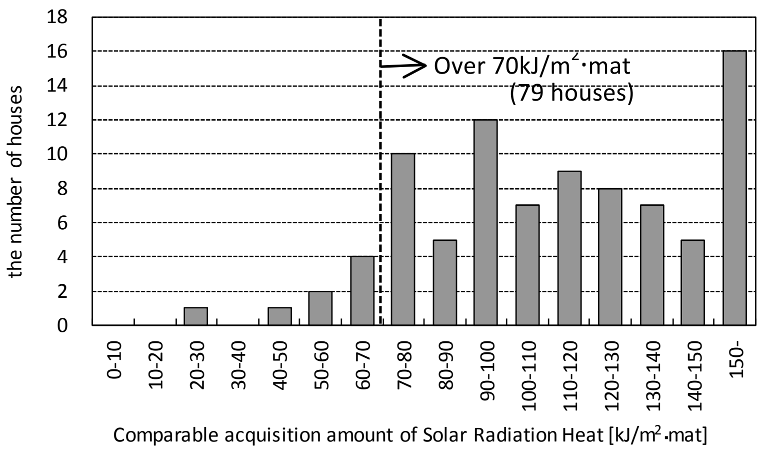

Figure 9. Results of the simulation of existing houses

If the threshold for judging overheating were set to too high/low figures, we could overlook the possibility of overheated houses or wrongly pick up rooms of non-overheated. To achieve 90% coverage, we temporarily set the optimum value for the threshold at 70 [kJ/m^2·mat] after trying several simulations.

Subsequently, we simulated the CASRH of three different solar shading devices to confirm the validity of the threshold using the weather data in Tokyo wherein most of the houses we provided were built. The simulation utilised the plan based on a typical Japanese room of 13.4 m^2 (eight mats) with a large window of 3.25 m^2 in the south wall and a small window of 0.6 m^2 in the west; both windows were made of double-glazed low-e glass in the model plan. Figure 10 illustrates the model plan and the results. The chosen solar shading devices were as follows: Mode-A with a window in the west changed to a double-glazed low-e glass to reduce heat from the sun, Mode-B with an outer solar shading device installed in the opening in the west and Mode-C with overhanging eaves over the southern window. We chose these solar shading devices because they were the most basic methods to reduce the acquisition of solar radiation heat against each direction.

The calculated CASRH values were Mode-A 69 [kJ/m^2·mat], Mode-B 59 [kJ/m^2·mat] and Mode-C 43 [kJ/m^2·mat], which were all under the threshold 70 [kJ/m^2·mat]. Thus, applying a solar shading device correctly could contribute to reducing CASRH to the level of below 70 [kJ/m^2·mat].

Considering these analysis, we set the threshold to 70 [kJ/m^2·mat] at this point.

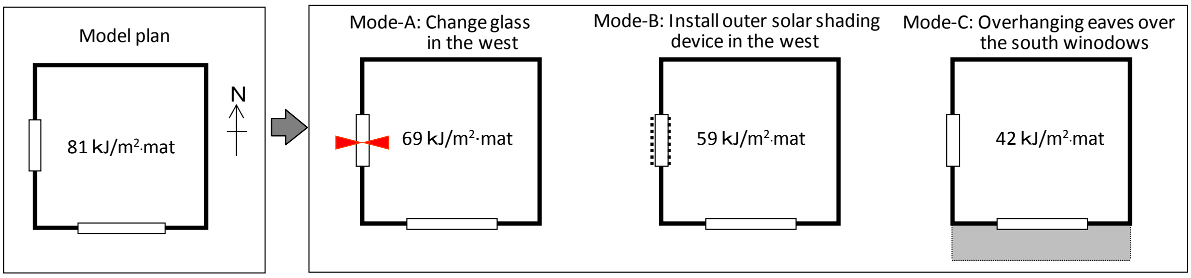

Figure 10. Results of the simulation of solar shading devices

Display of the simulation results

Figure 11 illustrates an example of the results alerting the possibility of overheating. The diagram on the left shows the result without countermeasures against overheating and that on the right shows the results after the plan is modified to prevent overheating.

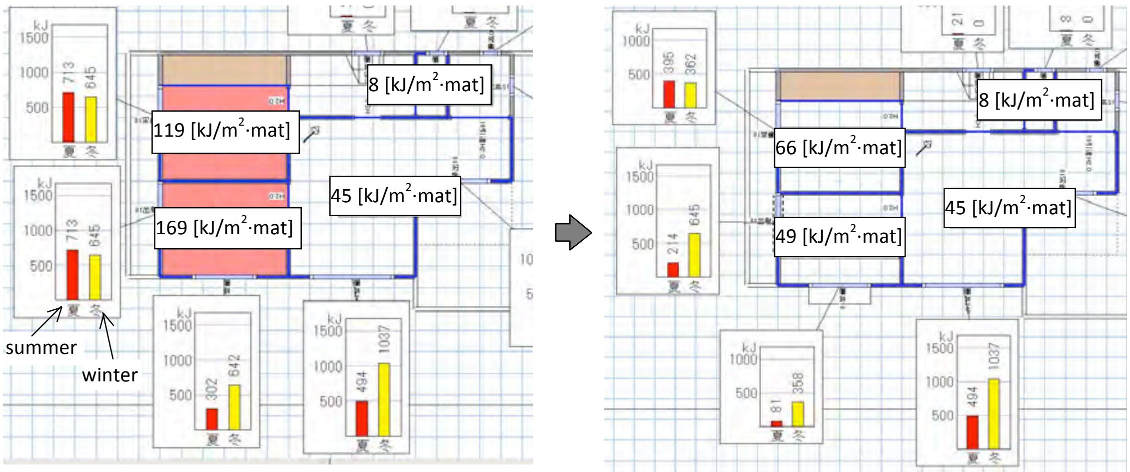

Figure 11. Illustration of an example of the results alerting the possibility of overheating (left: without countermeasures, right: with various solar shading devices)

Similar to the ARIOS simulation program, designers input the floor plan, choose the weather data of the place where the house was built and press the calculate button to simulate CASRH. The process takes only a few minutes. If the calculated CASRH is over the threshold of 70 [kJ/m^2·mat], the room is displayed in red and the simulated acquisition of the solar radiation heat through windows is marked at each window. Consequently, designers can easily find the rooms with the possibility of overheating in the stage of planning a house and provide an effective solar shading strategy for the window that gains much acquisition of solar radiation heat. In the illustration, we provide the acquisition of solar radiation heat through windows in winter because it varies with the season or method of solar shading. For example, a southern window with overhang eaves prevents much acquisition of solar radiation heat in summer, but it can gain abundant acquisition of solar radiation heat, which is effective in reducing heating energy in winter. Through the presentation of the acquisition of solar radiation heat in both summer and winter, designers can easily choose the most suitable solution for any situation.

Conclusion

To develop a simulation program that alerts designers of overheating, we conducted measurements using a full-scale model house and analysed existing houses that seemed to suffer from overheating. The measurements revealed that although the acquisition of solar radiation heat through windows was almost the same in the houses, the room temperatures in the rooms in the east and west were different. Moreover, the measurements showed the influence of solar altitude on the solar radiation heat acquisition ratio of glass. By analysing questionnaire and the floor plans of the existing houses we provided, we adjusted the parameters by which the threshold could identify the rooms with a possibility of overheating. Finally, we developed a simulation program that could help designers find potential overheating in houses.

In the future, the threshold will have to be adjusted if the thermal performance of a house is changed. This adjustment can be conducted easily using the proposed method.

Minimising Overheating in Passive and Low Energy Buildings Using Kriging-based inverse modelling techniques

Michael Wood[1], Matthew Eames[1] and Daniel Fosas[2]

[1] College of Engineering, Mathematics and Physical Science, University of Exeter, Exeter, UK
[2] Department of Architecture and Civil Engineering, University of Bath, UK.

Abstract: Preventing summertime overheating within passive buildings is important for the comfort of the occupants. The likelihood that a building will overheat depends on several factors, including the form of the building, the percentage glazing and the building's thermal mass and insulation. Furthermore, the amount of overheating depends on the criteria we use to measure it. We investigate the CIBSE TM52 overheating criteria and look at how they are affected by changes in the design of a *PassivHaus* style building. We calculate the percentage of possible buildings that pass each of the three CIBSE criteria using the *Gaussian process regression*-based *efficient global inversion* (EGI) technique. Our work is divided into two stages. First, we look at the sensitivity of the overheating criteria to the design (*i.e.* examining the building parameters that have the greatest effect on the overheating criteria). Second, we calculate the percentage of all possible building designs that meet these criteria using the EGI technique. This method provides an estimation of whether a building design will meet a criterion. This *surrogate modelling* method can be very accurate because the EGI technique 'tunes' the Gaussian process regression model to determine whether variables exceed a threshold. We explore the overheating criteria for 60,000 potential building designs. Our findings show that the relative glazed area has the greatest influence on the overheating criteria, whereas properties such as thermal mass and insulation have less effect than expected. Further work is needed to explore the effects on different building types in other climates.

Keywords: Overheating, Gaussian process, Inverse modelling, Design summer years

Introduction

To reduce the energy used by heating, many passive buildings are built with very low U-values. This minimises heat loss over the winter, but it can lead to overheating during the summer months. Since the form of the building affects overheating the most, buildings must be tested for problems before they are built (Jenkins et al., 2012). This means that we need to make use of computer simulations and simulated weather conditions so that design decisions can be made. Because of the need for computers in the design process, software simulations of buildings have a large influence on the building design.

The metrics used to measure overheating and the way that we measure overheating will influence the types of buildings that we design in the future. Our aim is to look at how *PassivHaus* style residential buildings might be affected by both the weather files and the parameters used to design them.

There are a potentially infinite number of building design parameters that can be adjusted, but some have been shown to be more important than others. These include the use (and size) of brise soleil, the amount of glazing, the orientation of the building and the relative amount of thermal mass (Eames et al., 2015; Banfill et al., 2012).

The weather files used for the dry in the simulation will also influence the building design. In the UK, design summer years (DSY) are used to test for overheating. In our work, we use the new CIBSE DSYs (Eames, 2016). These DSYs comprise of 42 weather years – 3 for each of 14 locations across the UK. The DSYs at each location each contain a moderate, and two separate near-extreme heat wave events (DSY1). One represents a year with a short more intense heat wave event (DSY2) and the other with a longer heat wave event (DSY3). We examine the effect of these extremes on the relative number of available building designs for each weather year.

We explore the effect of varying five continuous building feature on the potential overheating of the building as judged be various overheating criteria. However, as the building parameters are continuous, there are a potentially infinite number of combinations. Even if the features are limited to 20 discrete values each, the total number of simulations required would be 3.2 million. Therefore, to make this problem more tractable, we use a Gaussian process regression model to emulate the values for two of the three CIBSE overheating criteria from CIBSE TM 52 (Nicol, 2016)[1]. We have used GP models because the can be tuned to be very accurate at distinguishing between thresholds in a model. For example, if we know that we want one of our criteria to be below 3%, then we can tune the model to accurately predict whether certain building designs will be above or below this value.

Methods

Building model

The building model that we will analyse is a simple mid-terrace residential building. We simulate the results of the building model using *EnergyPlus v8.4* (US Department of Energy 2017). The building is designed to meet the standards required by *PassivHaus* (Hopfe & McLeod, 2015) and is shown in Figure 1.

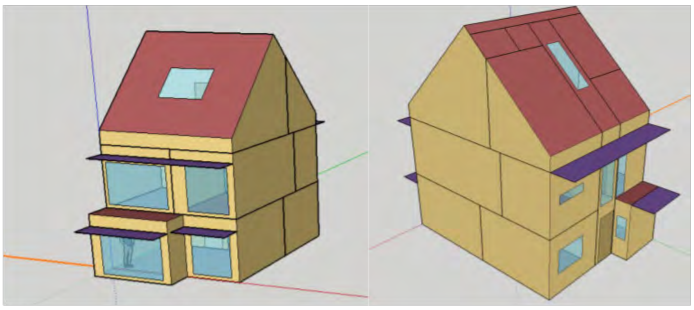

Figure 1: Building being modelled (maximum glazing and overhang shown)

The U-values for the building elements are shown in Table 1. The table also shows the glazing *g*-values, light transmission and the thickness of each of the elements used. We allow the glazed area, orientation, overhang distance, brick thickness, roof slab thickness and the position of the insulation to be varied. The maximum and minimum variables are shown in Table 2.

[1] We have not included CIBSE criterion 3 because we are not considering short temperature peaks.

Table 1: Thermal design of building

Variable	Value	Unit
U-Value Wall / Roof / Ground	0.10	$Wm^{-2}K^{-1}$
U-Value Door and $Window_{limit}$	0.85	$Wm^{-2}K^{-1}$
U-Value $Window_{real}$	0.76	$Wm^{-2}K^{-1}$
g-value	0.59	Ratio
Light Transmission	0.69	Ratio
Window layers (triple glazed)	5 / 12 / 4 / 12 / 5	mm / mm / mm / mm / mm

Table 2:Variables changed in the building model

Variable	Min	Max
Glazing area	2.6 m^2	26.0 m^2
Orientation (from North)	-90°	90°
Overhang distance (m)	0.1 m	0.9 m
Wall and roof thermal mass thickness (T_{thick})	100 mm	400 mm
Roof slab thickness	100 mm	400 mm
Relative size of internal to external wall leafs (R_{rel})	0.1	0.9

We use R_{rel} to calculate the relative thicknesses of the external (W_{ext}) and internal wall leafs (W_{int}) using the following equations:

$W_{\text{ext}} = T_{\text{thick}} \times R_{\text{rel}}$ and $W_{\text{int}} = (1 - T_{\text{thick}}) \times R_{\text{rel}}$

CIBSE TM52 Criteria

To test the buildings for overheating, we have used the new CIBSE design summer years (DSYs) for the UK (Eames, 2016). We used the DSY1, DSY2 and DSY3 weather files for Plymouth, London and Manchester and used them to calculate CIBSE 1 and 2 criteria (Nicol, 2016). CIBSE criterion 1 measures the number of hours where the internal operative temperature is above the maximum acceptable temperature (H_e) and CIBSE criterion 2 measures the *maximum daily weighted exceedance* (W_e). Both criteria are calculated based on a variable known as ΔT.

ΔT measures the exceedance of the maximum acceptable internal temperature. It is calculated on every time step of the simulation and is related to the operative temperature, T_{op}, that is in turn based on the air temperature, T_a, and the mean radiant temperature, T_r:

$\Delta T = T_{op} - T_{max}$ Where $T_{op} = \frac{T_a - T_r}{2}$

The maximum acceptable temperature T_{max} is dependent on the *running mean* temperature, T_{rm}:

$T_{max} = 0.33T_{rm} + 21.8$ (where T_{rm} is defined as: $T_{rm} = (1-\alpha)T_{od-1} + \alpha T_{rm-1}$)

Where T_{od-1} is the outdoor daily mean temperature for the previous day, T_{rm-1} is the running mean temperature for the previous day and α is an empirically derived coefficient (typically 0.8). These equations can be used to derive ΔT for each time step.

- **CIBSE Criteria 1: Hours of exceedance (H_e)** - Criterion 1 sets a limit on the number of hours where ΔT is greater than 1 between 1st May and 30th September. This is the number *hours of exceedance* and provides measure of the *duration* of the overheating periods. The criterion is expressed as a percentage of the occupied hours. To pass criterion 1, the percentage of occupied hours where ΔT is greater than 1, should be 3% or less.

- **CIBSE Criteria 2: Daily weighted exceedance (W_e) -** Where criterion 1 measures the duration of overheating, criterion 2 measures the relative *severity* of overheating events. The daily weighted exceedance, W_e, measures the daily overheating severity: $W_e = \sum_{h=1}^{24} \Delta T_h$ where h is the hours of the day. This criterion is satisfied if W_e is less than 6 for all days during the year.

Seeing the building as a mathematical function

The building model can be viewed as a function. This is because the computer model takes input variables (a vector of inputs, **x**, which describe the design of the building) and converts them into two outputs, CIBSE criterion 1 and CIBSE criterion 2. We can represent these outputs as $f_1(\boldsymbol{x})$ and $f_2(\boldsymbol{x})$. Note that the choice of weather file also affects the output (Figure 2).

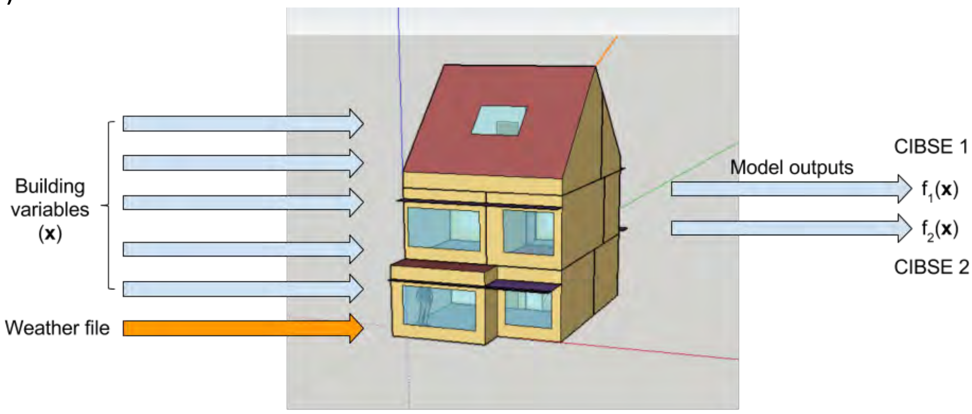

Figure 2: Representing the *EnergyPlus* building model as a function

Exploring the outputs of the building model using Gaussian process and Efficient Global Inversion

Since there is no analytic way to link $\boldsymbol{x}$ and $f(\boldsymbol{x})$, we need run the building simulator each time we want to obtain its output $f(\boldsymbol{x})$. It is possible to use the simulator alone for this, but if we want to explore a design space with more than 1 or 2 input variables, this quickly becomes a very large problem (see Bellman's curse of dimensions (Bellman 1957)). One solution to this problem is to use a surrogate model for the building model, $\hat{f}(\boldsymbol{x})$. Many different types of surrogate model can be used, but we use a Gaussian Process (GP) regression model.

We use GP regression in our model for two reasons. First, GP models allow us to explore a large sample of possible designs in a reasonable amount of time. The second is that GP regression models can be 'tuned' using a method called Efficient Global Inversion (Chevalier et al. 2014) to distinguish thresholds in the model with a relatively small number of training simulations. However, we first show how we create a regression model from the building.

GP regression has certain advantages over other regression methods. One of the nice properties of this method is that it requires relatively few training samples to provide good emulation, as little as 10 – 15 samples per input parameter (Loeppky et al., 2009) .

Efficient Global Inversion (EGI) iteratively improves the surrogate model and improves its ability to estimate a *threshold* within the model. This allow us to accurately predict whether a design will exceed an output value. In our case, we want to know whether the CIBSE criteria will be exceeded.

This is useful for our experiment in that we can build emulators with good accuracy at predicting whether the model has failed the criteria for the hours of exceedance (threshold at $H_e = 3\%$) or the daily weighted hours of exceedance (threshold at $W_e = 6$ degrees).

To improve the emulator at each threshold, EGI uses a three-step iterative process:

1. Create a surrogate model $\hat{f}(\boldsymbol{x})$ for the original building model $f(\boldsymbol{x})$
2. Predict the next sample $(\boldsymbol{x}_{n+1})$ that will improve the threshold estimate the most
3. Run the simulator at point $\boldsymbol{x}_{n+1}$ and return to step 1.

The surrogate model is created using a training set of inputs $\boldsymbol{D}$ (where $\boldsymbol{D} \in x$), which is created using a Latin hypercube design (Franco et al., 2011). This set of inputs are fed into the building simulator one at a time. This produces the *response* data $f(\boldsymbol{D})$. The input data and the response data are then used to *train* the surrogate model.

GP models are different from most linear regression methods as the outputs is represented as a multivariate Gaussian process:

$$\hat{f}(\boldsymbol{x}) \sim \mathrm{GP}(m(\boldsymbol{x}), v(\boldsymbol{x}, \boldsymbol{x}'))$$

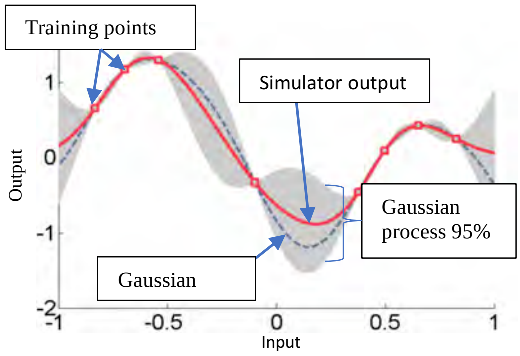

Figure 3: Gaussian process function and example realisation in one dimension

where $m(\boldsymbol{x})$ is the mean function and $v(\boldsymbol{x}, \boldsymbol{x}')$ is the variance function.

Although that output of the Gaussian process is essentially random Gaussian noise (with a mean of $m(\boldsymbol{x})$ and a variance of $v(\boldsymbol{x}, \boldsymbol{x}')$), this doesn't mean that we think the original simulator output is random. Instead, we are using the Gaussian process to allow us to express uncertainty in the output as demonstrated in Figure 3 above. The mean and variance functions of the Gaussian process model are estimated using a training set (□ shown in Figure 3). Standard functions govern the mean and variance. However, these functions require the tuning and estimation of hyper-parameters, who's derivation would be too lengthy to detail here. There interested reader is referred to *Gaussian Processes for Machine Learning* (Rasmussen & Williams 2006).

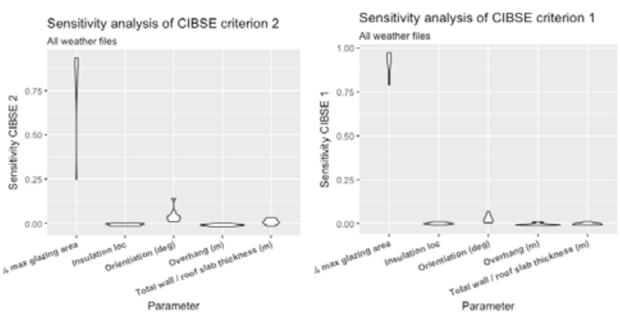
Results

Table 3 shows the percentage of buildings passing for both CIBSE criterion 1 and criterion 2 for each of the weather files tested.

Table 3: Proportion of emulated buildings passing the CIBSE criteria

Weather file	% passing CIBSE 1	% passing CIBSE 2	% passing both
London DSY1	49.8	5.4	5.4
London DSY2	86.5	66.0	66.0
London DSY3	43.6	0.4	0.4
Manchester DSY1	96.6	35.7	35.7
Manchester DSY2	90.9	27.2	27.2
Manchester DSY3	60.9	0.8	0.8
Plymouth DSY1	100.0	96.3	96.3
Plymouth DSY2	100.0	75.3	75.3
Plymouth DSY3	96.4	32.6	32.6

Figure 4: a) Sensitivity analysis of CIBSE 1 (left) of CIBSE 2 (right) for all weather files



The results of the sensitivity analysis show that the main first order effects on both CIBSE criterion 1 and CIBSE criterion 2 are the orientation and the % maximum glazing area. The analysis was conducted using the *sobol* function of the *sensitivity* package for *RStudio* (R Core Team, 2017; Sobol, 1993) . Figure 4 a) and Figure 4 b) shows a violin-plot of the sensitivities of the parameters across all the weather files tested. Figure 5 shows the compliant designs.

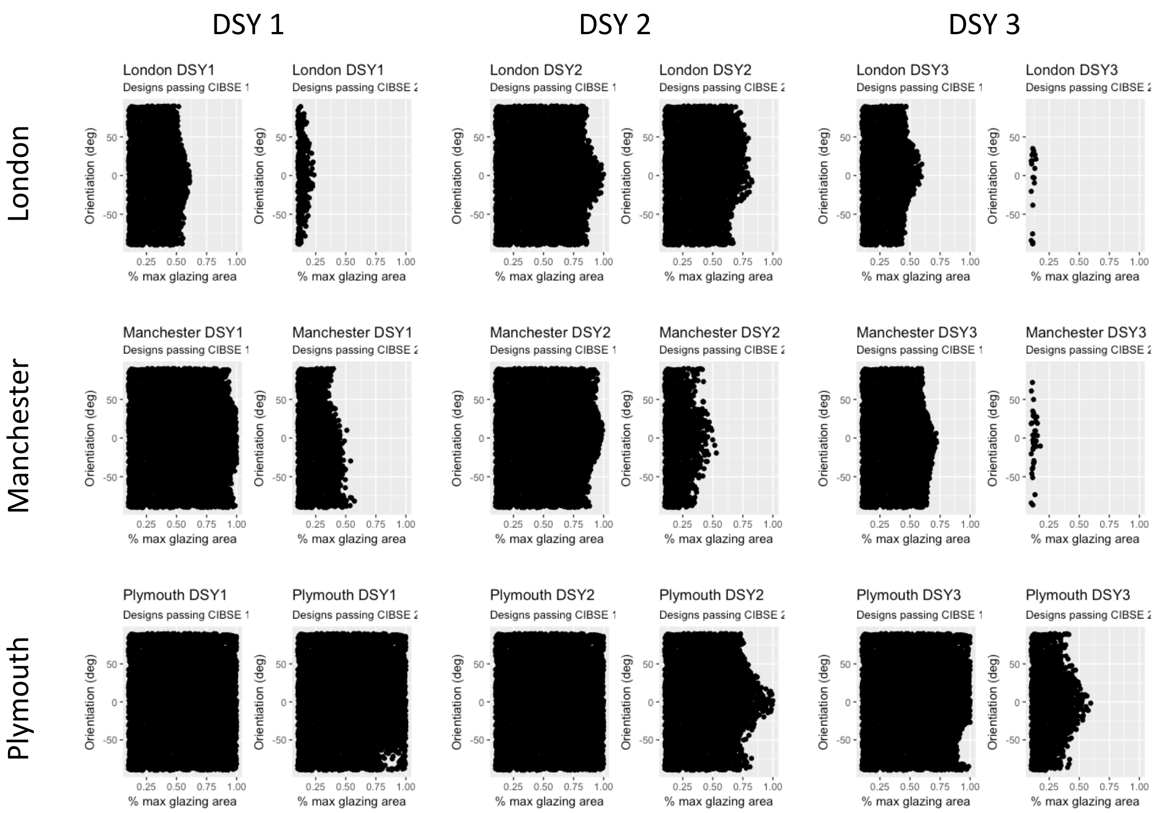


Figure 5: Plot showing the designs that pass the CIBSE 1 and CIBSE 2 criteria for each weather file

Discussion

The results in table 3 show that the % of buildings passing criteria 2 is overall less than those passing criteria 1. It also shows that a much larger percentage of buildings pass criteria 1 than criteria 2. The later as few as 0.4% of buildings pass criterion 2 for London DSY3. The percentage of buildings passing both criteria is the same as those passing criterion 2. Further investigation has shown that all buildings that passed criterion 1 passed criterion 2.

The results of the sensitivity analysis show how the biggest factor influencing both criteria 1 and criteria 2 was the glazing area. Across all weather files, the sensitivity of both criteria to the glazing area was between 0.79 and 0.97 (criterion 1) and 0.25 and 0.94 (criterion 2). Of the remaining variables, orientation has the greater influence, but this is not significantly more than the influence of the insulation location, overhang and the total wall / roof slab insulation thickness. Interestingly the amount of thermal mass appears to have limited influence on the overheating response in all cases (at least compared to the other variables).

Knowing that the orientation and the glazing were the biggest influencers of both overheating criteria, we plotted the buildings that pass each of these criteria in Figure 5.

The results of this analysis show a wide range of compliant designs. Not surprisingly, the buildings with the lowest glazing consistently pass both criteria in all cases. The exception is for London DSY3 and Manchester DSY3, where only a handful of buildings pass the criterion 2. The orientation also influences the overheating. In Figure 4, we can see a pattern where the number of compliant buildings increases for both criteria (though particularly criterion 2) where the lounge side of the building is facing due south (i.e. *orientation = 0 degrees*). This can best be seen for Plymouth DSY3 (criterion 2) and London DSY 3 (criterion 3).

It is well understood that solar radiation plays an important part in overheating. However, our results show that even with the same building designs, the pattern observed is different. For example, comparing the results of criterion 2 for Manchester DSY1 and DSY2 we see different patterns. Both have around the same number of compliant designs, but the *pattern* of where those designs lie is different (see Figure 4).

We expect the number of buildings passing DSY2 would be less, which is true (27.2% *vs.* 35.7%), but the pattern of building designs in DSY1 is more skewed to an orientation of -90 degrees, whereas the DSY2 has more high glazing options at orientations around 0 degrees.

Given that criterion 2 is based on a single day's-worth of overheating, there are several possible explanations for this pattern. One explanation is that cloud cover may play a major role. Since the hottest day will trigger criterion 2, then on this day, it may be that there is more cloud cover in the weather file during different periods of the day. There needs further investigation, but if cloud cover can influence the design in this way, then this has important implications for weather file design.

Conclusion

We have demonstrated the results for a *PassivHaus*-style building design. The results show that the glazing and orientation are the biggest determinants over the overheating risk. Further work is required to investigate these same relationships for other passive and low energy design methodologies. Also, these findings may also only be relevant to the CIBSE overheating criteria. Further work may also consider looking at other overheating criteria.

However, it is clear from the results that it is very likely that the relative glazing area is the biggest design parameter affecting the amount of overheating in passive-style buildings.

Passive Design Strategies for Energy Efficient Housing in Nigeria

Maryam Abbakyari[1] and Ahmad Taki[1]

[1] Leicester School of Architecture, De Montfort University Leicester, LE1 9BH UK

Abstract: The varying manifestations of climate change are greatly impacting our lives and livelihoods principally due to the activities of industries that pollute the atmosphere and use up non-renewable resources to fuel our growth and development. It is estimated that approximately one third of the worlds energy is consumed within buildings of which approximately 60% is through air conditioning systems. The aim of this research is to investigate various passive design strategies to improve the energy efficiency of a typical mass housing type in Nigeria. A case study of mass housing was carried out to select a sample that was used to conduct a thermal analysis using EnergyPlus tool. The first stage was optimising the building fabric which involved proposing a sustainable alternative to the conventional masonry material. Next was the application of passive strategies aimed at achieving lower energy load for cooling. The building simulation showed a significant 30% reduction in cooling. This is significant particularly because of the inadequate and unreliable electricity supply in Nigeria which leads to reliance on fuel based backup power generation systems.

Keywords: climate change, air conditioning systems, passive design, energy efficiency

Introduction

Climate change is having a tremendous effect on our fragile ecosystem where the acceleration of its effects is believed to have occurred as a result of human activities that release greenhouse gases (GHG) into the atmosphere (Golubchikov and Badyina, 2012). It is estimated that the building sector accounts for 40% of the world's energy consumption and related one-third of global GHG emissions where approximately 80% of the energy is through air conditioning systems and artificial lighting (UNEP-SCBI; Rupp et al, 2015). In the 4th Assessment Report of Intergovernmental Panel on Climate Change (IPCC AR-4) it is estimated that GHG emissions from building related activities could nearly double by 2030. However, the report concluded that the building sector has the largest potential for reducing GHG emissions. Studies have shown that the most effective and least expensive way of reducing the effects of climate change is by using less energy (Lechner, 2014).

The power sector in Nigeria is faced with a crisis of persistent epileptic supply of electricity due to vandalism of pipelines and shortage of gas to the power plants. The amount currently generated is far below the expected supply load of 12,800MW for the current infrastructure (Sambo et al, 2012). This short fall has left at least 50% of Nigerians without access to electricity which consequently led to reliance on back-up generators by household and businesses. The power produced by these petrol or diesel generators is estimated to represent about 80% of installed capacity of the national grid (Oyewunmi and Iwayemi, 2016). Carbon emissions from domestic generation in Nigeria are greater than those from workplaces, buses and trucks, and pose potentially risky challenges to people's health and the environment due to long-time exposure (Oseni, 2016). Hence, there is urgent need for the implementation of energy efficiency in domestic building design and construction in Nigeria.

Literature Review

Energy efficient buildings

The Chartered Institute of Building Service Engineers (CIBSE, 2012) describes an energy efficient building as one that provides the required internal environment and services with minimum energy use in a cost effective and environmentally sensitive manner. Research has established that by making relatively simple alterations to the building at the concept design stage can have a significant effect on the potential energy performance. Some of the environmental and economic benefits in delivering energy efficient buildings are reduced running costs, reduced environmental impacts, improved ambient condition and increased equipment life (Abimaje and Akingbohungbe, 2013).

Strategies for Energy Efficiency in Buildings

Strategies for Energy efficiency in buildings as described in CIBSE Guide (2012) are approaches through which the energy consumption of a building can be reduced while maintaining or improving the level of comfort in the building. Reducing demand is the most important principle of energy efficiency strategy because it gives designers the opportunities to design buildings in a way that tends to reduce their energy demands in the early stages (CIBSE, 2012).

Lechner (2014) illustrates the energy efficient strategies in form of "A Solar Fruit Tree" stating that efficiency is the low-hanging fruit as seen in Figure 1. The "Solar Fruit Tree" shows not only all the major solar strategies, but places them at various heights in relationship to the order in which they should be picked. "Some low-hanging-fruit strategies are free or can even save money by reducing the initial cost of a building" (Lechner,2014).

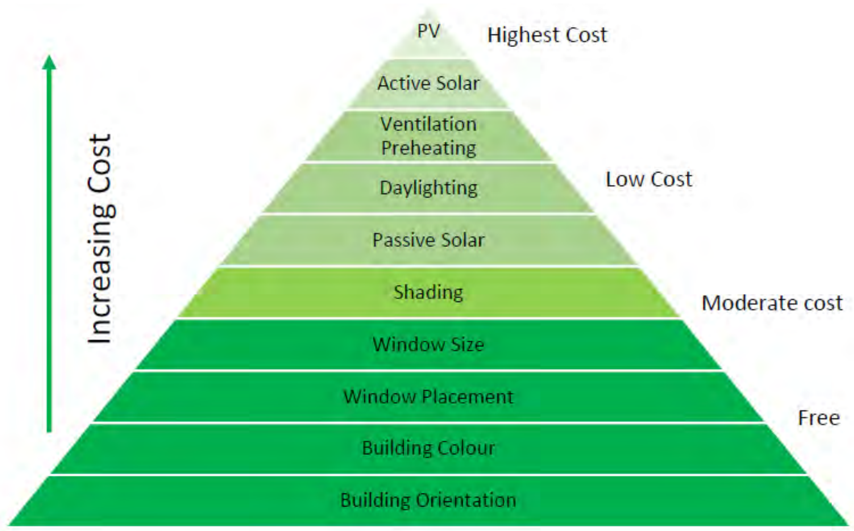

Figure 1. The solar fruit tree chart showing the free and costly strategies
Adapted from: Lechner (2014)

Passive design approach

Passive design is design that works with the environment to exclude unwanted heat or cold and take advantage of sun and breezes (Cairns Regional Council, 2011). One of the main passive design principles for buildings in tropical climates is avoiding heat gain through proper orientation, shading of walls and windows, insulation, use of thermal mass, use of heat and light reflective surfaces. To achieve the aim of this study, the solar fruit tree approach would be applied in selecting the free to low cost strategies. The elements to be investigated starting from the lowest hanging fruit are orientation, colour and window to wall ratio, and shading. Shading, although is not free would be included due to its high benefits in heat avoidance. These benefits could potentially be offset by the energy that would be saved.

Orientation

Orientation refers to the way a building is placed on site to take advantage of climatic features such as sun and cooling breezes (McGee,2013). East and west facing walls receive the highest amounts of radiation, especially during hot periods. Therefore, the best orientation in the tropics is rectangular with long axis running east-west in order to minimise solar heat gain through the long façade (Abimaje and Akingbohungbe 2013; Gut,1993).

Colour

Use of light colours on the exterior surfaces of the building fabric helps to lower heat build-up (Cairns Regional Council, 2014). Studies have shown that the total air-conditioning in many buildings can be reduced by 20% just by increasing the solar reflectivity of the roof and walls from a typical medium-dark value of 30% to a light-coloured value of 90%. Solar reflectivity, which is also known by the term “albedo”, is a number that indicates how much of the solar radiation is reflected from a surface. An albedo of 0 indicates that no sunlight is reflected while an albedo of 1 indicates that all sunlight is reflected. The colour white has the highest solar reflectivity with an albedo of about 0.9 (90% is reflected) if it is fresh, clean, and glossy (Lechner, 2014).

Window size and location

Glazed windows and doors have very important functions in letting in natural light and fresh air. However, in the tropics, they are the main sources of undesirable heat gain reaching up to 87% (McGee,2013). The ideal design would have only south and north windows and no east or west windows. When that is not possible, the number of east and west windows should be minimized and the number of north and south windows maximized. Making windows on the east and west facades smaller than those on the north and south facades is another free strategy to save energy for cooling (Lechner, 2014).

Shading

Shading is one of the most important strategies especially in the tropics where the solar angle is overhead throughout the year. (Stouter,2008). Shading buildings and outdoor spaces helps to moderate temperatures, improves comfort conditions and saves energy. External shading devices are the most effective barrier against the sun by preventing up to 90% of heat gain (Lechner, 2014; McGee,2013). Most shading devices consist of either vertical fins, horizontal overhangs or both combined. The overhangs have many variations and are the best choice to use for the south façade particularly in the tropics where solar heat gain is not desired. The eaves should be at least 800mm wide and located far above windows to ensure they adequately shade windows and walls from direct solar radiation (Cairns Regional Council, 2014).

Methodology

Sample location

The sample selected for the investigation is in Abuja which is Federal Capital Territory of Nigeria. Abuja is located within Latitude 9° 03' N and Longitude 7°29' E with altitude highs of

476m above sea level. It is surrounded by highlands, hills, savannah grassland and covers a land area of about 8000km^2. Abuja under Koppen climate classification features a tropical wet and dry climate. March is the hottest month and August the coldest with average temperatures of 30°C and 25°C respectively. Average humidity range in Abuja falls between 60-70% (Abdulkareem and Al-Maiyah et al. 2015).

Research Strategy

The methods applied for the research are analytical where a review of mass housing was carried out and experimental research which involves the computer based simulation to quantify the energy consumption of the sample as well as the manipulation of the variables to evaluate the potential impact on the energy load for cooling. This method was selected as appropriate due to its characteristics of being a standard tool for conducting experiment which also reveals objective results.

Sample description

The sample selected for study is a three -bedroom bungalow which is a typical mass housing type for the average family in Nigeria. The wall construction method consists of the conventional sandcrete blocks with plaster on both sides while the roof is a pitch roof with long-span aluminium roofing sheet covering. Refer to Figures 2 and 3 for the floor plan and cross-section of the building.

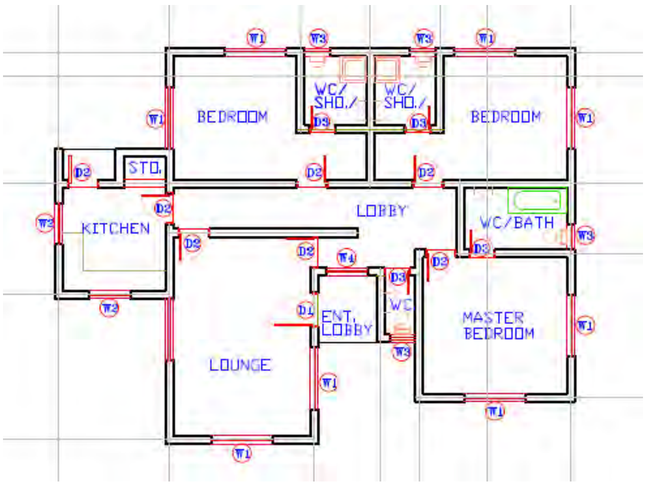

Figure 2. Floor plan- not to scale

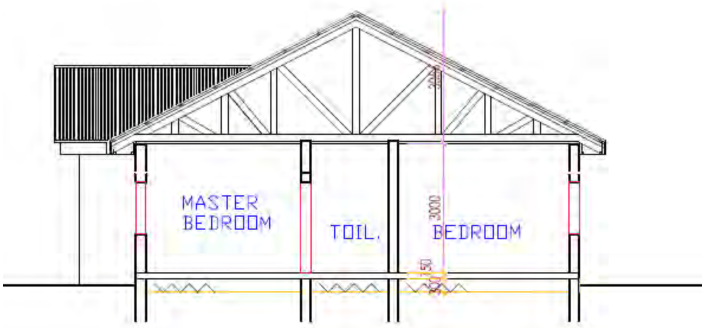

Figure 3. Cross section- not to scale

Building Simulation

EnergyPlus tool was used to construct a base-case model for assessing the thermal performance of the building for a range of dynamic thermal simulations. The constant variables throughout the simulation were building activity template, occupied floor area, occupancy, airtightness and lighting (LED-3.3W/m^2).

Energy Simulation of Base-Case Model

The base-case model was simulated to determine the annual energy consumption for cooling the building. The result shows the cooling load of **11245kWh**. This value would be used as the base for comparison after applying the passive design measures to improve the energy efficiency of the building.

Thermal Analysis Using Passive Design Strategies

The strategies for heat avoidance were used with the aim of investigating the effect of employing free to low cost strategies on the energy consumption for cooling the building. The elements were selected based on passive design strategies suitable for the tropical climate of Abuja. Before applying these strategies, the walls were replaced with a sustainable alternative. Compressed Earth Bricks was proposed to be used in place of the sandcrete blocks due to its cost effectiveness and better thermal properties. A reduction in cooling load of 8% was achieved.

Orientation

The model was analysed with the façade facing different orientations in where the North facing gave the least amount of cooling load. This gave a cumulative reduction of 12%.

Colour

The review of literature reveals that by simply changing the roof colour from red to reduces heat gain into the building. The simulation results gave a lower roof temperature by approximately 3^{o}C. A further cumulative reduction in cooling load of 16% was achieved.

Window to Wall Ratio(WWR)

To reduce the effect of direct solar radiation, the east and west facing windows were reduced while increasing the size of the north facing windows to let in cool air. These changes resulted in overall lower window to wall ratio from 24.8% to 21.4%. A cumulative reduction in cooling load of 19% was achieved.

Shading

Shading is not free but cost effective due to the amount of reduction in cooling load achieved. An extension of roof overhang was proposed as the most suitable low cost strategy for shading the windows in this analysis. A depth of 1070mm was calculated to shade the whole window but a depth of 1100mm was used to further shade part of the walls below the window sill. In addition, venetian blind was added to the outside of the east and west facing windows. This resulted in a cumulative reduction in cooling load of 30%.

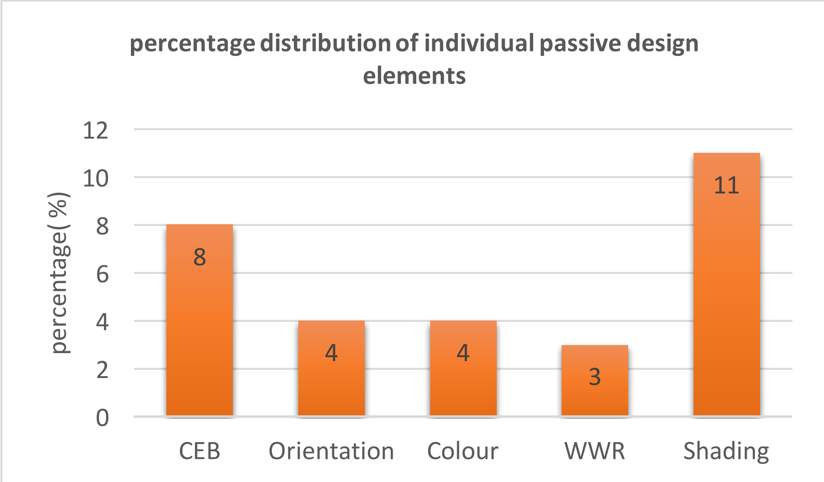

Figure 4. Percentage distribution of passive design elements

Energy Simulation of Improved Model

The energy simulation of the improved model resulted in a lower annual cooling load of **7928kWh.** This gives a difference of **3317kWh** between the base-case model and the improved model which is a **30%** reduction in cooling load as shown in Figure 5.

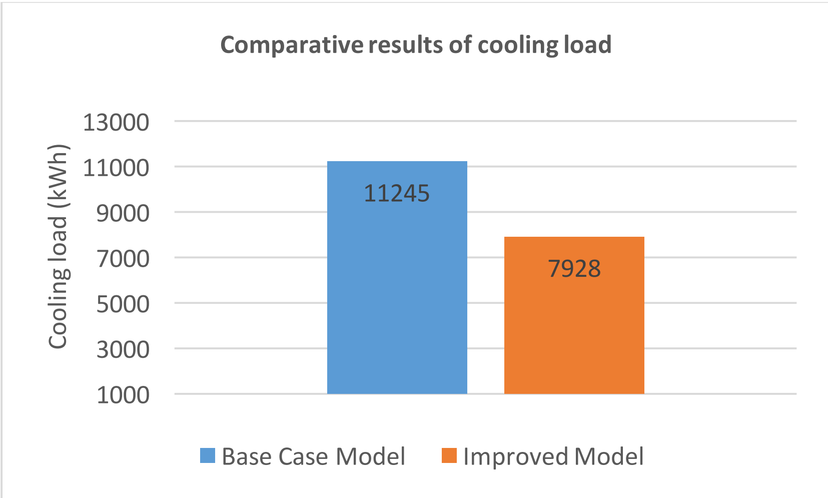

Figure 5. Comparison of cooling load between base case model and improved model

Conclusion

In recognition of the impact of climate change on the environment, this study investigated the effect of free to low cost passive design strategies on the energy efficiency of mass housing in Abuja. Abuja being the capital city of Nigeria is a focus of economic activities that has led to an influx of people contributing to a rise in housing demand in the city. In view of this, the implementation of passive design strategies is a simple and cost effective means of providing energy efficient housing.

This research reveals that heat avoidance is the first and most important passive strategy for energy efficient buildings. These were best achieved by picking the 'lowest hanging fruit' i.e. beginning with the simple and free strategies before reaching the costly ones. The masonry material was first replaced with Compressed Earth Brick (CEB) as a sustainable alternative to the conventional sandcrete blocks before applying the passive design strategies. The overall performance of the building gave a result of 30% reduction in cooling load. Overall this research has proven that energy efficiency can be achieved at low cost. The outcome concurs with IPCC AR-4 report where it states “the energy consumption in buildings can be cut by an estimated 30-50% without significantly increasing investment costs”.

Passive cooling consideration in the effective planning and design of public buildings in Nigeria

Solomon Adewumi[1], Joseph Fadamiro[2], Vincent Onyango[1], Dumiso Moyo[1] and Husam Alwaer[1]

[1] Architecture and Urban Planning, University of Dundee
[2] Federal University of Technology Akure, Nigeria

Abstract: The rapid increase in the growth of Nigerian cities as a result of mass rural-urban migration has led to a demand for more public buildings. The ongoing campaign on sustainability backed up with the statistics that confronts us daily have necessitated the need to deliver more environment-friendly public buildings. This study is aimed at enhancing sustainable utilization of energy through passive cooling in the planning and delivery of public buildings with optimum design condition for users' comfort in Nigeria. The objectives are: (i) to identify the factors that enhances the passive performance of a building (ii) to measure these factors through case study survey and post occupancy evaluation of three existing public buildings (iii) to arrive at optimum design conditions using passive cooling in public buildings. Findings showed inadequate consideration of the design strategies that enhance the passive performance of a building due to dependence on the active cooling means in public buildings visited. The paper recommended a policy framework for the planning of public buildings and canvassed the need for professionals in the built industry to consider how key design strategies can be considered in the early stage of their design decisions that will lead to sustainable public buildings.

Keywords: Energy, passive cooling, policy, public buildings, thermal comfort

Introduction

According to recent statistics, the building industry accounts for more than 40% of the total energy consumption (Edward, 2012; Santamouris, 2005). While the awareness on climate change continues to intensify, it is needful to cut energy consumption to a reasonable amount because the quality of urban life and the global environmental quality of cities is dependent on net energy consumption (Santamouris, 2005). Consequently, energy efficiency is now a basic requirement for the designing professions (Roaf and Hancock, 1992). Going forward, active cooling which involves the use of air conditioners to maintain thermal comfort in a building needs to be critically reconsider for a passive approach for an effective planning and delivery of building projects (Ghiaus and Roulet, 2005).Passive cooling strategy employs a non-mechanical means to achieve a comfortable indoor temperature (Kamal, 2012; Larsen, 1998). Passive cooling helps to reduce the temperature of buildings without need for energy or power consumption (Taleb, 2014). Some of the passive cooling strategies include: solar shading; insulation; induced ventilation techniques (such as solar chimney, air vents, and wind tower); relative cooling; evaporative cooling; and earth coupling among others (Adewumi, 2012; Santamouris and Asimakopolous, 1996). However, due to the differences in climate and technological know-how, the passive cooling strategy adopted for use in a particular region may not be applicable for use in another context (Taleb, 2014). For example, design solutions employed in the tropics is likely to be a misfit in a temperate region.

This paper attempts to investigate how passive cooling consideration can enhance effective planning and design of public buildings with optimum design condition for users in Nigeria. This is with the rationale that building occupants are not passive in relation to their thermal environment as they tend to seek comfortable environments (Humphreys, 1992; Lush, 1992). The choice of public buildings is justified on the basis its energy demand is higher compared to residential buildings (Liu et al, 2012). Other sections of the paper include: section 2 which is a critical review on passive cooling identifying the factors that enhances the passive performance of buildings; section 3 explains the methodology of the study while section 4 highlights the results and discussion of findings; and section 5 gives the conclusion and recommendations.

Theoretical concepts of passive cooling

Passive cooling operates with the principle of preventing heat from entering into the building or removes it once it has entered into the building (Kamal, 2012). This principle helps to reduce energy consumption from peak cooling load. Ability to maintain a cool environment during warm periods is crucial for optimum utilization of human resources and productivity (Santamouris and Asimakopolous, 1996). With its environmental, indoor air quality, and economic benefits, the passive cooling of a building can be enhanced by its passive performance which is a function of its:

(i) Planning and design and;
(ii) Passive cooling strategy.

Planning and design

Jackson and Jackson (1997) suggested the following design attributes which define the passive performance of a building as explained:

Building Orientation
A building's orientation is its position with respect to the geographical coordinates. Proper building orientation increases the energy efficiency of a building which makes the building cheaper to maintain as it reduces the chances for the need for heating and cooling systems. Givoni (1994) asserts that the main consideration in building orientation is the positioning of its windows. High penetration of solar energy through large openings in a hot weather can increase the indoor temperature causing thermal discomfort and increasing the building's cooling load. A south-facing window will most times receive most sunlight while a north-facing window will only have it on few occasions in the early morning and late evening (Littlefair et al, 2000). A detailed site analysis is therefore essential early at the planning phase which will provide adequate information on temperature, wind, humidity, rainfall, and solar radiation among others.

Building shape
The geometry of a building in terms of its width, depth, and height determines its passive performance. To enhance passive cooling, buildings should be compact with surface area of its external envelope been kept as small as possible so as to reduce the heat flow into the building.

Windows and opening sizes
Size of windows needs to be considered to optimise passive cooling in a building. Large openings tend to admit more solar radiation than smaller ones. Givoni (1994) posited that heat gain through windows per unit area is much higher than through walls or roof especially in the absence of sun shading devices. Building design in a tropical area should aim at minimizing heat gain indoors and maximizing evaporative cooling (Lawal et al, 2012). Ventilation rate should be kept to the minimum required for health to reduce the heating of the interior by the outdoor air. Proper ventilation can improve thermal condition in indoor spaces and decrease energy consumption of air conditioned buildings (Santamouris, 2005; Routlet, 2005; Roaf et al, 2007)

Shading characteristics of building
Shading devices are essential for reducing the heat (solar radiation) entering buildings which helps to improve thermal comfort and reduce cooling loads (Littlefair et al, 2000) by blocking 90% of solar radiation. Shading devices can either be adjustable or fixed. The latter which are architectural elements provide means to articulate building facades while the fixed which can either be external or internal are operable. Examples of shading devices include overhangs, colonnades, movable screen and shutters.

Passive cooling techniques

In hot climates characterized with high solar radiation all through the year, passive cooling is one of the most difficult problems to solve. The simplest and the most effective solution for active cooling is to introduce air conditioning. However, as these systems do incur high initial cost with huge operational cost for installation, energy and maintenance, a passive cooling system is more desirable. Givoni (1994) identified the following seven passive cooling strategies: (i) comfort ventilation; (ii) nocturnal ventilation cooling; (iii) radiant cooling; (iv) direct evaporative cooling; (v) indirect evaporative cooling; (v) soil cooling; (vi) cooling of outdoor spaces.

Methodology

Case study and survey research designs were adopted in order to achieve the aim of this study. The study entails site visit to selected public buildings using events hall as a representative sample. This is justified on the basis of its high cooling load demand compared to other public buildings in Nigeria. Emphasis in the course of the case study was on:

(i) The passive performance of the building in terms of its building orientation; shape; windows and openings sizes; and shading characteristics of building;
(ii) The passive cooling techniques of the building

Sequel to the case study, a Post Occupancy Evaluation was conducted in a survey where self-completed questionnaires were administered to investigate the level of thermal comfort achieved by building users. This was conducted in the rainy season (April-October); harmattan (December- January); and the dry season (November to March). Since Nigeria falls within the tropics where the climate is seasonally damp and very humid, the atmospheric weather condition of the study location ranges between 28^{0}C to 32^{0}C. The thermal comfort was measured in qualitative terms based on the perception of each of the respondents which were randomly selected. The public buildings are:

(i) Mapo city hall Ibadan
(ii) Archbishop Abiodun Adetiloye Hall, Ado-Ekiti, Nigeria
(iii) Lagos city hall, Lagos Nigeria

Results

Mapo city hall, Ibadan Nigeria

This section of the paper presents the result from both the case study conducted and the post occupancy evaluation (POE) which investigated respondents' perception of thermal comfort.

Building orientation and shape
The hall covers an approximately 3810.24 square meters on the site. The main building mass is oriented in the east west direction allowing maximum solar radiation.

Window size and openings
The use of large openings in place of windows at the ground floor enhances more ventilation as it aids air flow. According to the design of the building, the north and south elevation on the ground floor level has no windows except these openings. Windows are only placed at the gallery floor level (see figure 1).

Shading characteristics of building
The deep verandah and balcony at the ground floor and upper floor serves as a shading device. Tropical climate requires consideration for effective shading device for building elevations and passive cooling for users comfort. The hall employed basically for its elevations, horizontal shading device with the use of long and deep verandahs supported with columns (see figure 2). There are no window hoods in any of the elevations.

Figure 1: The interior view of the hall
Source: Researcher's field survey, 2012

Figure 2: Long and deep verandahs as a shading device

Passive cooling strategy
The hall employed both active and passive cooling techniques in achieving thermal comfort for the occupants. However despite the building's design which encourages passive cooling, the hall makes use majorly the active means of cooling with the aid of standing fans and the split unit air conditioning system. There are 22 number split unit air conditioning systems equally placed on both sides of the building interior.

Post occupancy evaluation
A total number of 120 post occupancy evaluation questionnaires were administered, 115 questionnaires were retrieved out of which only 80 are regular users of the hall whose responses will be used for the post occupancy evaluation of the building. During the rainy season, 57 respondents (71.3%) achieved thermal comfort by passive cooling, 46 (16.3%) did not and 10 (12.4%) were unconcerned. In the harmattan season, 46 (57.5%) achieved thermal comfort, 25 (31.3%) did not and 9 (11.2%) were unconcerned. However for the dry season of the year, 39 (48.8%) achieved thermal comfort, 34 (42.5%) did not, while 7 (8.75%) were unconcerned.

Archbishop Abiodun Adetiloye hall, Ado Ekiti Nigeria

Building orientation and shape
The main building mass is oriented in the N-S direction presenting minimal solar radiation on the building façade

Window size and openings
Some windows especially at the gallery level have hoods of little thickness which to some extent block solar radiation from entering the building interior.

Shading characteristics of building
Cross ventilation was adopted to enhance air flow within the building interior. This was also aided with the use of high level window in a process known stack effect. To shade incoming solar radiation, the building employed for most of its elevations deep verandah of about 2.4metres supported with columns (see figures 3 and 4).

Figure 3: The air-conditioning unit of the hall
Source: Researcher's field survey, 2012

Figure 4: The deep veranda of the hall
Source: Researcher's field survey, 2012

Passive cooling strategy
Despite the building design, it still relies on both the active and the passive cooling techniques to enhance thermal comfort for its occupants. The active cooling systems are the split type air conditioning unit and hanged mechanical fans. Although the building is cross ventilated, the active cooling system is used most of the time for comfort.

Post occupancy evaluation
A total number of 100 post occupancy evaluation questionnaires were administered, 90 questionnaires were retrieved out of which only 60 are regular users of the building whose

responses will be used for the post occupancy evaluation of the building. During the rainy season, 45 respondents (75%) achieved thermal comfort by passive cooling, 9 (15%) did not and 6 (10%) were unconcerned. During the harmattan season, 39 respondents (65%) achieved thermal comfort, 13(21.7%) did not and 8 (13.3%) were unconcerned. 38 (63.3%) achieved thermal comfort, 17 (28.4%) did not while 5 (8.3%) were unconcerned during the dry season.

Lagos City Hall, Lagos Nigeria

Building orientation and shape
The building approximately occupies about 9214 square meters on site.

Shading characteristics of building
The only noticeable shading device noticed are the deep roof overhang and the columns supporting the roof deck (see figure 5). Also at the approach view on the first floor is a deep rectangular canopy which shades the lobby leading to the banquet hall.

Figure 5: The deep roof overhang of the hall
Source: Researcher's field survey, 2012

Figure 6: Use of courtyard in the hall
Source: Researcher's field survey, 2012

Passive cooling strategy
The design of the building is such that passive cooling should be adequate with the incorporation of two courtyards of about 420 square meters each (see figure 6). However, the building operates entirely with active cooling. In fact there is a chiller pump room which supplies all the floors in the building the required fresh air through a central control unit. At times, the two courtyards are used to achieve thermal comfort of occupants

Post occupancy evaluation
A total number of 180 post occupancy evaluation questionnaires were administered, 170 questionnaires were retrieved out of which only 145 are regular users of the building whose responses will be used for the evaluation of the building. During the rainy season, 96 respondents (66.2%) achieved thermal comfort by passive cooling, 37 (25.5%) did not and 12 (8.3%) were unconcerned. During the harmattan season, 91 respondents (62.8%) achieved thermal comfort, 40 (27.6%) did not and 14 (9.6%) were unconcerned. However for the dry season of the year, 80 respondents (55.2%) achieved thermal comfort, 47 (32.4%) did not while 18 (12.4%) were unconcerned.

Discussion

The average thermal comfort of respondents varies with the three seasons of the year. Except for the Mapo city hall, the post occupancy evaluation indicates that respondents attained thermal comfort more in the rainy season. Findings showed that building design is a crucial factor that enhances the thermal comfort level of building occupants. The Adetiloye hall recorded the highest percentage of respondents that achieved thermal comfort with an average of 68% of respondents all year round. Lagos city hall had 61% of respondents while Mapo city hall had 52%. The minimal solar radiation experienced by the Adetiloye hall due to the building's orientation helps to reduce the cooling load. The hall also adopted the stack effect which enhanced adequate air flow in and out of the building. The two courtyards enhances air flow in and outside the Lagos city hall which helps to maintain a good air flow. The Mapo city hall recorded lesser percentage due to the building design and orientation which allows high solar penetration into the building interior.

Aside from the building design, the use of natural landscape elements was also observed to contribute to good microclimate of the events hall visited. This also aids the thermal comfort of building users. At the Mapo city hall, non-usage of landscape elements especially plants and shrubs resulted to the low microclimate condition of the site (see figure 2). This is not ideal as landscape elements are vital in maintaining a good microclimate. The conscious landscaping of the Archbishop Abiodun Adetiloye and the Lagos city Halls is commendable with diverse plant types, shrubs which contributed immensely to the good microclimate of the site (see figures 7 and 8).

Figure 7: The Archbishop Abiodun Adetiloye hall
Source: Researcher's field survey, 2012

Figure 8: The landscape design of the Lagos city hall

Passive cooling needs to be well thought of at the early stage of the design process. This undoubtedly should continue at the design phase till the completion of the entire building project. Passive cooling if well-conceived and thought of can help to realise the cooling load thereby enhancing the utilisation of energy and most importantly the thermal comfort of building occupants at certain seasons of the year without the use of active or mechanical cooling means. What is needed to enhance passive cooling in Nigeria is a policy framework which advocates for assessing the 'passive cooling passport' of a building especially public building prior to its approval for physical development. This will in a way undoubtedly compel professionals in the built environment to consider the following recommendations among others which will enhance passive cooling in the design of public buildings: (i) Buildings should be properly oriented so as to reduce solar heat gain in the building interior. Orientation towards wind breezes will enhance natural and cross ventilation; (ii) Glazing area and in fact glass performance should be optimum. It is advisable to use low E- glass to avoid having buildings behave like a greenhouse; (iii) Shading is expedient for solar control performance. Windows should be large enough where there is no direct solar radiation and vice versa; (iv) Landscape elements enhance passive cooling in the design of public buildings.

Determining the courtyard thermal efficiency and its impact on urban fabric: A contextual study of Baghdad, Iraq

Omar Al-Hafith[1], Satish B K[1], Simon Bradbury[1] and Pieter de Wilde[2]

[1] Plymouth University, ADA School, Plymouth, PL4 8AA, UK, omar.al-hafith@plymouth.ac.uk

Abstract: Many researchers advocate readopting the courtyard pattern in hot climate regions for being more thermally efficient than the modern western ones, such as the detached housing. The courtyard helps through reducing heat gain and having sufficient natural ventilation to have a comfortable indoor environment. But, it is suggested that this building pattern loses its efficiency by being out of its compact urban fabric context due to having high exposure to the solar radiation. Aiming at finding a thermally efficient solution for the hot climate regions, this research investigates the thermal efficiency of courtyard pattern and examines its relevance in the present urban context. To achieve this aim, the thermal performance of a courtyard and a detached non-courtyard house was simulated. The courtyard house was tested in two locations: a traditional compact urban fabric and a modern less compact one. DesignbBuilder simulation tool was used for this purpose. The simulation results are derived from fieldwork carried out in Bagdad, where both traditional and contemporary neighbourhoods can be found. They clearly demonstrate the efficiency of courtyard pattern in the compact urban environment. These results support adopting the courtyard pattern in contemporary and future buildings, with due consideration for the urban environment.

Keywords: Baghdad, DeisgnBuilder simulation, Courtyard buildings, Thermal efficiency

Introduction

The thermal performance of buildings has been one of the main considerations in building design. It affects occupants health and productivity in addition to its impact on buildings' energy performance (Indraganti and Rao 2010). In the hot-arid climatic zone, many studies advocate re-using the traditional courtyard pattern to achieve a thermally comfortable indoor environment. Through having various experimental studies, they showed that it is more thermally efficient than the other patterns, such as the detached, semi-detached and row patterns (Ratti, Raydan et al. 2003; Manioğlu and Yılmaz 2008; Al Jawadi 2011). Its main characteristic is that it includes an open space in the building's core to which all spaces access and open to get light and ventilation. Supported by other environmental elements, such as the thermal mass, the basement and the wind-catcher (Behbood, Taleghani et al; Ali, Turki et al. 2013; Manioğlu and Yılmaz 2008), the courtyard works to regulate buildings' thermal conditions (Sthapak and Bandyopadhyay 2014; Edwards 2006). Its environmental performance depends on two environmental strategies: to protect the building for heat gain and to reduce temperature through, basically, controlling building exposure to the solar radiation and having natural ventilation (Al-Hemiddi and Megren Al-Saud 2001; Muhaisen 2006). But, it is suggested that its thermal performance is highly governed by being in a compact urban fabric (Khan and Majeed 2015; Behbood, Taleghani et al. 2010), which is significantly different from the modern less compact one (Al-Thahab, Mushatat et al. 2014).

Out of its context, its performance might reverse as courtyard buildings will get higher heat gain resulted from having a larger area exposed to the direct solar radiation and heat exchange (Gupta 1987; El-deep, El-Zafarany et al. 2012).

Aiming at determining the thermal impact of having a courtyard in buildings and the possibility of adopting the courtyard pattern in the modern less compact urban fabric, this research investigates the thermal performance of a courtyard building and a modern detached building in Baghdad, which has hot climate and both building typologies. It also tests the change in the courtyard building's thermal performance if it is moved to a context of modern less compact urban fabric.

Research aim, methodology and limitations

Within the ongoing efforts to define a thermally efficient solution for the hot climate regions, this research aims to investigate the thermal performance of the courtyard pattern. It focuses on determining the thermal impact of using the courtyard, this pattern's featured environmental element, and testing the urban fabric impact on its performance.

This study used the experimental research method to determine the relationships between buildings' thermal performance, their urban context and the existing of the courtyard. The experiment included using DesignBuilder as a simulation tool, which has been widely used to simulate buildings thermal performance with sufficient accuracy (Baharvand, Ahmad et al. 2013). Baghdad, the capital of Iraq, was selected as a case study and one of its traditional courtyard houses was used as a sample. This city has hot climate and traditional and modern housing patterns. The selected Baghdadi courtyard house was used to represent three cases. The first one involved simulating the thermal conditions of the selected courtyard house in its original conditions in a compact urban fabric (TCH). The second one is similar to the first case, but with relocating the courtyard house in a context of a modern neighbourhood as a detached house (DCH). The third case involved using the same context of the second case but with closing the courtyard and placing spaces' windows on the outside, to represent the detached modern housing pattern (DNCH). Comparing the performance of three cases indicate the courtyard pattern thermal efficiency and the impact of urban fabric pattern on courtyard buildings' thermal performance.

Analysing the three cases thermal performance

Baghdad context: climate and housing patterns

Baghdad has a long and hot summer, when the temperature might reach 51.0 C° (Iraqi Meteorological Organization, 2016), while the comfort limits have been defined to be between 18C° and 30C°(Saleem 2011). Regarding Baghdad's houses, until the middle of the last century, the courtyard pattern had been used as the housing pattern in the city. However, a number of factors including the social, cultural, and political changes, the development in the construction industry and the changing in the architectural styles have led to adopt the modern western housing patterns, including the detached houses, which do not have courtyards (Al-Thahab, Mushatat et al. 2014; Mohamad 2012). Spaces' windows have been placed on the outside. The new building patterns and the use of cars have led to a less compact urban fabric with wide streets instead of being compact with narrow organic roads (Al-Thahab, Mushatat et al. 2014; Ali 2009; Mahmood 2004).

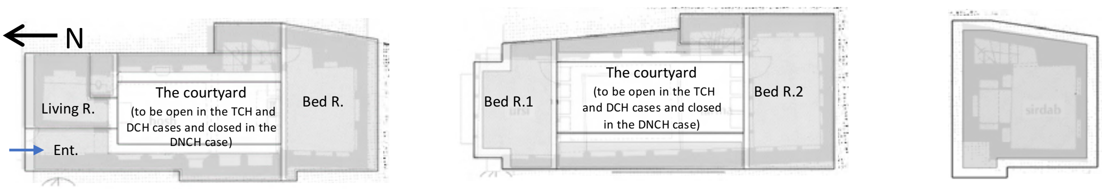
Defining the research variables

Occupants' thermal comfort has been used by studies to determine the built environment thermal performance. It is affected by a number of factors, which have been defined by researchers to include six key factors: occupants' activity level, clothing thermal resistance, air temperature, Mean Radian Temperature, air velocity and humidity (Fanger 1970; CIBSE 2016).

Building on this, occupants' thermal sensation is this research's dependent variables and the affecting factors are the independent variables. The research measures the former through considering the Operative Temperature, which is of the indices that have been developed to measure occupants' thermal sensation, but it has been defined as the most correspondent index to occupants' sensation. It combines the integrated impact of air temperature and Mean Radiant Temperature (De Dear, Brager et al. 1998; Nicol and Humphreys 2010), which are in turn affected by heat gain and natural ventilation (Doick and Hutchings 2013; Armson, Rahman et al. 2013; Atmaca, Kaynakli et al. 2007; Amos-Abanyie, Akuffo et al. 2013). Accordingly, this research's independent variables are air temperature, Mean Radiant Temperature, natural ventilation and heat gain.

Selecting and modelling the study sample

To reduce the factors that might affect the thermal performance other than the courtyard space and the urban fabric compactness, a simple courtyard house was chosen, which has the typical features of Baghdad's courtyard houses, to be used for the thermal simulation purpose. It is a two floors house with a basement and a central open courtyard (Figure 1).



Ground floor First Floor Basement

Figure 1. The selected Baghdadi courtyard house.
Floor plans were drawn in DesignBuilder depending on (Warren and Fethi 1982)

The simulation included determining the thermal conditions, the heat gain and natural ventilation of the research three cases: TCH, DCH and DNCH on the 21st of July, which is one of the hottest days in Baghdad. All of the three cases have neither mechanical ventilation nor cooling systems. They were modelled to include only natural ventilation. The research considered in modelling the three cases to make them identical in all aspects, except the considered aspects for the test (Figure 2) (Table 1) .

The results: Analysis and Discussion

The results show that there are significant differences between the thermal conditions of the three tested cases (Figure 3), (Figure 4). Regarding the heat gain, the results demonstrate that heat gain happens during the night through the three mechanisms of heat transfer in buildings: convection, conduction and heat radiation (Stein 1997). From 18:00 o'clock until 00:00 o'clock, heat gain is higher in DNCH and DCH than TCH. This can be attributed to the time lag in heat radiation from the construction materials in DNCH and DCH typologies. At this time, Walls are protected in the TCH typology; they do not get direct solar radiation and, as a result, do not have stored heat radiation. On the other hand, from 00:00 o'clock until 8:00 o'clock, TCH and DCH have heat gain, which happens at the same time as occupants operate windows to get natural ventilation. This heat gain can be traced back to impact of opening the windows to the courtyard where the air temperature is higher than the outside temperature, but still have cooling impact as its temperature is less than the spaces' temperature (Figure.4- A,D,E), (Figure.5- A,D,E). The maximum measured heat gain is 0.35kW in (Bed R. 1) on the first floor of the DCH typology due to having the highest exposure to the solar radiation. As a consequence, It has the highest air temperature, the highest Mean Radiant Temperature, and the highest operative temperature, which is around 33C° (Figure 4 –A,D). The low heat gain in the first evening hours in the TCH case can be traced back to the use of the courtyard, which enables to have buildings attached to each other, which protects the outer walls from the solar radiation.

Natural ventilation works during the night time to reduce the temperature by replacing the hot air with cold one. It is more active in TCH and DCH than the DNCH (Figure. 4-E,F), (Figure.5-E,F). The courtyard stimulates air movement through having the heated air by the walls heat radiation going up to be replaced by cold air (Mohammad 2010)

As a result of heat gain and natural ventilation, spaces' air temperature and Mean Radiant Temperature change and affect the operative temperature (Figure.4-A, B, C), (Figure.5-A, B, C). The lowest measured Operative Temperature is around 21 C°, which is in the TCH'S ground floor bedroom. This space has the least exposure to the solar radiation and one of the highest heats loose through natural ventilation. In total, DNCH has the highest operative temperature. This result might be different if the tested houses are of low thermal insulation, as, in this simulation, the DCH higher exposure to the solar radiation might be overcome by the natural ventilation cooling impact and the high insulation level. On the other hand, the TCH has the lowest operative temperature. It is around 7 C˚ less than the outside temperature in the ground floor and 2 C˚ in the first floor. The open courtyard space itself provides a stable air temperature during the whole day which is up to 7.5 C˚ less that the outside temperature in the midday.

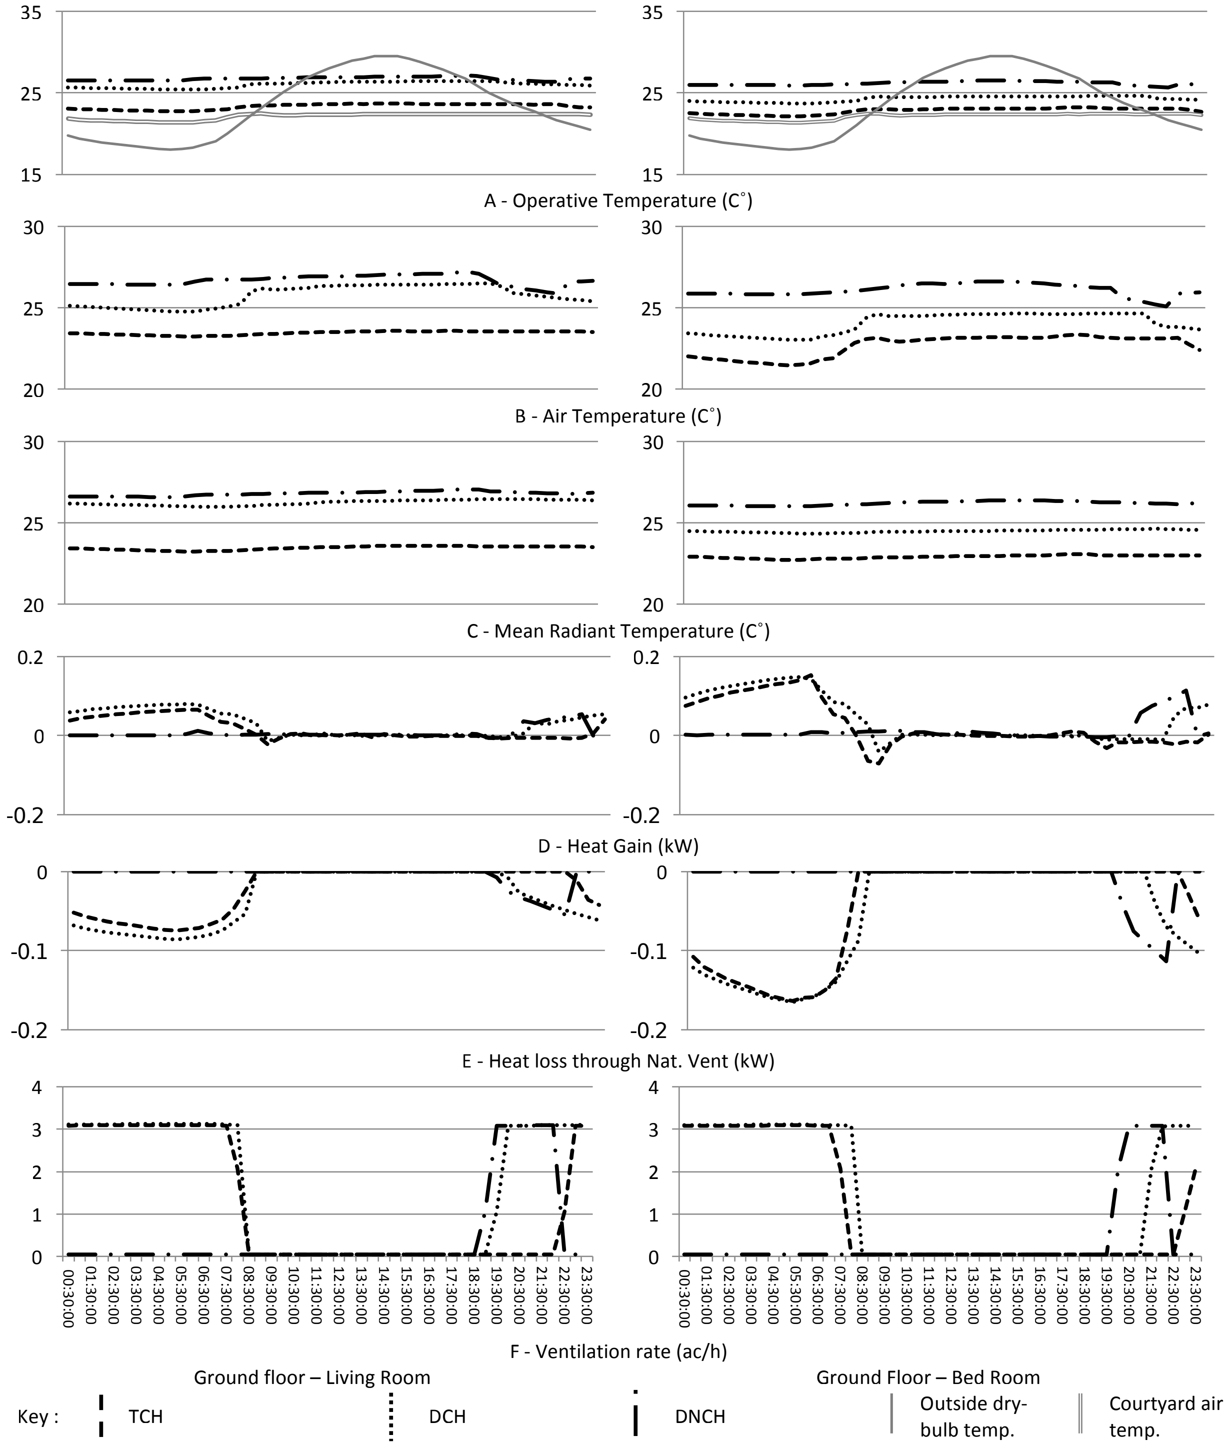

Figure 3. The ground floor two residential spaces thermal conditions.

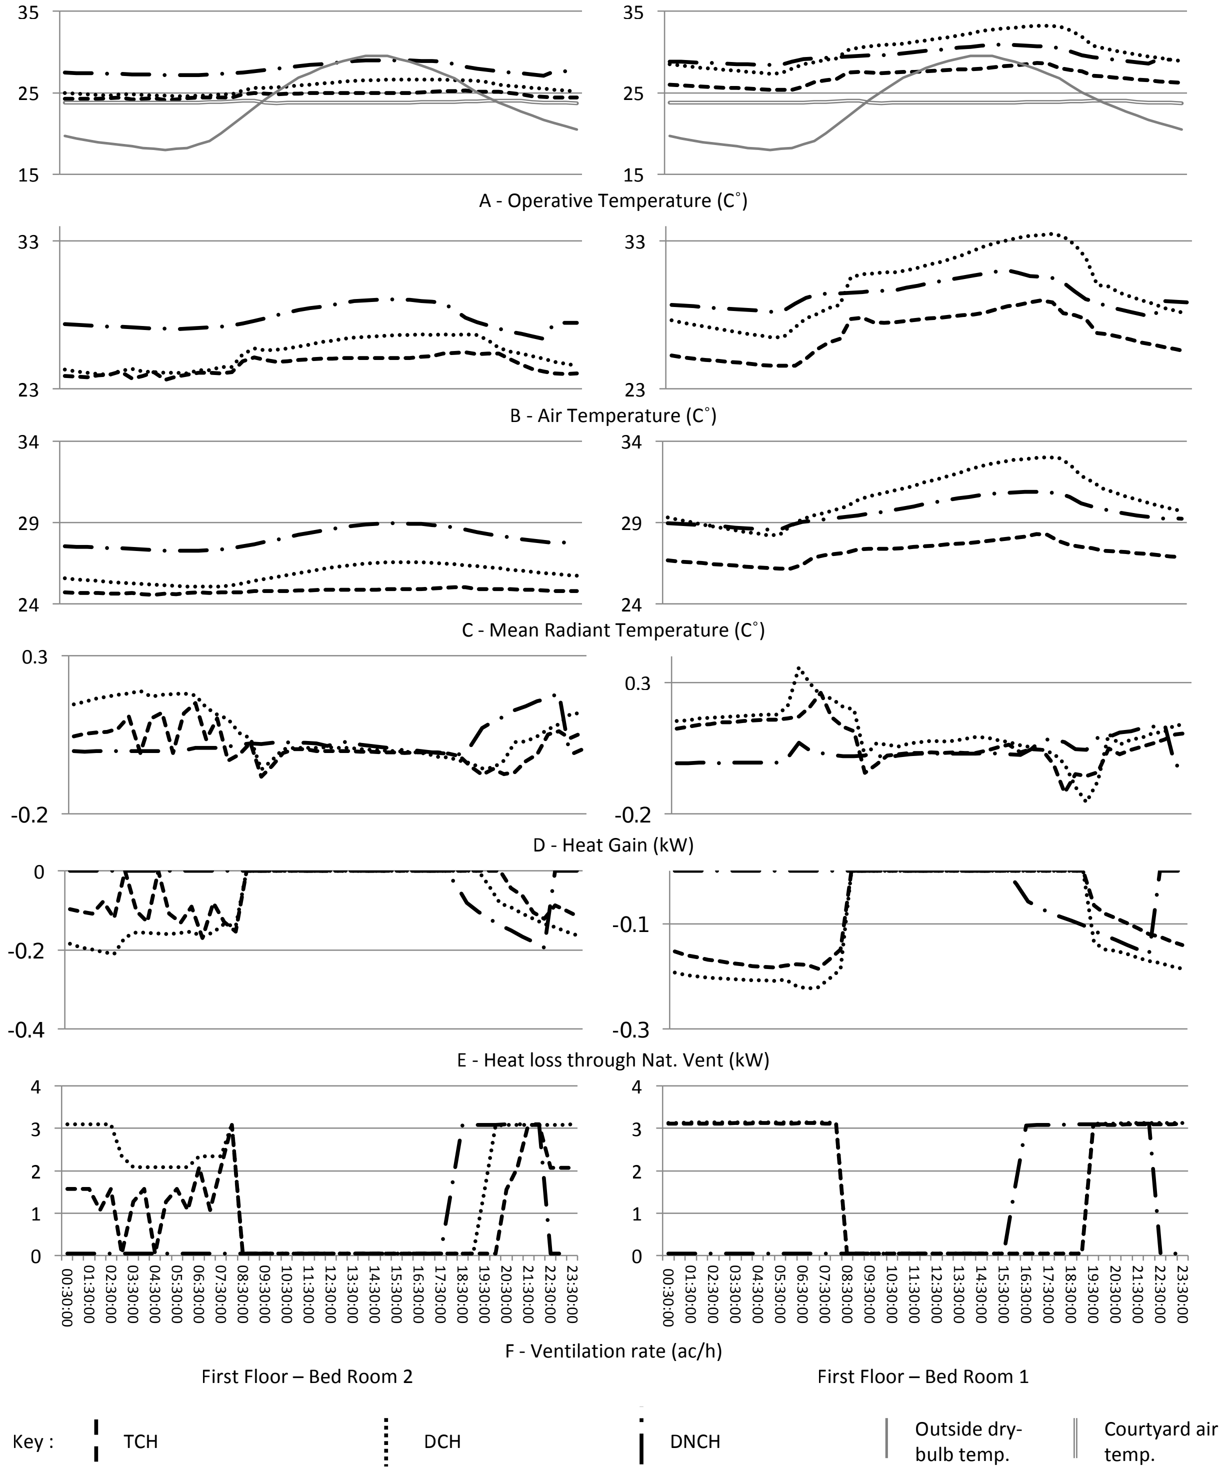

Figure 4. The first floor two residential spaces thermal conditions.

Conclusions and Recommendations

The courtyard pattern might offer an opportunity to have thermally comfortable indoor environments. Comparing the thermal performance of the TCH and the DNCH cases indicate the courtyard pattern efficiency, which can be traced back to the use of the courtyard element inside buildings. It enables to have buildings attached to each other as spaces have their openings to the inner courtyard. On the first hand, this protects external walls from the direct solar radiation and the resulted heat gain. On the other hand, it offers air with lower temperature to be used to have sufficient natural ventilation.

This research demonstrates that the courtyard house offers its maximum thermal efficiency by being in a compact urban fabric. This efficiency decreases by being in a less compact urban fabric where the courtyard building becomes more exposed to the solar radiation and as a result, having higher heat gain during the day time. The decrease in its efficiency depends on how much heat will the building gain during the daytime. To a specific extent, it might become less efficient than the other housing patterns. However, having high insulation level, as what has been considered in this research, might help to keep the heat gain in the minimum rates and enable the courtyard building to keep a sufficient level of thermal efficiency.

This research recommends adopting the courtyard house for the current and future housing developments in the hot regions with considering having compact urban fabric. For future studies, it recommends conducting further studies on testing and quantifying the courtyard pattern thermal performance. A special consideration should be given to determining the impact of each of its elements and environmental strategies to help in developing this pattern to have more efficient and comfortable buildings.

Abstract: This study investigates the detailed thermal environments in the existing Dutch colonial buildings in Bandung, Indonesia through field measurements to find out the embedded passive cooling strategies, focusing especially on the effects of veranda spaces. Major thermal parameters were measured at 1.1 m above floor in the center of selected rooms and veranda spaces of the buildings. The vertical distributions of air temperature were also measured at the same points. The results revealed that daytime indoor air temperatures in the buildings maintained relatively lower values (3.4-5.6°C lower) compared to the corresponding outdoor temperatures due primarily to the thermal mass effect. A large vertical gradient in air temperature was seen in the rooms because of the high ceiling height, which is about 5.3-5.7 m. The high ceiling contributed to maintain lower daytime air temperatures at the occupant's level even when the windows were opened. When a veranda space was enclosed, it played a role as a thermal buffer and daytime air temperature inside was approximately 3.4°C lower than that adjacent to a semi-open veranda space. Meanwhile, the veranda space prevented the direct solar radiation from entering the rooms during the peak hours, while ensuring cross-ventilation.

Keywords: Vernacular architecture, Passive cooling, Thermal comfort, Veranda, Dutch colonial building, Hot-humid climate

Introduction

The Dutch colonial building is considered to be one of the vernacular architecture that still exists until today in Indonesia. Indonesia had been colonialized by the Dutch for more than 300 years since the early 17th century. During the period, at first, the Dutch built the buildings by replicating those in the motherland without considering hot-humid climate of Indonesia. From that time, it started to adopt environmental techniques to cope with the local climatic conditions (Widodo, 2007). As such, a number of studies on the Dutch colonial buildings in Indonesia have been carried out to date, but intensive studies on their thermal environments are still limited. This study aims to investigate the detailed indoor thermal environments of Dutch colonial buildings in Bandung, Indonesia and to analyse the embedded passive cooling strategies based on the results of field measurements, with an emphasis on the effects of veranda space on indoor thermal environments.

Bandung is the capital of West Java province with the total population of 2.5 million and the population density was 14,768 people/km² as of 2014 (Badan Pusat Statistik, 2015). Since its establishment in 1811, Dutch built a lot of buildings with various architectural styles in the city. As reported, about 1,500 Dutch colonial buildings still exist in Bandung alone (Nurfindarti and Zulkaidi, 2015). Bandung is located on the highland (approximately 760m above sea level), and therefore the climate is relatively cool. The monthly average temperature is recorded around 22.5-24.2°C, while the monthly average relative humidity ranges from 53-83%.

Methods

Case study Dutch colonial buildings

Two Dutch colonial buildings were selected for case studies through classifying the existing colonial buildings in terms of the building form and building usage. Field observation was also conducted to take their environmental designs into account in the selection. Only free-running buildings were chosen in the selection. As a result, the two buildings were selected, namely Case 1 and Case 2 (Figure 1).

Case 1 is a two-storey school building constructed with timber for the main structure and brick and lime cement for the walls (approximately 40 cm thick). The front façade is facing the north, whereas a large veranda (3.35 m width) is located on the opposite side (south). The veranda on the ground floor is enclosed while it is semi-open on the first floor. The doors facing verandas are louver doors (permanently open) while upper ventilation openings are placed above some of the windows/doors. Meanwhile, Case 2 is a single-storey school building with large verandas on both sides. It is an L-shape building with the front façades facing west and south. The main structure is concrete, while brick and lime cement are used for walls with the thickness of approximately 28 cm. The width of both verandas is 3.0 m and they are well shaded by long eaves. As seen in Case 1, the upper ventilation openings are also placed above some of the windows/doors. Both buildings were occupied by students and teachers during weekdays.

Procedures of field measurement

Field measurements were carried out during the hottest period of the dry season in Bandung, from August to October 2015. In Case 1, the measurements were conducted in two class rooms (Rooms 1-1 and 1-2) (Figure 2a). These rooms are located at the same position between the north-facing front façade and the rear veranda, but on the different floor (Room 1-1: ground floor/GF, Room 1-2: first floor/1F). Room 1-1 is slightly smaller than Room 1-2 in size (80 m^2 and 91 m^2, respectively). Both rooms have high ceilings (5.5 m and 5.7 m) with large windows on both sides of the rooms. Meanwhile, the measurement in Case 2 was carried out in one of the office rooms (Room 2-1) located in between the two verandas (east- and west-facing). Room 2-1 has a floor area of 64 m^2 with the ceiling height of 5.3 m (Figure 2b).

Major thermal parameters including air temperature, relative humidity, wind speeds and globe temperature were measured at 1.1 m above floor in the center of rooms and verandas of the buildings, respectively. The vertical distributions of air temperature were also measured at the same points (see Figure 2). The measurements were conducted under the occupied conditions. During the field measurements, daytime ventilation was adopted over weekdays while night/full-day ventilation was applied over weekends. Occupancy and window/door opening conditions were recorded. Outdoor thermal conditions were recorded by a weather station located in the measurement sites.

In addition, a brief questionnaire survey was conducted to the students in Rooms 1-1 and 1-2 respectively during the same measurement period to investigate their perceived thermal comfort conditions. Thermal sensation, thermal preference, and thermal comfort,

Figure 1. View of the selected buildings, (a) Case 1 and (b) Case 2.

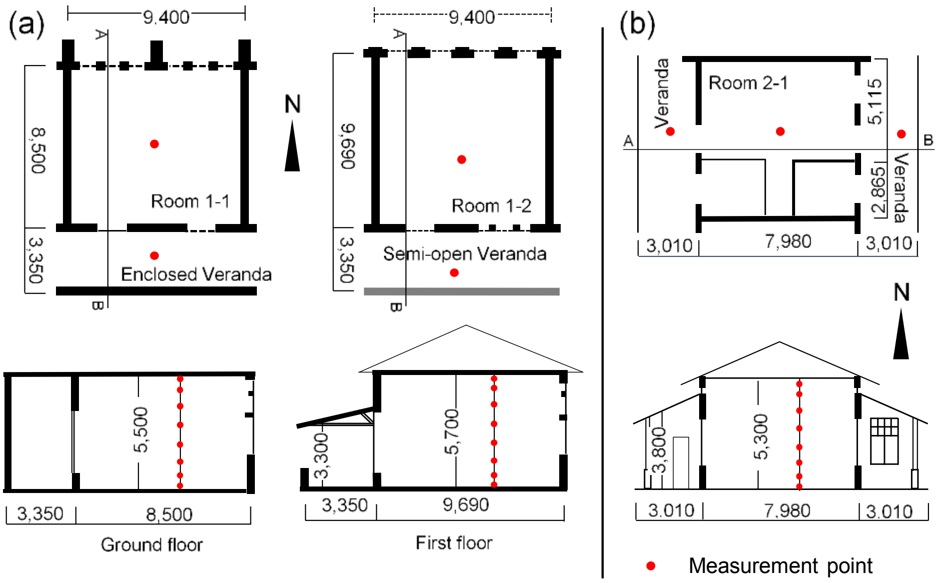

Figure 2. Floor plan, sections and measurement points of (a) Case 1 and (b) Case 2.

etc. during morning class time (07:00-11:00) and afternoon class time (12:00-15:00) were asked using a questionnaire form at the ends of the respective periods.

Results and discussion

Indoor thermal environments

Figure 3 presents the temporal variations of measured thermal parameters in the rooms, verandas and outdoors in the two cases, while Figure 4 shows the statistical summaries of air temperature measurements, under different ventilation conditions. As shown, outdoor air temperature ranged from 18.2 to 32.8°C with the average of 25.1°C, while the outdoor relative humidity ranged from 16 to 97% during the measurement periods. The daily global horizontal solar radiation measured at 11.6-26.3 MJ/m^2. Average outdoor wind speeds in the two cases were approximately 1.1 m/s (measured at 12.6 m above ground level). Rooms 1-1 and 1-2 were occupied with about 30-35 students during the school time, while that of Room 2-1 was less than 10 people (office workers).

Figures 3 and 4 show that indoor air temperature profiles are largely different between the floor levels (i.e., between Rooms 1-1 and 1-2) rather than those caused by various ventilation conditions. As shown, daytime indoor air temperatures on the ground floor (Rooms 1-1) obtained lower values (2.4-5.6°C lower than the outdoors) than those of the first floor (Rooms 1-2) (1.6-3.4°C lower), regardless of the ventilation conditions. Meanwhile,

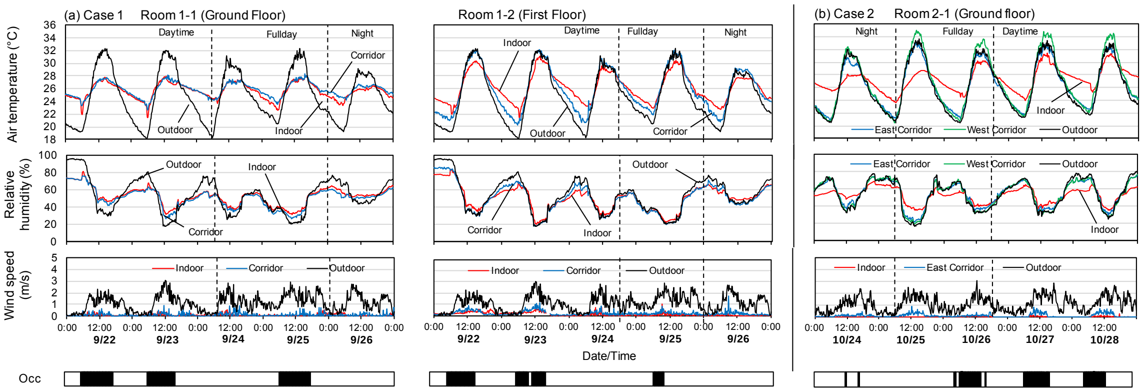

Figure 3. Temporal variations of thermal parameters in (a) Case 1 and (b) Case 2 under different ventilation conditions.

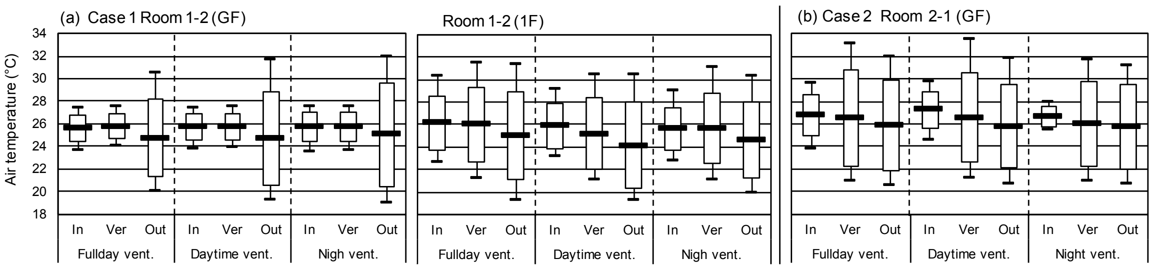

Figure 4. Statistical summary (5% percentile, average, 95 percentile and average ± standard deviation) of air temperatures in (a) Case 1 and (b) Case 2 under different ventilation conditions.

nocturnal indoor air temperature profiles show the opposite patterns, particularly in Case 1: indoor air temperatures on the ground floor are rather higher (4.1-6.2°C higher than the outdoors) than those of the first floor (2.5-5.0°C). These differences are not only due to the floor levels but also due to the difference in the veranda types (enclosed/semi-open verandas).

Overall, indoor air temperatures in the room adjacent to the enclosed veranda spaces (Room 1-1) maintained narrow diurnal temperature ranges compared to those of the corresponding outdoor temperature even when the windows/doors were opened for the whole day (i.e., full-day ventilation). In fact, as indicated in Figure 3, the measured wind speeds in the Room 1-1 during daytime were lower and almost absent (up to 0.2 m/s) compared with the rooms adjacent to the semi-open verandas (i.e., Rooms 1-2 and 2-1) with wind speeds of up to 0.5 m/s (see Figure 8). This is simply because the enclosed veranda discouraged the cross ventilation in the adjacent room (Room 1-1). On the other hand, air temperatures in the semi-open verandas closely followed the corresponding outdoor air temperatures, resulting in the increase in daytime air temperature in the adjacent rooms (Figure 3). But still, the diurnal ranges of indoor air temperatures particularly in Room 2-1 was narrower than those of the outdoors mainly due to thermal mass effect of the building: the thermal mass of Cases 1 and 2 calculated at 2,819 and 2,685 kg/m², respectively.

Thermal effects of veranda spaces

Figure 5 shows the correlations between indoor, veranda and outdoor air temperatures in all the rooms under the different ventilation conditions. As shown, air temperature profiles are almost the same between indoor and veranda spaces in Room 1-1 (enclosed veranda) regardless of ventilation conditions, while those profiles are different in Rooms 1-2 and 2-1 (semi-open veranda). Figure 5a indicates that the enclosed veranda space plays a role as a thermal buffer space. It was particularly effective during the daytime, although it prevented

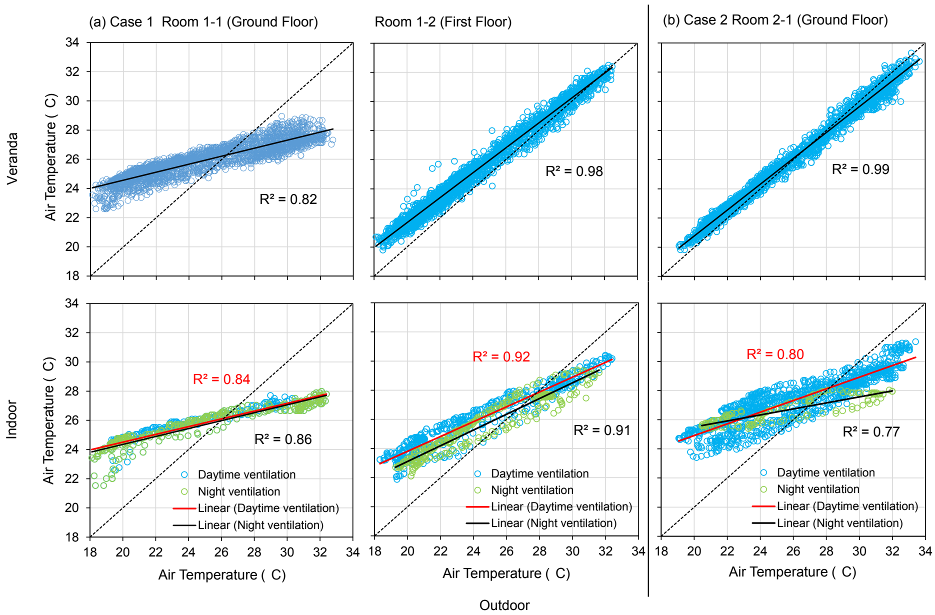

Figure 5. Correlation between veranda, indoor and outdoor air temperatures in (a) Case 1 and (b) Case 2 under different ventilation conditions.

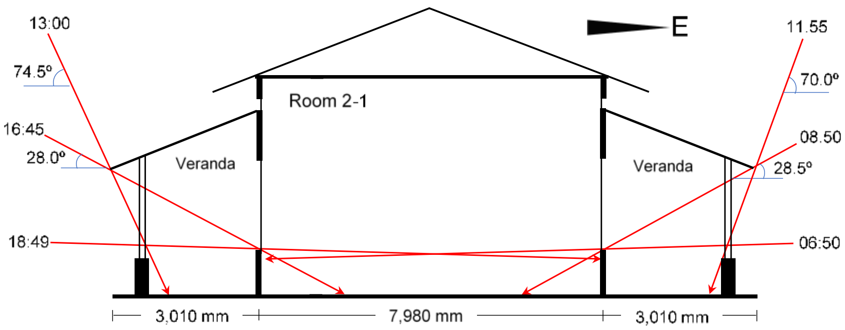

Figure 6. Illustration of solar radiation through the windows in Case 2.

the heat from releasing during the night-time when it was enclosed. However, even if it is a semi-open veranda such as those for Rooms 1-2 and 2-1, the indoor air temperature adjacent to the veranda was not as low as the outdoors at night due primarily to the thermal mass effect (Figure 5).

Nevertheless, the semi-open veranda is effective to improve cross-ventilation while shading. As shown in Figure 6, although Room 2-1 is facing both east and west, the long eaves of veranda spaces prevent solar radiation from entering indoor spaces, and thus the indoor air temperatures maintained relatively lower values than the outdoors even during daytime (Figure 5). As shown, the Room 1-2 received the direct solar radiation through the windows for about two hours during the morning period (6:50-8:50) and for about two hours during the afternoon period (16:45-18:49).

Figure 7 shows vertical distributions of air temperatures in the two cases under the different ventilation conditions, i.e. daytime ventilation and night ventilation. Overall, the ceiling surface temperatures during the daytime in Rooms 1-2 and 2-1 obtained higher values than those in Room 1-1 simply because the former was situated below roofs. Both roofs and ceilings were not insulated in the two buildings and heat was transmitted to the rooms below. The vertical temperature gradients are evident even in the Room 1-1. The temperature gradients seen in these rooms are attributed not only to the transmitted heat from the ceilings,

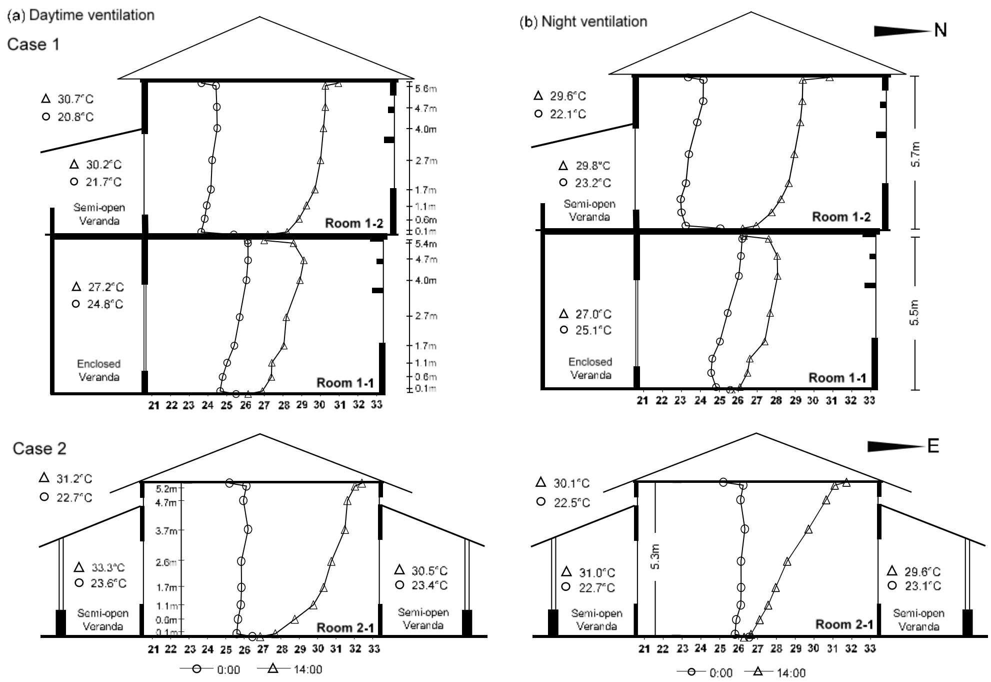

Figure 7. Vertical distribution of air temperature in Case 1 and Case 2 under (a) daytime and (b) night ventilation conditions.

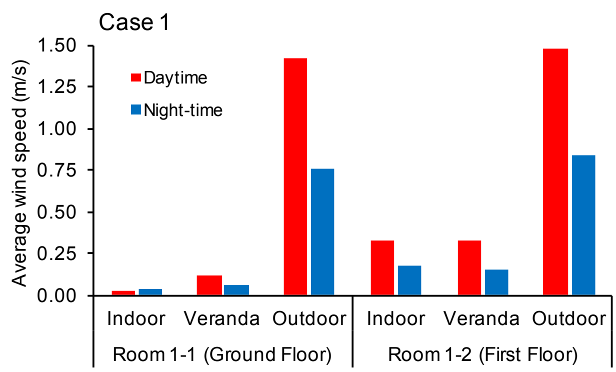

Figure 8. Average daytime and night-time of wind speeds in Case 1.

but also to the high ceilings (5.3-5.7 m). It should be noted that indoor air temperatures at the occupant's level (around 1.1 m above floor) maintained relatively lower values (approximately 27.4-29.8°C) even when windows/doors were opened during the daytime. This implies that a high ceiling would contribute to maintain relatively lower daytime air temperature even when the windows/doors are opened during the daytime (i.e., daytime ventilation).

Figure 8 indicates the average wind speed during the daytime and night-time in Rooms 1-1 and 1-2, respectively. As shown, the average wind speeds during daytime and night-time in Room 1-2 were relatively higher than those in Room 1-1. This implies that cross ventilation was ensured by the semi-open veranda in Room 1-2 (even when windows/doors were closed during the daytime). This is because there were permanent ventilation openings and louver doors above the doors as described before.

Thermal comfort assessment

Indoor thermal comfort was indexed by using the operative temperature (OT) and SET*. Furthermore, the thermal comfort was evaluated by the Adaptive Comfort Equation (ACE)

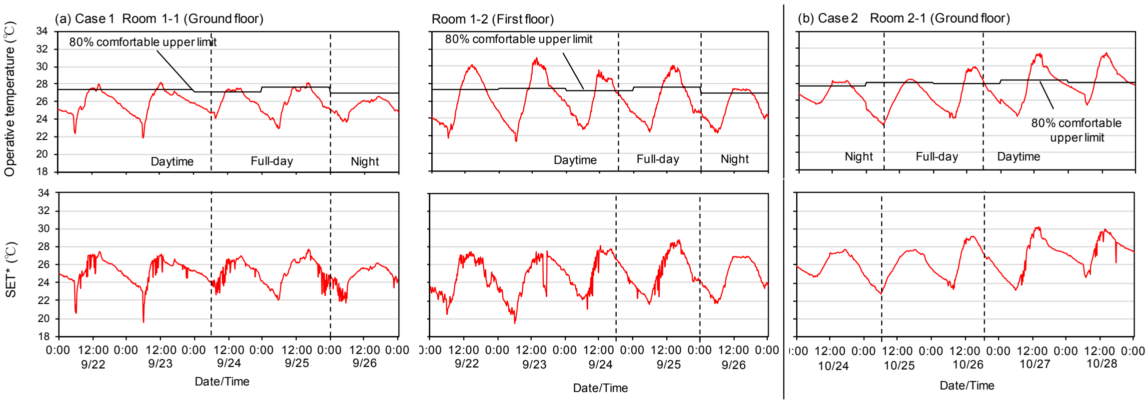

Figure 9. Thermal comfort evaluation using operative temperature (OT) and SET*.

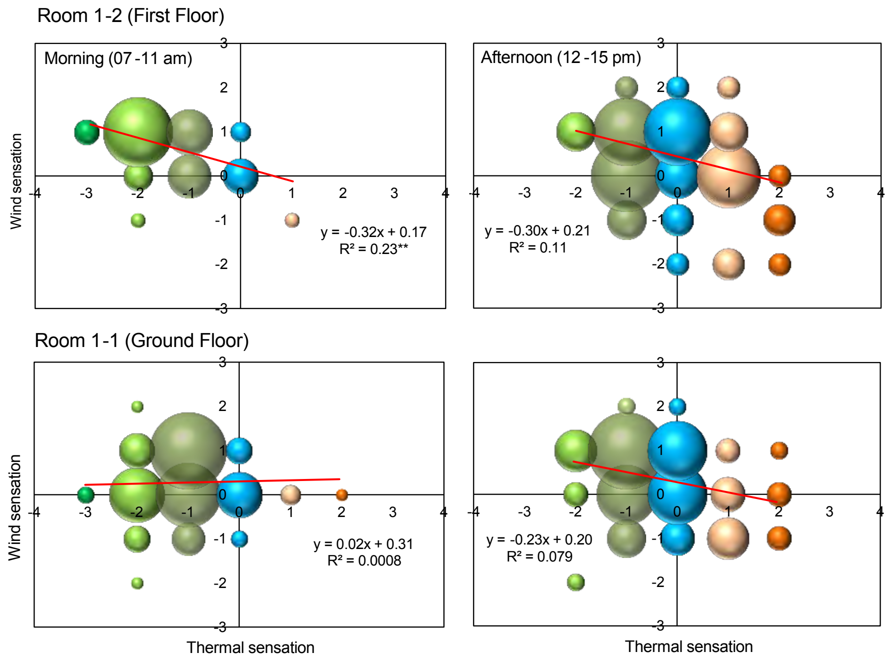

Figure 10. Relationship between thermal sensation and wind sensation in Rooms 1-1 and 1-2.

proposed by Toe and Kubota (2013) for OT. Figure 9 presents the evaluation results of indoor thermal comfort in the three rooms by the two indices, respectively. As shown, during most of the periods, OT in Room 1-1 does not exceed the 80% upper comfortable limit regardless of ventilation conditions. Meanwhile, in the other rooms (Rooms 1-2 and 2-1), OT exceeds the limits during most of the daytime periods. Nevertheless, if the sweat evaporation effect is taken into account by using SET*, the resulting SET* values in Rooms 1-2 and 2-1 become 0.8-2.1°C lower than the corresponding OTs. As previously described, these rooms received slightly higher wind speeds during the daytime. This means that indoor thermal comfort was improved by the sweat evaporation induced by the increased wind speeds from the semi-open veranda. Permanent openings (or louver doors/windows) are also important to let winds enter the rooms even during daytime.

From the questionnaires, a total of 206 responds were obtained for the morning survey, while 154 responds were collected for the afternoon survey. Figure 10 presents the relationships between wind sensation and thermal sensation in Rooms 1-1 and 1-2, respectively. As shown, during both periods, significant relationships can be seen only in Room 1-2 (adjacent to the semi-open veranda). As the wind sensation increases (when they feel stronger winds), they tend to feel cooler. As previously discussed herein, this result also proves that thermal comfort in Room 1-2 was improved by the increased wind speed due primarily to the cross ventilation improved by the semi-open veranda.

Conclusions

The selected Dutch colonial buildings maintained relatively low daytime indoor air temperatures compared to the corresponding outdoor temperature mainly because of the thermal mass effect. Both roofs and ceilings were not insulated and therefore the rooms located on the top floor observed relatively higher air temperatures. The thermal comfort evaluation results showed that indoor thermal comfort, particularly that in the rooms adjacent to the semi-open verandas, was improved by increased wind speeds during daytime. Even when the windows and doors were opened during the daytime, the indoor air temperatures maintained low values at the lower occupant's level due primarily to the high ceiling, which was approximately 5.3-5.7 m.

Abstract: Various passive design strategies to attain environment thermal comfort in the building project in one of the capital city in hot dry climate region are designed and examined by using Autodesk Ecotect software. Cairo in Egypt, Africa was selected as site location because of the renowned passive architecture design strategies which have been applied since the ancient times. Natural ventilation, passive solar strategies, thermal mass, and evaporative cooling are the main strategies that will be used in this project. *Mashrabiya*, *malqaf*, and *shuksheika* were modified and applied in the building. After the model was simulated, compared to any other strategies, thermal mass and evaporative cooling have a higher impact to enhance thermal comfort. Cairo has unique weather conditions due to its location near the desert, but Nile river nearby helps to provide humidity. Stage of building design to achieve better performance building consists of several phases. First, understand weather condition, analyzing vernacular architecture in the region, designing the architectural idea, simulating the model in the software, analyzing the result, and lastly is decide the best alternative design and materials.

Keywords: passive design architecture, thermal comfort, building performance

Introduction

Cairo as a capital city of Egypt is one of the largest city in the Middle East. Known as mega-cities, Cairo is now facing the thriving of energy problem (El-Gamal, 2014). Many modern buildings not using passive design architecture and as a result, they tend to use mechanical ventilation and cooling devices to reduce heat in the summer which caused a large amount of energy consumption. Whereas, Egypt has vernacular architecture from the ancient times to deal with the harsh weather of Egypt. Passive design architecture such as natural ventilation, passive cooling, evaporative cooling, and thermal mass has been used by utilizing natural energy resources (sun, wind, and water).

Literature Review

From the ancient time, Egyptian vernacular architecture has been dealing with the characteristic of weather in hot and dry climate. Primary techniques were applied to achieve human comfort inside and outside the building. The utilization of building orientation, building material, building color, roof structure, openings, and ventilation are effective to reduce the ambient temperature inside and around the buildings.

Building Orientation

Considering the sun position and prevailing wind when designing building orientation is important. In accordance with Hassan Fathy's studies, slight overhang in the window will block sun radiation in summer and allow them to pass the building in winter to provide heating (Fathy, 1986). From this study and the solar simulation, west and east façade should have less opening because the altitude of the sun is lower in the morning and afternoon which causing the wall received higher solar radiation. Therefore, north-south orientation for the longest façade is preferable in hot and dry climate region.

Building Material

In the traditional architecture of Egypt, natural building materials with a low value of thermal conductivity and high thermal mass were used to control heat and cold weather. Bricks and mud with high thickness is the most widely used material in vernacular building in this region. Reducing temperature environment in summer and enhancing higher temperature in the winter could be achieved by utilizing thick and heavy wall which have low value of thermal conduction. This is in contrast with this modern time where the trend of the building is using concrete and glass, causing more energy needed to provide heating and cooling in the building. The coefficient of thermal transmittance in hot and dry climate region would be better if it has a value approximately 1.1 kcal/hm^{2}C^0 (Lavafpor, 2011).

Wall Material	Wall Thickness (m)	Thermal Transmittance (kcal/ hm^{2}C°)
Hollow brick block	0.30	1.10
Double-wall brick with holes and 8-cm cavity	2 x 0.12	1.12
Brick wall with holes	0.38	1.03
Sand-lime brick	0.51	1.25
Hollow block sand-lime brick	0.51	1.16
Lime	0.51	1.10-1.35
Concrete	1.00	1.20

Source: (Hassan Fathy, 1986)

Figure 1. Thermal transmittance of various material

Figure 1 shows the thermal transmittance for different wall thickness in various kinds of material used in modern buildings at hot and dry climate region. Besides, insulation also has a better impact into the building because it can delay heat flow. Choice of light color of the building envelope in this region will reflect sun rays and decrease heat transfer into the building and works better than darker color (El-Gamal, 2014).

Ventilation

Ventilation plays an important role to provide a pleasant environment in the building interior. Egypt ancient architecture has applied *malqaf* as wind catcher in order to manage fresh air circulation (Attia et al, 2009 and El-Shorbagy, 2010). Temperature differences could be achieved when prevailing winds comes to *malqaf* and then it goes through the atrium and another room before it goes out to the openings. *Malqaf* also could reduce the sand which come together with the wind because the fewer solid material in *malqaf* compared to another room beneath it (Fathy, 1986). On the other hand, *Mashrabiya* as lattice wood panel has various functions, besides giving privacy, it can control air flow, sunlight, humidity, as well as temperature (El-Gamal, 2014). The air circulation within building that applied all these traditional passive design architectures can be seen in figure 2. Regrettably, the application of *mashrabiya* in modern housing or buildings in Cairo is depleted. They prefer to close the window and implement mechanical cooling devices such as air conditioning.

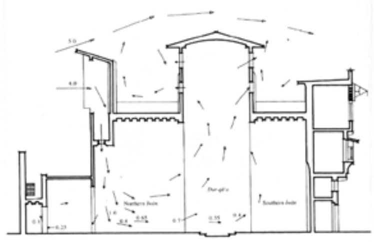

Figure 2. Air circulation concept within building

Evaporative Cooling

Various ways of cooling temperature were applied in hot and dry climate. Water features such as a pond, fountain, and *salsabil* were recognized since ancient time in Egypt to humidify environment and lowering dry bulb temperature (El-Gamal, 2014, Mahmoud, 2011, and Lavafpor, 2011). To maintain satisfying indoor and outdoor temperature in the region which has wide range weather is not an easy task. Several studies were conducted and one of the most influential technique is adding water features in the roof. Studies by Eduardo Kruger, Eduardo Gonzalez Cruz, and Baruch Givoni represent that roof pond is advantageous to reduce the temperature in summer and provide more comfort for building occupant (Kruger et al, 2010). Another study by Sahar N. Kharrufa and Yahyah Adil, roof pond has stabilized interior temperature and added fan will enhance evaporation process and diminish cooling loads of the buildings (Kharrufa et al, 2008).

Project Location and Weather Conditions

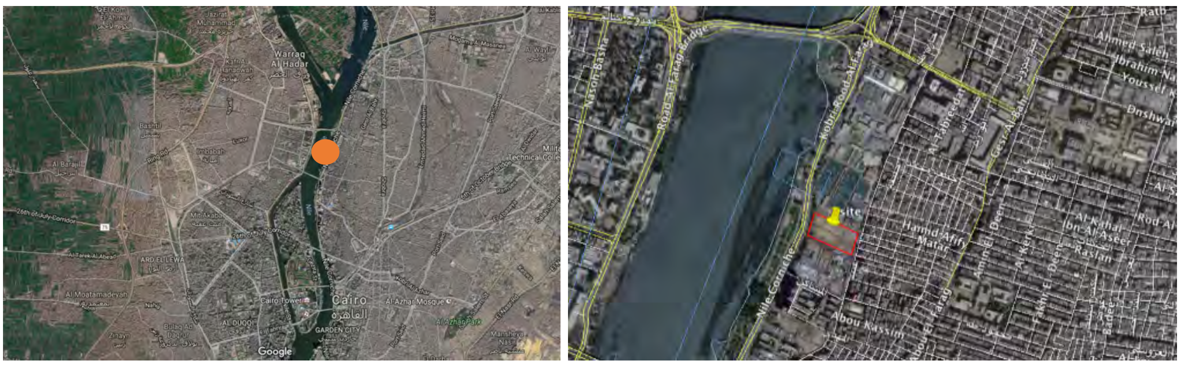

Figure 3. Site Location in Cairo, Egypt

As seen in figure 3, the site of this project is located on the west side of Cairo Governorate in the city of Cairo about 90 m from the Nile River, at the Nile Corniche Road. Cairo is located in (30.05° N, 31.23° E) and classified as BWh Climate Zone, which B is dry climates are characterized by little rain and a huge daily temperature range, W for arid or desert, and h for dry-hot with a mean annual temperature of 18º C in B climates only (Khater et al, 2012). Cairo has two seasons in a year, summer between May and October with temperatures are ranging between 22º C - 35º C on average, and a mild winter from November to April with an average high at around 19 - 29º C during the day but the night the temperature drops dramatically with ranges between 5º C-11º C. In March and April each year, sometimes the hot '*khamasin*' wind with dust and sandstorm blows to the city direction. The mean annual average of solar radiation on a horizontal surface is 876 Wh/s.q.m per hour. Altitude angle at noon in the winter is 33º and in the summer 86º (Al-Shaali, 2002).

Site Plan

In this study, the shape and dimension of the building have been decided which is only the box, but the site plan arrangements need to be studied to respond the location and climate. After did some simulations with CFD and Ecotect to know which layout works best with the ventilation and energy, the site plan layout in figure 4 was chosen. The idea of buildings organization is to make them close to each other so that they can be shading device to the building next to them in the summer and make the space between buildings as a courtyard. Furthermore, because of sun path oriented, most of the south wall will receive a large amount of solar radiation in the winter.

Figure 4. Proposed Site plan

Architectural Design Strategies

Vernacular architecture of Cairo was adapted to this office building to achieve thermal comfort inside and outside the building. North-south orientation building, *mashrabiya* and *malqaf* as natural ventilation, shading devices as passive solar, atrium, *shuksheika*, dome roof, roof pond as evaporative cooling devices, and low thermal conductivity building material were adopted. All these ideas were applied to achieve better thermal conditions and reducing energy demands of the building throughout the years.

Entrance with light structure canopy is on the west side near the main gate of the site (figure 9). In the first floor (figure 5), the north building is public area contains receptionist area with big void and dome roof above, restaurant, meeting point, and toilet. Connected to the south building by outdoor pathway, there is open space office with two meeting rooms. In second floor, north and the south building are connected by a bridge (figure 6). This is a private area which consists of the office area with manager room and meeting room while director room is on the third floor. The section of the building that shows passive designs could be seen in figure 7.

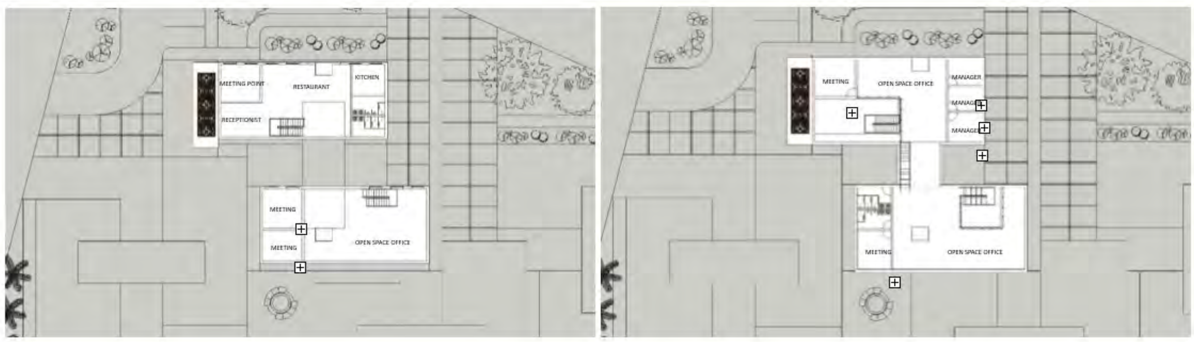

Figure 5, 6. Proposed Floor plan

Figure 7, 8. Building section and Exterior perspectives

Passive Design Application

Mashrabiya panels were placed in all part of façade. In the north wall, to receive prevailing winds, the dimension of the window is bigger than those in the south. Different with a window in north wall, the window has shading device to prevent high amount of solar radiation in summer but receives enough amount in winter (figure 8). The angle of shading devices is 83^{o} in accordance with Hassan Fathy's study about sun altitude. The type of this window was adapted from *mashrabiya* design, which wood material was expected to help lowering the ambient temperature (figure 9).

Figure 9. *Mashrabiya* window detail

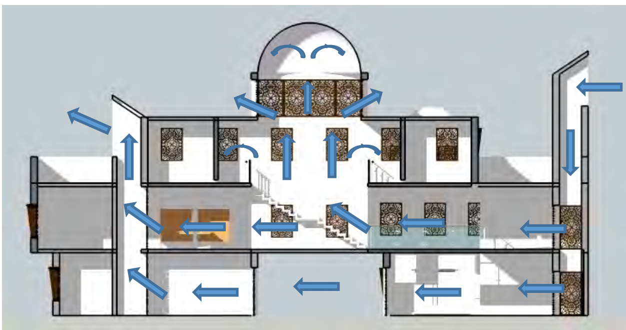

Figure 10. Air circulation within the designed building

Figure 10 above is the diagram of air circulation with the application of atrium, *malqaf*, *suksheika*, and a dome roof in the designed building. It was expected that the wind could penetrate into building with the application of natural ventilation.

Building Material Application

In this studies, building with 3 arrangements of materials was simulated in Ecotect to examine the effect of passive design architecture application as mentioned in the literature review. The first building was using a common material of building in Cairo, 300 mm mud bricks for the walls (figure 11). Double hollow bricks with insulation inside as wall material and window with *mashrabiya* without glass were for the second building (figure 12). And lastly, the materials for the second building were combined with application of roof pond for the third building (figure 13,14).

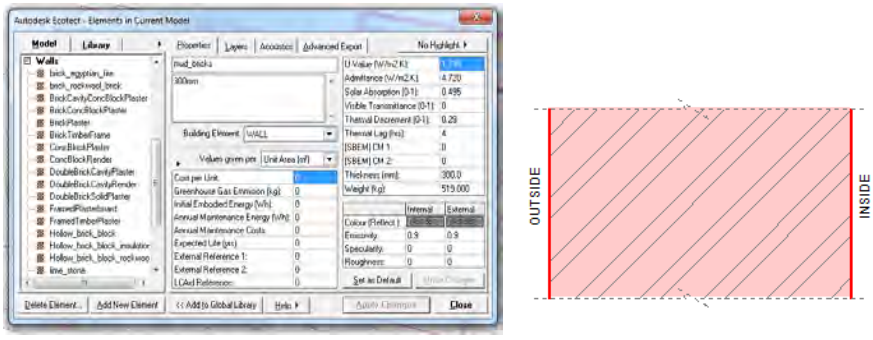

Figure 11. Mud bricks specification for the first building in Ecotect analysis

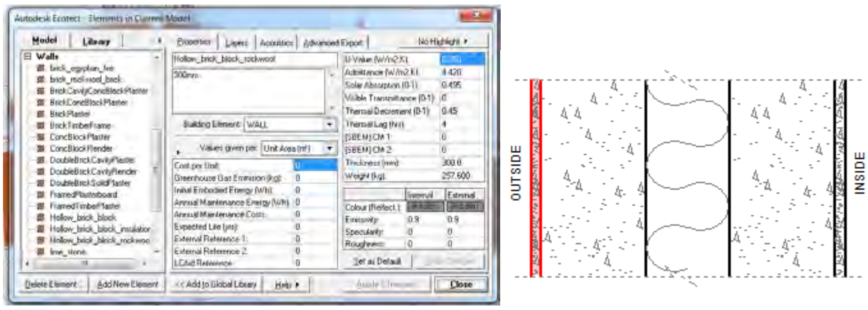

Figure 12. Double hollow brick wall with insulation for the second and third building in Ecotect analysis

Layer	Conductivity (W/m K)	Density (kg/m^3)	Specific heat (J/kgK)
Roof (from inside to outside)			
Prefabricated concrete beam	1.75	2300	920
3 mm Steel sheet	46	7900	454
0.2 mm Polyethylene foil	0.33	1526	1645
30–40 mm Water	0.582	1000	4187
300–900 mm Ventilated air layer	0.026	1223	1063
0.2 mm Polyethylene foil	0.33	1526	1645
200–300 mm Ventilated air layer	0.026	1223	1063
10 mm Polystyrene sheet	0.036	41	1500
0.8 mm Galvanized steel sheet P white	46	7900	454

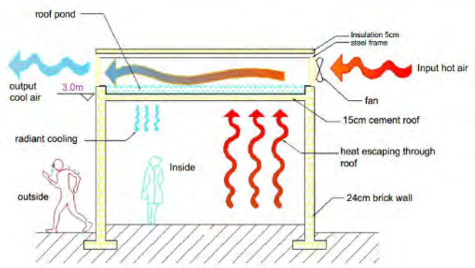

Figure 13, 14. Detail material for roof pond for the third building (Kruger et al, 2010)

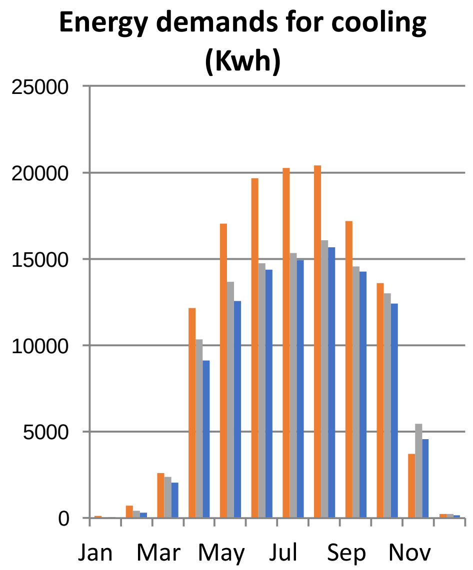
Take advantage of water features in the roof was the idea of this building design with the expectation that it will decrease a number of cooling loads and achieve a pleasant environment in the interior compared to the unsatisfying weather outside. Learn from attainment previous study about roof pond, simulation in Ecotect was carried to verify whether the thermal transmittance of water and other material will give a better result. Utilizing fan in the roof will decrease the temperature further because it accelerates evaporation process. However, this fan did not include in the simulation on Ecotect.

Energy Characteristic

The result from Ecotect simulation shows that building with invented material and passive design architecture perform better compared to building with the usual material. Although mud bricks are the sustainable material from Egypt, the invention of technology in building material affecting the performance of the building. In this simulation, the assumption was used that the building using full air conditioning to get the actual energy demands for providing heating and cooling.

From the figure 15, first, second, and third building, consume a total 127,726 kwh, 106,300 kwh, and 100,463 kwh for cooling energy in a year, respectively. August is the peak cooling energy consumption for all these buildings. In the cold season, the energy demands for heating are not as high as for cooling. However, it could be clearly seen in figure 16 that the first building consumes the highest amount of total heating energy in a year of 3,683 kwh, second building of 560 kwh, and third building of 895 kwh. With this result, it could be concluded that the total energy for cooling and heating for the third building which using double hollow bricks with insulation as wall material and window with *mashrabiya* without glass and combined with the application of roof pond is 5.43% less than the second building and 29.65% less than the first building.



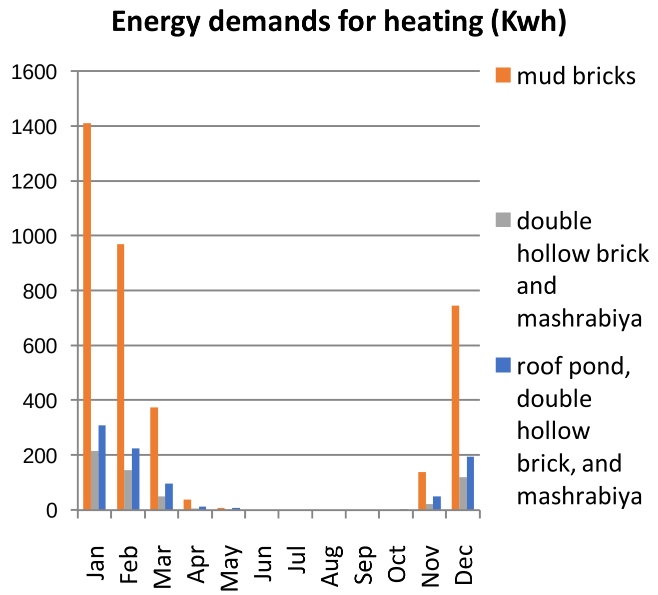


Figure 15, 16. Energy demands for heating and cooling with two alternatives materials and system applications

Conclusions

The design of this office building has been examined by modeling simulation in Ecotect. The result shows that passive design from vernacular architecture, invented with technology give better performance. From Ecotect simulation, energy demand for cooling and heating loads in building using double hollow bricks, roof ponds, and *mashrabiya* panel was lower compared to traditional material. It was because thermal conductivity in this material obstruct outdoor thermal environment coming to the building interior. For future studies, adding water features in *malqaf* would be better because evaporative cooling has proven as an effective technique to achieve comfortable thermal environment, indoor or outdoor.

Passive design for building in hot dry climate can be achieved by implemented these strategies:

- Natural Ventilation: Buildings and trees arrangement to maximize the air flow in the site and courtyard. North – South building orientation and placing evergreen trees in the North sides will caused optimum effects because in Cairo, prevailing winds come from North. Not only shades building, deciduous trees and dense trees in the South side also help to break the winds with sands from South. Large openings should be placed in south side which receive optimum sun radiation in winter. However, the west part of the building should be considered more as solar radiation increased during summer. The courtyard also has a great influence to provide thermal comfort.
- Using elements of traditional architecture concept in Cairo. For instance, *Malqaf* as a prevailing wind catcher and blows the air down to building in the interior, *Shesh* to allow

air flow and control sunlight into the building, and the *Taka* which embodies cross ventilation in the building. Using *Mashrabiya* as an air and light controller, decrease ambient temperature and increase humidity inside the building.

- Direct and Indirect Evaporative Cooling: Using water features in open space to add moisture to the air on the site, such as ponds in the garden and fountain in the courtyard. As a good modifier of micro-climate, water lifting large amounts of heat in the evaporation process to maximize cooling. Beside that, roof pond also could be used to decrease indoor temperature and energy demand for cooling and heating.
- Thermal mass effect strategies, using building material and structure such as thick walls and sandstone which can store heat and provides inertia against temperature fluctuation (Haglund et al).

The study of thermal comfort conditions as a tool in the early design stage of sustainable school buildings

Kleo Axarli[1] and Maria Kostoula[1]

[1] School of Architecture, Faculty of Engineering, Aristotle University of Thessaloniki, Greece, axarli@arch.auth.gr, kostoula.m@gmail.com

Abstract: It is well known that the school environment has a significant impact on educational activities. There is a strong correlation between the inside environmental conditions and the health and academic performance of pupils. This paper presents a method, developed to be used in the early stages of school building design process, based on the evaluation of thermal comfort conditions according to the climate. The research focuses on Mediterranean climate conditions, specifically those of Greece. Therefore, psychrometric charts of representative cities of Greece, with the most distinctive climatic differences, were examined. The appropriate strategies, defined by the analysis, resulted in the formation of a prototype design for classrooms block that creates thermal and visual comfort conditions, while providing good quality indoor air.

Keywords: school, thermal comfort, psychrometric charts

Introduction

The increasing concern of the indoor school environment has raised the environmental issues related to building design, of prime importance.

It is well known that buildings' climate responsive design moderates the indoor climate for human wellbeing, results to energy conservation and finally to a sustainable design. For school buildings, it is even more important. Thermal and visual comfort, the daylight and sunlight in classrooms and the adequate ventilation are important parameters that affect health, emotions, and academic performance of the pupils, as well as the energy consumption of the school building (Axarli et al, 2008; Dudec, 2000; Hyde, 2000).

The aim of this paper is to investigate the involvement of environmental parameters in designing school buildings and to suggest the design of a classrooms block, which corresponds effectively to different climatic conditions in Greece.

Prevailing climatic conditions in an area, concerning air temperature, determines the length of heating and cooling period and of the transitional periods with very low heating and cooling loads. At the same time, air temperature along with relative humidity are the main climatic parameters influencing design decisions in terms of the quantity of available thermal mass, the degree of thermal insulation, the need for shading and the appropriate cooling system, in order sufficient ventilation, heating and cooling in the school building is provided.

Psychrometric charts are valuable tools for defining the thermal comfort conditions in a place, throughout the year and the potential design strategies for extending the thermal comfort zone (Lechner, 2001). Psychrometric charts drawn for the different seasons of the year of selected Greek cities, provide qualitative feedback as to the potential effectiveness of a given design strategy for the classrooms concerning the architectural synthesis and the envelope configuration, while achieving thermal comfort. The selected design strategies based on the study of psychrometric charts are also evaluated on the basis of visual comfort and indoor air quality conditions created, which are crucial parameters for the school environment.

The time and the requirements of the schools' operation in Greece are worth mentioning. Occupation period is from September to June, Monday to Friday, from 8:00 to 16:00h. The requirements for the indoor environment of school buildings are specified in the following table considering the Greek and the international standards.

Table 1. Thermal -Visual Comfort and Air quality requirements for classrooms.

Thermal Comfort
Recommended conditions of thermal environment in school buildings

	Heating period	Cooling period	
Operative Temperature	min. 20^{o}c	max . 26^{o}C	TOTEE 20701-1(2010), EN15251(2007)
Temperature range	20-24^{o}C	23-26^{o}C	EN15251(2007)
Occupied set point	71^{o}F(21,6^{o}C)	74^{o}F(23,3^{o}C)	ASHRAE(2011)
Relative Humidity	35%	45%	TOTEE 20701-1(2010)

Climate in Greece and thermal comfort analysis

Generally speaking, Greek climate is a temperate climate characterized by its cold, humid winters, hot and dry summers and the four distinct seasons. Winter temperatures often fall below freezing point and summer temperatures can reach 40^{o}C, while the amount of insolation is significant in all places. However, the diversity of landscape, the vicinity with the sea and the existence of mountains and rivers influence a lot the local climate. A wide range of climatic types can be found across the country.

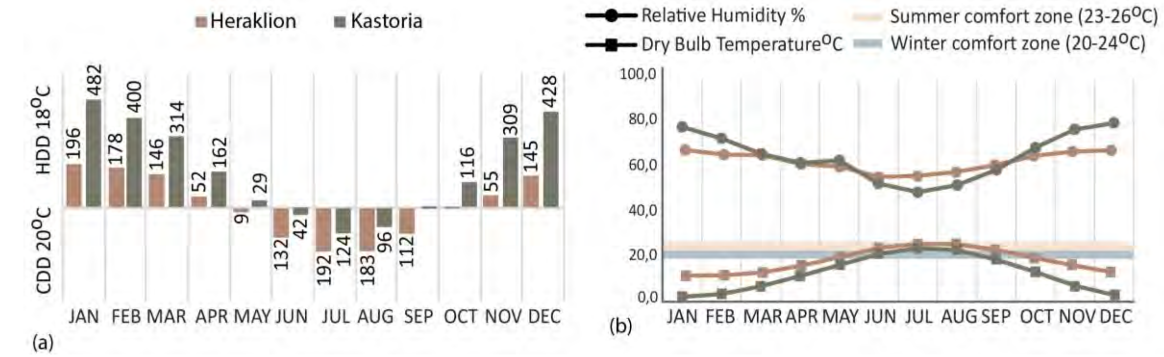

Figure 1. (a)Heating Degree Days 18^{o}C, Cooling Degree Days 20^{o}C of Heraklion and Kastoria and (b)Warm zone (Heraklion) and cold zone (Kastoria) Climate Conditions.

According to Heating Degree Days, Greece is divided in four climatic zones. This research focuses on A and D climatic zones, the warmest and coolest one respectively, as they are considered representatives of the variety of Greek Climate and it examines the climatic conditions of the two cities, Heraklion and Kastoria accordingly. The climate of Heraklion (lat. 35,20^{o} long. 25,11^{o}, alt. 39,3m -zone A) is characterized by high temperature and sunshine in summer, while the climate of Kastoria (lat. 40,27^{o}, long. 21,17^{o}, alt. 660,9m -zone D) by low temperature with periodically severe cold winds in winter.

The monthly calculation of Heating Degree Days determines the months of the heating period which are November to April for Heraklion (A' Zone) and October to April for Kastoria (D' Zone). Cooling period includes July and August for both cities, while transitional periods include September, October, May and June for Heraklion and September, May and June for Kastoria (Figure 1). The annual fluctuation of average monthly air temperature and relative humidity is more intense in Kastoria than in the warm city of Heraklion. In summer, the levels of average air temperature are within the predicted limits of acceptable thermal environment in both cities, while in winter the significantly low temperature observed in Kastoria, results in increased heating load. The variation of humidity levels appears to be bigger in Kastoria, due to high rainfall, than in Heraklion, which is mostly characterized by dry conditions and less rainfall (Figure 1).

Thermal Comfort Analysis of Greek Climate Zones

Using the software "Climate Consultant" © of UCLA Energy Design Tools Group, the warmest and coldest Greek climate zones are analyzed based on an hourly calculation, in order to define the periods with thermal comfort conditions (Figure 2). The potential extension of the thermal comfort zone is investigated by suggesting specific strategies as indicated in Givoni and Milne bioclimatic chart. The analysis takes into account clothing 1.0 clo for winter and 0.5 clo for summer and metabolic rate 1.2 met (ASHRAE 55, 2009).

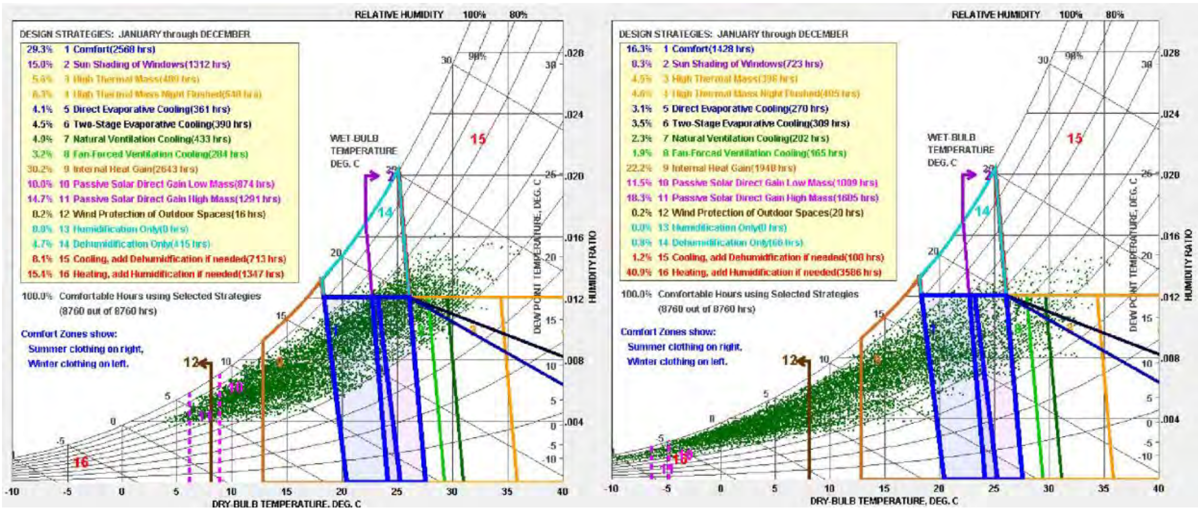

Figure 2. Psychrometric charts of Heraklion (warm zone) and Kastoria (cold zone)

In the warm zone (Heraklion), it is observed that in prolonged periods of time, especially during the transitional periods, thermal comfort conditions exist (Figure 3-a). Pupils in the warm zone experience more hours in thermal comfort conditions during the annual school operation than in the cold one. On the contrary, in the cold zone (Kastoria), the lower air temperatures cause noticeable discomfort conditions during winter while comfortable conditions exist during summer school break (Figure 3-a). It seems convenient enough to prolong school operation in summertime in both zones especially in the cold one.

Due to high levels of occupancy in classrooms, the internal heat gains can cause a considerable air temperature increase thus lowering the heating loads in both zones especially in warm zone (figure 3-b). Their effect depends on the airtightness of the building envelope and the level of thermal insulation, but as the internal gains are related to metabolic activity, good ventilation is essential to remove excessive humidity due to respiration and sweating during the occupancy period. In cold zone, internal heat gains can contribute to the maintenance of thermal comfort during the whole year (Figure 3-b).

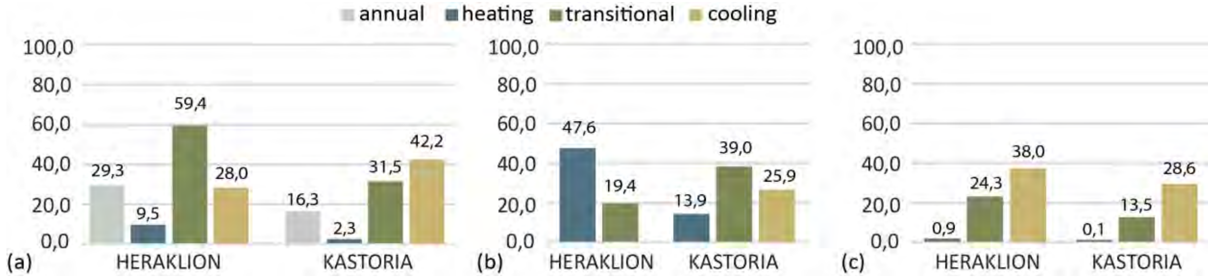

Figure 3. (a)Annual conditions of thermal comfort, expressed as percentage of the total amount of hours and contribution of (b) internal heat gains and (c) sun shading of windows, in thermal comfort

The passive solar heating systems are effective enough to counterbalance the increasing heating loads in both climatic zones (Figure 4-a). Exploitation of solar radiation with direct gain passive solar systems has a strong affect in thermal performance. High mass internal elements can be used effectively to store and distribute solar heat to the classrooms for a significant number of hours in both zones. In the cold zone, it is mostly effective during transitional periods, while in the warm zone can lead to a greater reduction of energy demands. However, the increased heating load in the cold zone enable the low mass structures to be heated immediately, when ambient conditions are favorable. In this case spaces, such as corridors, can be used as thermal buffer zones either providing heat build-up or protecting the main usable spaces from harsh winter conditions. In any case tighter building envelope and high thermal insulation are required.

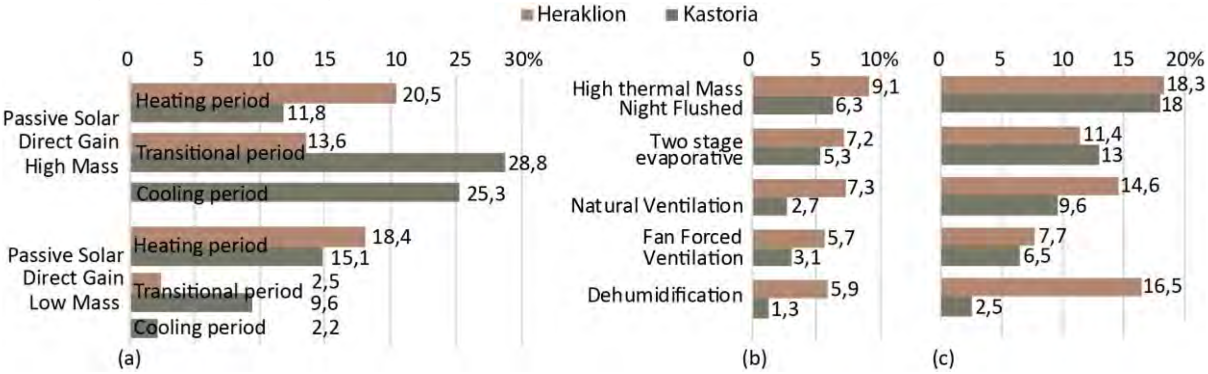

Figure 4. Effectiveness (% of comfortable hours) of (a) Passive Solar Direct Gain heating systems for the whole year, (b) cooling systems for the transitional period and (c) cooling systems for cooling period.

High mass is proven to be highly effective during cooling period, for both zones, while different cooling systems are predominantly effective for the climatic conditions of A’ and D’ zone (Figure 4-b,c). Indirect evaporative cooling systems are more suitable due to low humidity levels in the cold zone. On the contrary natural ventilation seems to perform better in the warm zone due to the higher needs of dehumidification. However, this strategy seems to be less effective during the day when there is high outdoor air temperature. Yet, some advantage can be taken of the low night time air temperature, thus applying night ventilation. Nevertheless, good ventilation is extremely necessary in school buildings because of the high occupancy, as long as discomfort caused by draught is avoided.

Sun shading of windows designed for passive solar heating is mostly important during summer, unlike heating period when solar radiation is welcomed (Figure 3-c). During transitional periods sun shading needs also increase, especially in the warm zone. It is worth mentioning that solar control in order to avoid risk of overheat and glare can be easily managed with shading devices, preferably movable ones, due to solar path in both areas, although the lower sun orbit in Kastoria (23^0 solar altitude angle on 21st of December) during winter should be taken into consideration. However, as shading devices can limit glare together with the amount of light penetration, the level of daylight achieved has to be investigated as well. An adaptive façade configuration is important to provide well-balanced indoor environmental conditions concerning thermal and visual comfort.

Strategies for thermal, visual comfort and good air quality

The analysis of the climatic conditions of the coldest and warmest Greek climatic zones and the discussion on the results of psychrometric charts set a guideline on appropriate strategies to be used in the early design stage for school buildings in Greece (Table 2).

Table 2. Weighting factor of selected strategies applied at the early stage of designing school buildings

Passive Heating and Cooling Systems

South facing glazing is the simplest and most effective solar passive system for school buildings. In the warm Greek climatic zone, windows should be operable, thus undesired heat can escape. In the cold zone, low U-value of windows is essential to eliminate heat loss. In general, passive cooling systems should optimize both, local breezes, which are common in Greece and the available natural sources (water mass, geothermal energy) to support hybrid systems when needed. Using the Adaptive Comfort Model (ASHRAE 55-2010), for thermal comfort analysis, it is clearly defined that there is a significant increase of natural ventilation effectiveness (from 4,9% to 24,7% of the hours in comfort in the warm zone and from 2,3% to 10,4% of the hours in comfort in the cold zone). When occupants are allowed and encouraged to manually control their thermal environment, by means of operable windows and shading systems, their ability to adapt to the indoor conditions increases.

Strategies providing good quality of air

Passive cooling systems in order to compensate for the excessive internal heat gains should be related to sufficient ventilation rate. Levels of occupancy and activity and consequently the need for high ventilation rate have to be taken into consideration so as the selected strategies (i.e. as cross ventilation, fan forced, stack effect) effectively correspond to most adverse conditions. A system combination is ideal as long as it can be supported from building form. For example, a stack effect ventilation system combined with heat recovery is a suitable solution in case of cold climate (as in D' zone) when a compact configuration is appropriate. Roof monitors can also contribute to natural ventilation.

Solar and Light control

Horizontal or vertical louvers and overhangs (depending on orientation), are appropriate shading devices to avoid heat trapping inside the building (Palmero-Marrero et al, 2010). They can also contribute to the distribution of daylight. Shading devices acting as light shelves have a positive effect not only on sun shading but also on daylight distribution inside the classrooms, in the same way as high glazing and glazed roof apertures contribute to daylight uniformity (Antoniou et al, 2006; Axarli et al, 2007). The ability of shading devices to permit or block the solar radiation, distribute the daylight and facilitate natural ventilation provides high building performance and the potential of manual control of indoor environment.

Thermophysical building envelope features
Great thermal inertia of buildings against temperature fluctuations results in high building thermal performance in both hot and cold conditions. Buildings in the cold Greek climatic zone have increased need of high mass, insulation and airtightness in order to keep the collected heat from the sun. On the contrary, in the warm zone, where there is a risk of overheating, movable panels with thermal insulation have better effect. However, it is essential that thermal insulation meets the relevant regulations, in both zones. It is worth mentioning that sufficient and appropriate vegetation improves microclimate conditions thus thermal comfort conditions.

Prototype design for a classrooms block

The aim of the research is the design of a classrooms block taking into account strategies to improve thermal comfort conditions throughout the year, as analyzed above. The proposed prototype design has to fulfill the environmental requirements for both, the cold and warm climatic zones in Greece and to create a thermal and visual comfort environment with good quality air and the minimum heating and cooling load.

The basic design requirement for the fabric is to comply with the Greek Regulation for the energy performance of buildings, i.e. U_m=1.26 W/(m^2.K) for the warm climatic zone and U_m=0.96W/(m^2.K) for the cold zone (the ratio of floor area to volume, is approximately 0,20). The prototype classroom block consists of four classrooms attached to a double height corridor.

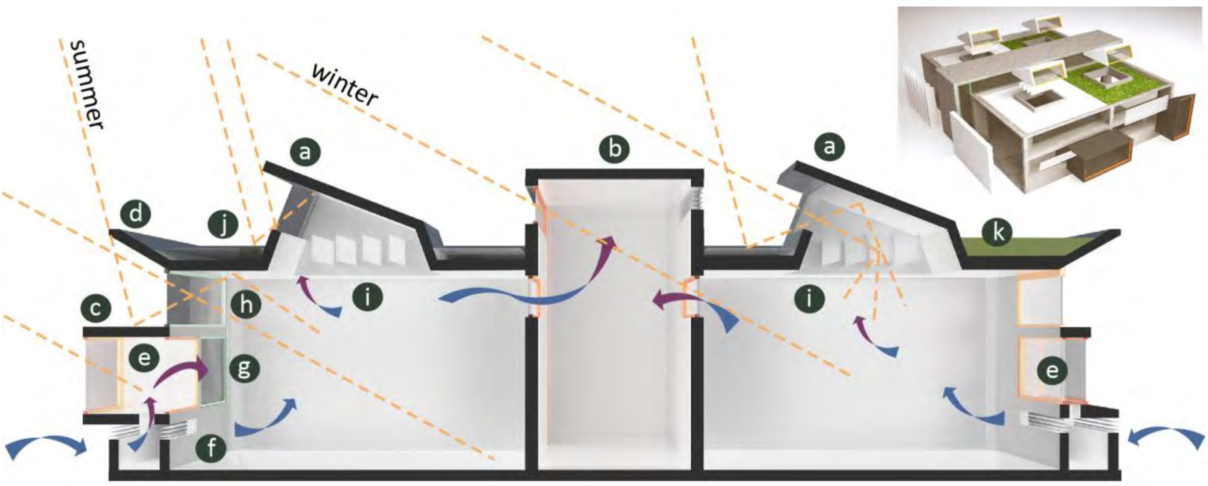

Figure 5. Section across classrooms and corridor and alternative design practices.

Sets of classrooms blocks can develop building wings, preferably along E-W axis so as classrooms will have south or north oriented glazing. The configuration meets Greek regulations for minimum classroom dimensions (7.0m X 7.0m and 3m height). For better daylight penetration the classroom height in the proposed design, is set to 3.9m.

The building is characterized (Figure 5) by south facing, slightly inclined, roof monitors [a] and a raised central corridor [b] so as to provide uniform daylight, ventilation and solar heat benefits avoiding risk of glare. Structural elements of reinforced concrete, form light shelves[c] and inclined overhangs[d] that contribute to solar control. A passive system [e] attached to north and south facades consist of two glass panes with a wide air cavity. It acts as a collector for solar radiation in order to provide preheated air for the south oriented classrooms and as a thermal buffer zone, protecting the northern oriented classrooms from cold outdoor conditions.

The building envelope, made of precast concrete double wall system, offers protection from undesirable environmental conditions (noise, air temperature, wind) and the potential to house systems that assist the envelope environmental functions (i.e. fans for evaporative cooling and ventilation) [f]. Windows are arranged in distinctive zones for view [g] or daylight penetration[h] and with characteristics that meet the requirements for effective thermal performance under Greek climatic conditions. All windows can be manually operated to avoid overheat. Roof monitors are equipped with daylight reflectors[i]. Cool roof [j] and reflective materials are more effective in warm zone, while in cold zone green roof [k] is used as an additional thermal layer.

Evaluation of the prototype design of the classrooms block

The assessment of the prototype design of the classrooms block refers to the adequacy of visual comfort levels and the ability to use efficiently the ventilation system applied.

The visual comfort was examined for Heraklion-A' Zone and Kastoria-D' Zone using the Autodesk Ecotect Analysis© 2011 software for urban conditions (see table 3). The percentage of average daylight factor was measured 5,62% and the average daylight level was calculated 449,45lux for Heraklion (warm zone) and 365,18lux for Kastoria (cold zone). Daylight levels meet sufficiently the requirements of at least 250lux illuminance at 75% of the classroom area. The shape of the proposed classrooms block increased the uniformity of daylight distribution and the penetration of daylight to the back space of the classroom, compared to a typical classroom meeting the minimum Greek requirements (Table 3). Although the passive system with the double glazing applied to the proposed design reduces daylight levels, visual comfort is achieved (table 3).

Table 3. Required Fenestration for prototype Classrooms-Block and daylight analysis of (a) the conventional design and (b) the proposed design

Daylight Illuminance Calculation Assumptions	
Time	9:00am & 3:00pm
Date	Spring Equinox (20 March)
External Daylight Illuminance	CIE Overcast Sky Model Heraklion 8000lux Kastoria 6500lux
Daylighted area	75% X(7,0m X 7,0m)
Plane	0,80 above the floor

Fenestration Characteristics	
Window to Floor Area Ratio (According to greek regulations)	10%
Window to Wall Area Ratio (According to greek regulations)	20%
Total Window area to Floor Area Ratio (ASHREE 2011)	7%
View Window to Floor Area Ratio	7%
Daylighting Fenestration to Floor Area Ratio	
South Orientation	
Glazing above light shelves	7-10%
South-Facing roof monitors	6-8%
North Orientation	
High glazing	10-13%
South-Facing roof monitors	6-8%

(b)

ClassVent© tool, developed by the British Department for Education, was used to investigate the capability of building envelope in allowing the air flow procedure. It is assumed that the average required volume flow is 7lt/sec/ person (equivalent to 25m^3/h/per or to 4ach) so as to meet the standards of Table 1. The analysis proved that the size and the location of ventilation inlet areas and the stack outlet area are efficient, so that air can flow smoothly into the stack (Table 4). Results show that the design of the classroom block and its fabric configuration enhance the natural ventilation; thus, ventilation needs are covered sufficiently without undesirable effects. It is worth mentioning that cross-ventilation compared to stack effect ventilation is more difficult to be applied in school buildings as it demands a higher value of wind speed and a wider range of temperature between indoor and outdoor conditions.

Table 4. Required Classrooms Block ventilation openings' area

Ventilation Openings' area Calculation Assumptions		
Stack Outlet height from ground		6,2m

Conclusions

This study has taken a step to the direction of studying the quality of the environment in classrooms and revealed that it is important to understand the local environment before being able to develop a suitable climate responsive school building. Extensive research on the particular climate characteristics of a country can lead to the more specific early stage design strategies for school building design. The evaluation of the proposed design strategies applied in the prototype design of the classrooms block has shown that if appropriate design climate matching issues are taken into account in the early stage design process, they can contribute to the creation of space with high environmental quality and good performance in both the warm and cold climatic areas in a temperate climate as those of Greece. Also, when designing in terms of sustainability, understanding the interrelationship between the applied design practices is essential, in order to maintain a balance between thermal and visual comfort.

The Practice of Architecture in the Tropics: Integrated Design Approach

Nitin Bansal[1], Manit Rastogi[1] and Piya Gupta[1]

[1] Morphogenesis, New Delhi

Abstract: Architecture in some of the densest cities in India (and the world) demands highly conscious spatial consumption with office design standards reaching efficiencies as low as 50sq.ft./person. Consequently, high internal gains and stress on available resources have led to innovative developments in the way these buildings need to be designed and built. Sustainable architecture must not only have a reduced impact on the environment but also needs to be flexible enough to cater to the changing usage of the building over an extended time period. Affordability or cost effectiveness, a key development factor in emerging nations often overrules the intention of sustainability, making it essential for these design strategies to be economically viable too. The critical balance between efficiencies for structure, area, occupants and resources needs to be established right from the conception level. Exploring the potential of adaptive comfort can help realize the possibility of using protected open spaces for user- interactive functions of a programme.
The paper outlines the dynamics of an integrated design approach to practicing sustainable architecture in India, through an office building in Hyderabad. Located in the most prolific climate typologies in India, the design results demonstrate a balance of sustainability, spatial efficiency, economy and occupant satisfaction taking shape into 4 climate-responsive buildings.

Keywords: Energy, Sustainability, Office-Design, Density, Commercial

Background

Practicing environmental architecture in a developing country like India has unique advantages as well as challenges. Vernacular architecture is deeply rooted in passive design while urbanization has led to highly populous cities with 60% of the urban population living in metropolitan cities like New Delhi, Mumbai, etc. This has resulted in overcrowding, lack of space and consequently sky-rocketing real-estate rates equivalent to any other metropolitan city in developed nations. Design efficiency for the built environment is hence crucial and must bring together a comprehensive understanding of the principles of structural flexibility, optimised indoor environment controls, occupant comfort creating a holistic sense of identity for the overall macroclimate. The metrics of Sustainability, Affordability, Identity and

Figure 1.Key parameters for commercial architecture in developing countries

Livability extensively cover both **requirement** and **result** for good architecture, as depicted in Figure-1.

Sustainability and affordability come together to create contemporary and global architecture, yet respond to the local climatic conditions and subtly to our deep rooted socio-cultural instincts. This process of integrated design has been illustrated through an IT-office project in the hot-humid climate of Hyderabad.

Climate

Analysing the climate is the first step towards understanding the possible passive strategies applicable to the site. This process is critical in setting the project parameters for comfort and usability of open spaces. The prevalent tropical climate in India demands a combination of passive strategies for year-round comfort. Considering conventional occupancy for commercial buildings (9am-6pm), the external conditions indicate the potential to employ evaporative cooling strategies for the hot-dry period of the year. Physiological cooling is the most effective strategy for extremely humid situations demanding approaches that utilize the prevalent East-West winds at over 2.5m/s. High intensity of solar radiation adds to the challenge of creating a glare-free, 100% day-lit working environment while ensuring effective solar control (for reducing cooling loads). *The Indian Model for Adaptive Comfort study (Green Rating for Integrated Habitat Assessment* (GRIHA)-Appendix-1, The Energy and Resources Institute, 2015) addresses the thermal adaptability of people living in tropical climate typologies inherent to the country.

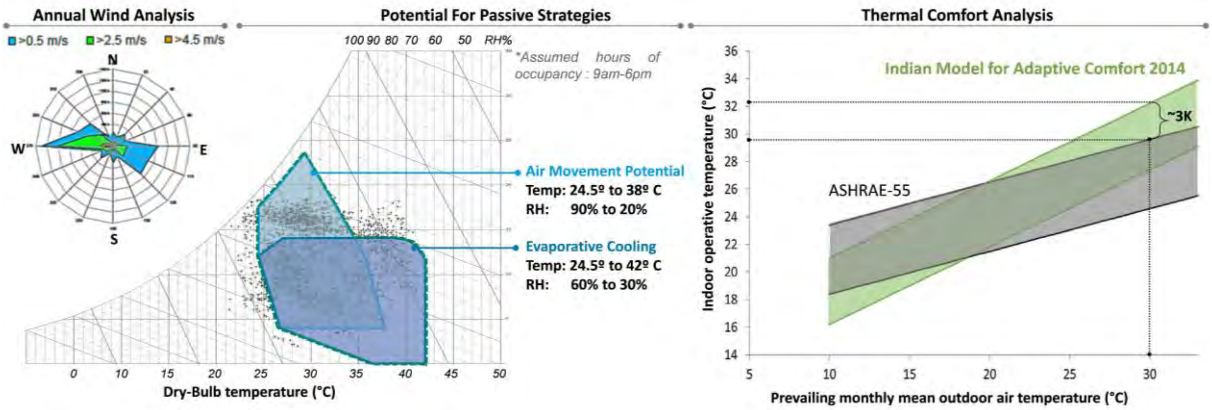

Figure 2. Climate analysis and Thermal Comfort Standards in Hyderabad

Sustainable Design Brief

Historical precedents suggest that architecture itself was a response to lack of availability of resources and response to climate, the principle being that nothing was ever wasted. This approach of 'No is More', i.e., imagining one has no resources at one's disposal, becomes an inspiration for creating truly optimised built-spaces catering to present-day issues of stress on resources. Based on an approach that began with the carrying capacity of the land, the 100 acre site for an IT campus in Hyderabad was found to be capable of sufficing the conventional water demand of 14,400 persons. A 3m deep water reservoir of approximately 14 acres was designed to be located in the low-lying section of the site. The annual energy consumption for the project was targeted at 60kWh/m^2/yr. with primary energy consumption estimated at 35kWh/m^2/yr. and 25kWh/m^2/yr. being load from equipment. Integrating renewable resources to offset the energy demand presented a requirement of a 13 acre solar farm. Comparable spatial requirements allowed the solar farm to be planned on top of the water reservoir, expected to significantly reduce evaporative losses while cooling the solar panels at the same time.

Table 1. Carrying Capacity for water resources.

Site Area	4,09,961	sq.m

Urban Design and Masterplanning

Designing for utilizing prevailing winds, visual comfort through day-lighting and solar control resulted in a series of urban design solutions. 6 schemes were generated without imposing any pre-conceived notions of aesthetics, responding purely to the density and environmental performance targets. The schemes were first analysed through the process of computational fluid dynamics to understand the movement of air in open spaces and the potential to naturally ventilate the buildings. The built-mass was staggered to enhance natural air-movement allowing most facades to be opened-up for natural ventilation. Less deep building floor plates provided good daylighting potential and allowed for natural cross ventilation. Constructional phasing of the proposed development was considered critical for all practical purposes. The resultant was a masterplan translating the sustainable design brief thereby generating a microclimate of comfortable outdoor and semi-outdoor spaces with the potential of being utilised for the interactive common functions of the programme. In order to maximise on the functionality of the courtyards, the effect of introducing a roof, elevated air-speeds and dry mist systems were explored as targeted strategies for open spaces. The PMV (predicted mean vote) prediction model developed by Fanger in 1970 was used as the basis for testing comfort in outdoor spaces as it considers physiological processes of the human body which are crucial in the perception of comfort. The hot-dry period from March-June would require high thermal mass combined with evaporative cooling and elevated air speed for good thermal outdoor comfort. Moreover, shaded and ample natural ventilation along with the use of fans to elevate air speed proved to create good thermal outdoor comfort from July to February. Strategies of evaporative cooling and evapo-transpiration (shade by plants and vegetation) were considered for further enhancing the outdoor comfort conditions. Direct solar control strategies for the courtyard helped almost double the period of comfort during occupancy hours. Enhancing the air-movement by morphology as well as introducing active methods like fans proved to be successful in increasing the hours of comfort to 60%

annually but also increased the capital cost negligibly by £1/sq.ft. Moreover, mist cooling systems drastically improved the microclimate by achieving comfort in 97% of the occupied hours, also adding to the investment by £4/sq.ft. Finally, common functions like the food court seating and even part of the library were designed as semi-outdoor protected spaces encouraging a dialogue between the natural environment and the users, proving applicability of adaptive comfort strategies in hot-humid climate conditions. Using the above processes, over 1,00,000 sq.ft., comprising 9% of the total built-up area, was successfully eliminated

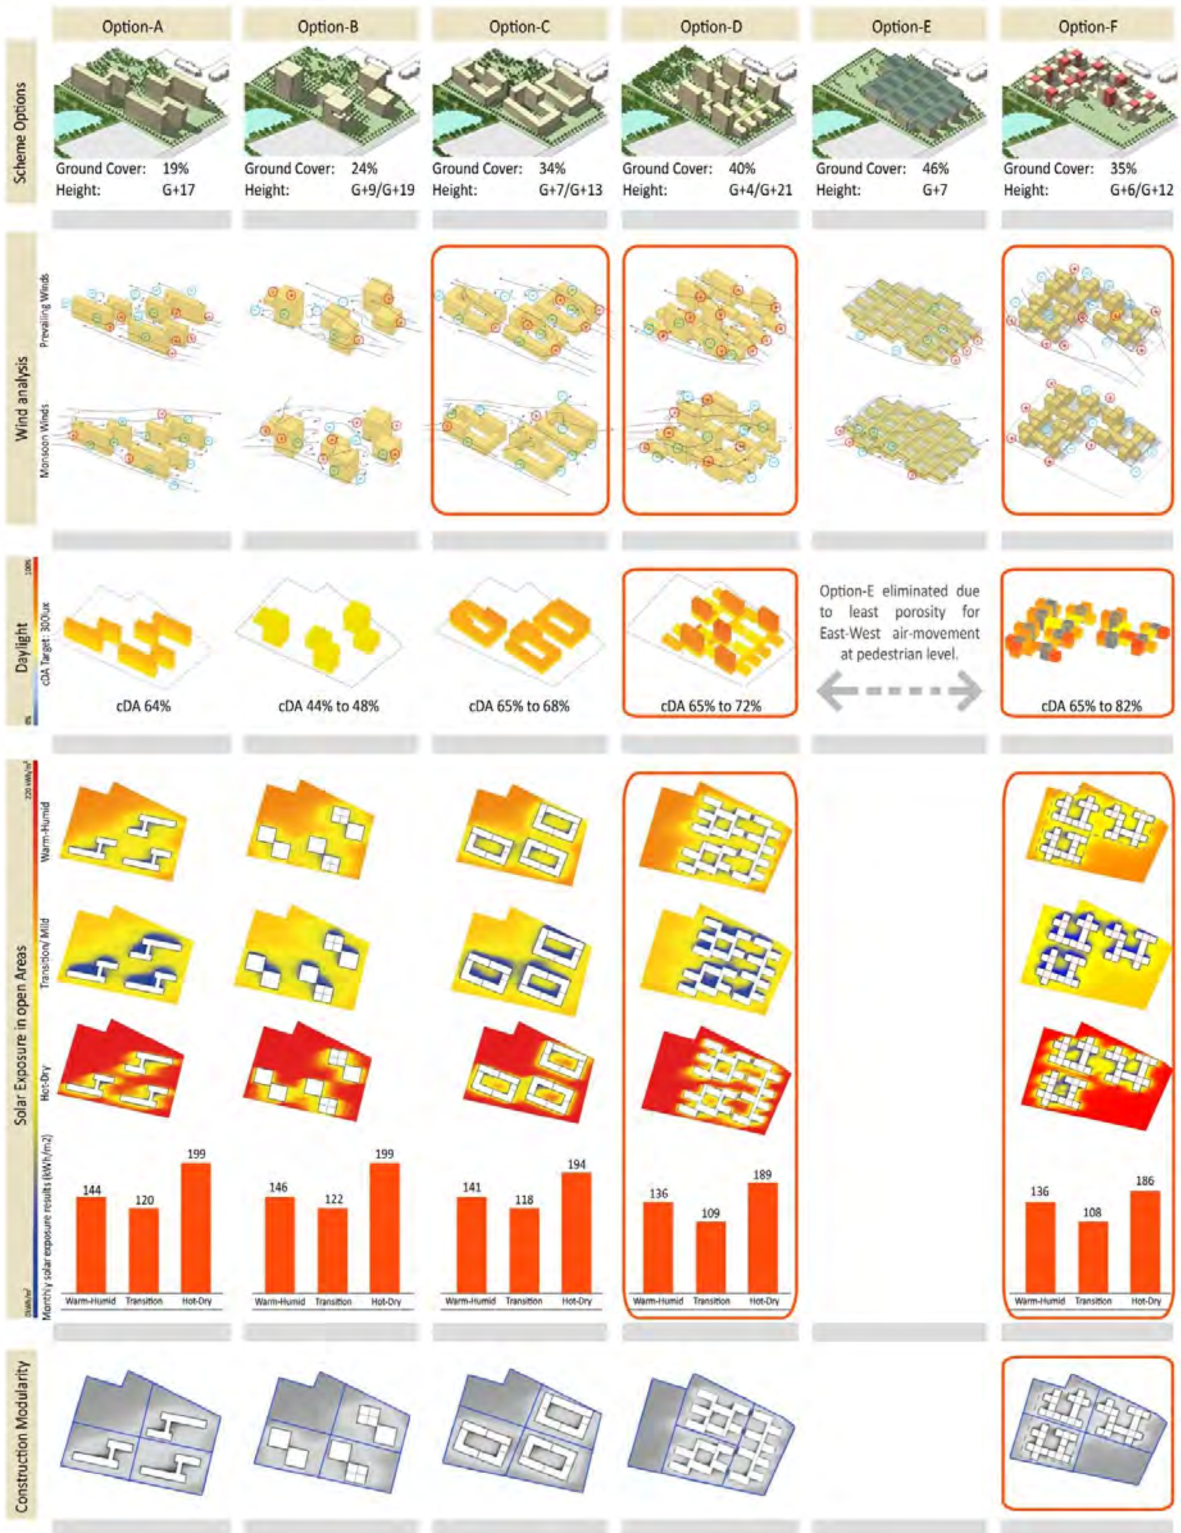

Figure 3. Methodology of Urban Design and Masterplanning for an IT campus in Hyderabad

from the construction requirement. Moreover, in addition to being a grand arrival plaza, the courtyard becomes a multi-functional gathering space at 10% of the conventional capital cost.

Built-Form

Modular efficiency involved an inside-out approach using a structural grid of 11.5Mx8.5M that could be a multiple of a workstation module as well as a car parking bay as the lowest

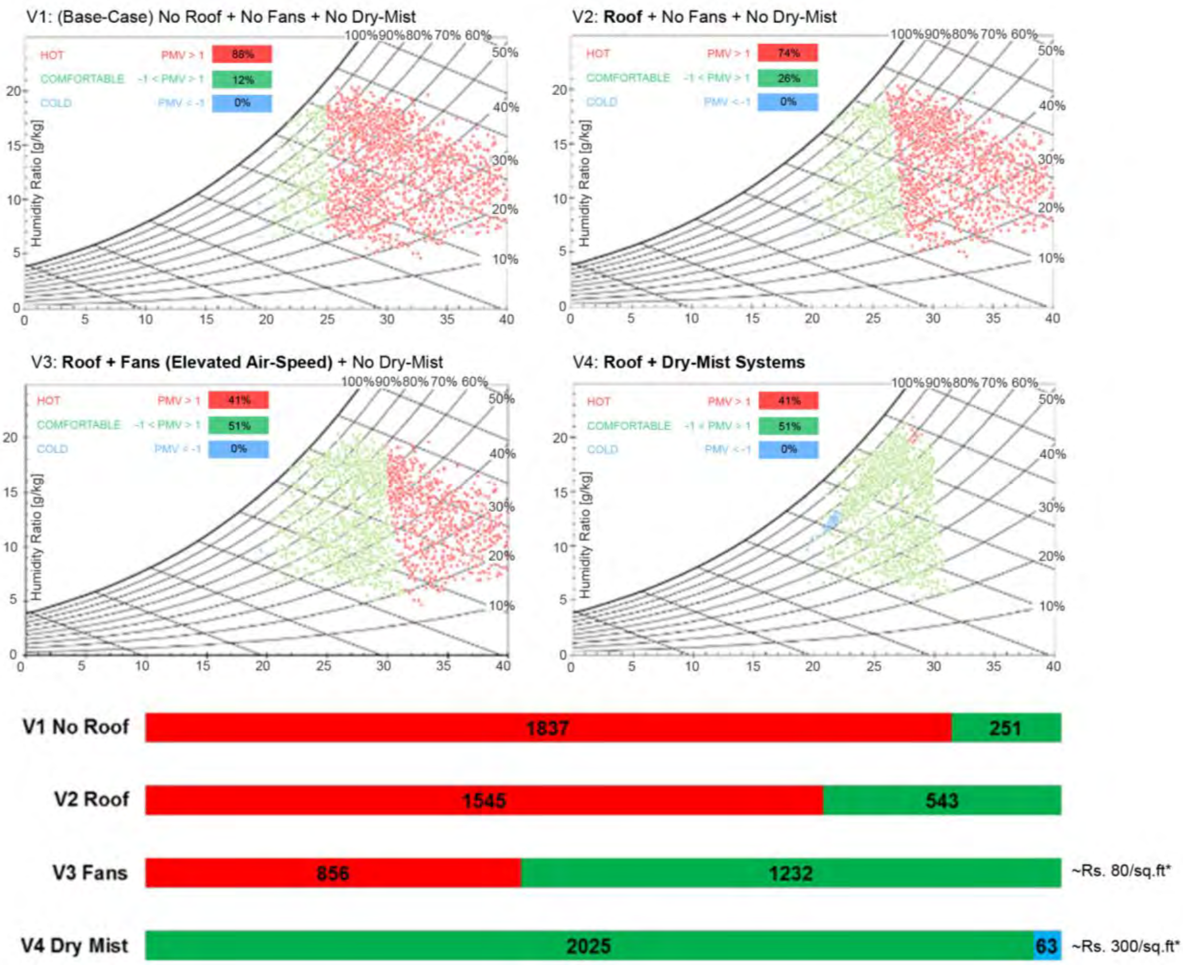

Figure 4. Comfort & Cost Evaluation for Outdoor spaces using the PMV model for adaptive comfort

unit. Workspace efficiencies of upto 45sqft./person were achieved with an overall 85sq.ft./person on built-up area. This further saved 15% of construction area as compared to conventional standards of 100sqft/person. High density work-spaces were expected to lead to high internal gains due to large no. of computers over a relatively lesser area.

Design of the built envelope was governed by balancing shade, glare, daylight distribution, solar heat gain reduction. Solar control for the external facade involved vertical fins and overhangs spaced according to the different orientations. Shading devices were designed with conscious attention to controlling glare without hampering the daylight distribution. External façade treatments are more often than not, eliminated during the course of a typical project as capital cost is generally given more thought over controlling operational costs. Moreover, maintainability of these features becomes more challenging over time due to high intensity of sun and air pollution levels in larger cities. These issues led to an integrated façade designed as an extension to the structure of the building with concrete slab projections and monolithic vertical fins, spaced relevant to the orientation.

The facades facing the courtyards were mostly protected by the roof coverings and could therefore be allowed to open up to the microclimate. Illuminance targets of 110lux were achieved by effective daylight distribution. The cumulative solar heat gains from the designed façades were calculated to assess the overall thermal efficiency of the envelope. Finally, the solar heat gain for the entire building was calculated and resulted in an overall thermal efficiency of 0.8W/sq.ft.

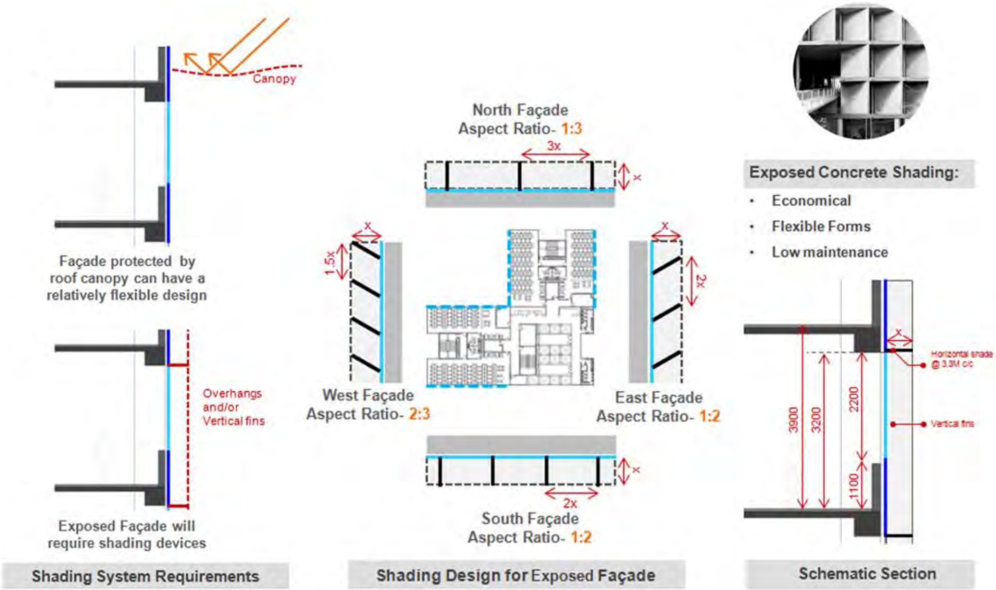

Figure-5. Integrated façade design for reducing solar gains through building envelope

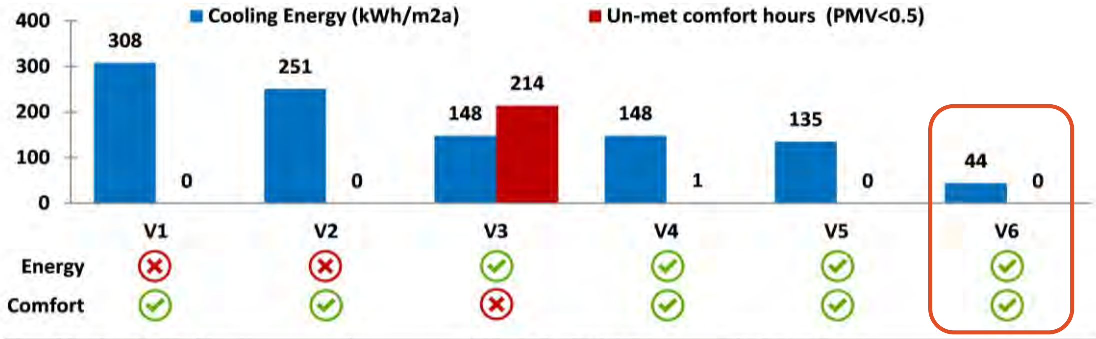
Active Systems

Thermal comfort has proven to be crucial in achieving occupant satisfaction as well as workplace productivity. Setting comfort targets when the end user is not involved makes it essential to consider not only the adaptive factor but also expectations of comfort which may vary for different climate typologies. Working spaces demand consistent and controlled indoor environments for minimal distraction during focused tasks. Although minimal, the cooling loads as a result of microclimate creation and robust envelope design needed to be countered with active systems to achieve the desired comfort levels indoors.

Multiple cooling systems were analysed to achieve the most optimised solution specific to the project constraints. Innovative mechanical cooling systems including radiant cooling, under-floor systems as well as ceiling fans were explored in exclusive as well as combination scenarios. Feasibility analysis studies concluded with the selection of under-floor cooling system for controlled thermal comfort requirements in working spaces. The primary advantage was that the system offers flexibility in internal layouts enabling any future changes in market standards and user requirements. An iterative process was followed where finally the mechanical system allowed higher operative temperatures at elevated air speeds of 0.5-1m/s using ceiling fans was finally concluded (Figure-6). Under-floor cooling systems are generally useful due to the stratification of air in high-volume spaces. Adding air-movement at ceiling level is undesirable in such cases as it is expected to counter the process. However, floor heights limited to 3.9-4.5M are unable to benefit from stratification since temperature variations only upto the range of 0.5-1°C are achieved. Enhanced air-movement in such spaces hence, significantly adds to the physiological comfort. The overall advantages offer flexibility to the architecture as well as active systems.



Case	Cooling Method	Comfort Conditions	Interventions
V1	Under-floor air-conditioning (UFAD) system	Operative temp. ≤ 24°C, RH%≤ 60% Mechanical ventilation=20cfm	AC
V2	UFAD + Heat Recovery Wheel		HRW introduced
V3	Hybrid Tempered	PMV (with elevated air speed) < 0.5 mechanical ventilation=20cfm	Hybrid Tempered
V4	Hybrid Tempered		Internal gains from equipment reduced
V5	Hybrid Tempered	Operative temp. ≤ 25-26°C, RH%≤60% mechanical ventilation=13cfm Return air =30cfm	Mechanical ventilation system altered
V6	Hybrid Tempered	Operative temp. ≤ 28-29°C, RH%≤ 60% mechanical ventilation=13cfm Return air = 8.5cfm	

Figure-6. Sensitivity Analysis for Hybrid Systems integrating elevated air-speeds

A combination of natural ventilation and evaporative cooling may work for hot-dry conditions but highly humid environments make it very difficult to open to the outdoors without adding systems for dehumidification and enhanced air movement. Learning from the analytical studies where the effect of elevated air speeds on the microclimate was tested through installing ceiling fans in indoor spaces thus, creating hybrid systems to reduce mechanical cooling loads. Robust envelope design enabled common interactive functions within the built-spaces to be opened up for natural ventilation by using the same strategies of dry-mist systems in combination with fans. The basic understanding was that when occupants are not at work or are involved with interactive activities in a work environment, they tend to be more accepting and adaptive to their surroundings. Consequently, the microclimate could be further extended to comfortable transition spaces where another 35% of the total built-up area of the office building was made comfortable at half the cooling energy requirement of conventional practices. Combining passive principles of solar control and active systems for cooling proved to save another 50% of cooling energy in fully air-conditioned spaces (Table-3).

Table 3. Relative savings in construction area and cooling energy consumption

Area Distribution	*Use*	*Measures Considered*	*% age Area*	*Cooling energy savings*
Air Conditioned Spaces	Workstation areas, meeting rooms	**Under-floor cooling + Fans**	**56%**	**45%-67%**
Naturally Ventilated Spaces	Cores, Library, Food Court, Gym, Lobbies, discussion areas	**Natural Ventilation + Fans + Dry Mist Systems**	**35%**	**50%**
Shaded Outdoor Areas	Outdoor open cafeteria seating, recreation, library, arrival plaza	**Tensile Roof + Fans + Dry Mist Systems**	**9%**	**49%**

Conclusion

The comprehensive design process discussed above concluded at an overall construction cost falling well within £40/sq.ft. This factor was extremely crucial when addressing the budget constraints of projects in developing nations where saving in capital investment usually trumps operational costs. Overall, the office project in hot-humid conditions of Hyderabad can be seen as an exemplar for successful application of sustainable principles in hard-core cost-driven markets like India.

Pushing the potential of sustainable design requires expert inputs from multiple contributors like architects, climate engineers, structural consultants, mechanical, electrical, plumbing consultants, etc. Designing optimised systems and low energy consumption starts making commercial sense only when complemented by spatial efficiency. Energy consumption per capita becomes a crucial factor in analysing the efficiency of sustainable architecture in high-density markets. Similar applications of integrated design across the various tropical climate typologies have proven to be equally effective as can be seen in figure-7.

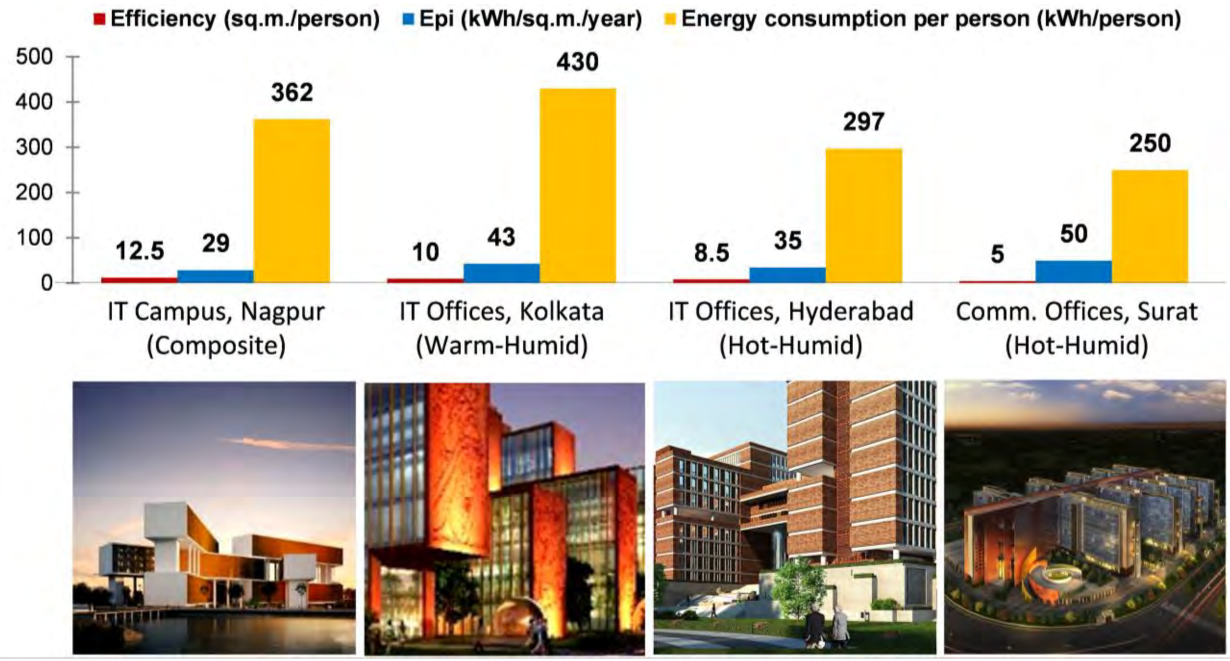


Figure-7. Applicability Of Integrated Design Approach Across Different Tropical Climate Typologies

Acknowledgments

We would like to thank Sonali Rastogi (Founder Partner, Morphogenesis) and members of the project design team at Morphogenesis, New Delhi, for their hard-work and dedication. Special mention is needed for the project team of Transsolar KlimaEngineering for helping realise the potential of sustainable design strategies.

Passive Design Indices: Quantifying the Potential of Passive Design Strategies in a Climate

Jaydeep Bhadra[1], Prasad Vaidya[2] and Saket Sarraf[3]

Abstract: The study focuses on developing indices to assess the potential for passive cooling strategies for a climate. Diverse microclimatic conditions are found within broader climatic regions at the scale of a few kilometres. Currently available climate analysis tools do not explore the interrelationships between different climatic parameters. Earlier work showed that it is possible to develop a weather-data-based classification to map the potential of some basic passive design strategies, such as building orientation. This study takes that approach forward to establish weather-data-based indices for advanced passive design strategies such as evaporative cooling, comfort ventilation, radiant cooling, earth cooling, and night ventilation. Weather data variables are identified for each strategy. Adaptive thermal comfort models represent the indoor comfort conditions. TMY weather data of 59 Indian cities and 2 international cities are analysed to develop the indices. Thermal Autonomy and Discomfort Degree Days are the metrics developed to measure the potential of the passive strategies. These will enable policy makers to develop climate zone maps that highlight the potential for specific low energy solutions in a region.

Keywords: Passive design, Indices, Climate, Potential, Low energy cooling

Introduction

Buildings consume more than 40% of world's primary energy and have a significant impact on Climate Change. Cooling accounts for 40%-60% of summer peak load in large metropolitan cities with hot climates like Delhi, and air conditioner (AC) sales in India are growing at 30% per year (CEM, 2014). Improved energy efficiency can be achieved using low-energy systems and passive design strategies. Identification of appropriate passive design strategies in early design stages thus becomes important to counter increasing energy use. And, understanding the potential for low energy and passive cooling solutions in a location enables the manufacturers and supply chains to market their products more effectively. However, there is a lack of regulation and support for widespread implementation of passive design strategies (Pawar, Mukherjee and Shankar, 2015). Earlier work shows that it is possible to develop a weather data based classification to map the potential of some basic passive design strategies, such as building orientation (Pawar, Mukherjee and Shankar, 2015). Development of such maps first requires developing a methodology for calculating indices that summarize the potential for passive strategies.

These passive design indices can be considered analogous to Cooling Degree Days (CDD) and Heating Degree Days (HDD). CDD is used to understand the thermal stress a climate places on a building, and provides an index to quantify the relative intensity of use of AC equipment across different climates; similarly, passive design indices can be used to understand the potential and relative intensity of use for low energy cooling methods to provide autonomy from air-conditioning. Literature suggests that most previous work on classifying a climate is based on a quantification of the stress, and passive strategies have been recommended based on the prevalence of certain climatic conditions. These recommendations do not use a quantified potential of any strategy in a climate i.e. it does not give any indication of the number of hours for which a strategy can be effective to achieve comfort. Furthermore, since within many regions, variations in microclimatic conditions can be found at a scale of a few kilometres, such recommendations may not be applicable similarly for specific locations within a climate zone. Therefore, there is a need for indices generated to identify the opportunity and potential of passive strategies in a climate for a location.

Levitt, Ubbelohde, Loisos, & Brown, (2013) proposed "Thermal Autonomy" as a metric and design process that links occupant comfort to climate, building fabric, and building operation. This metric is framed to avoid energy use and embrace the opportunities of the climate. It measures how much of the available ambient energy resources a building can harness, rather than how much energy heating and cooling systems will consume.

(Chiesa and Grosso, 2015) assessed the geo-climatic potential applicability of natural ventilative cooling for 50 reference cities in Mediterranean area based on a climate-dependent evaluation of the Natural ventilative Cooling (NVC) potential for different location using Residual Cooling Degree Hours (CDH_{res}) as a metric. CDH_{res} is defined as the AC-related virtual cooling needed for each location after the application of natural ventilative cooling.

This study develops the calculations to adapt Thermal Autonomy as a metric that can be used to assess the potential for 5 passive cooling strategies in a climate and remove the confounding variables that would otherwise make the calculations specific to a given building condition. Here, the objective is to calculate the maximum potential available for a strategy in a climate. Similarly, the study also adapts CDHres in to a metric called Discomfort Degree Hours, by replacing the Balance Point Temperature with the Adaptive Thermal Comfort control set-point. An analysis tool is developed to calculate these metrics for TMY weather data. The results from the tool that include data for 59 Indian cities and 2 international cities are presented.

Methodology

Identification of strategies and climate variables

Literature was reviewed to identify relevant climatic variables, heat sinks and physics for 5 passive cooling strategies (Evaporative Cooling, Comfort Ventilation, Night Ventilation, Ground Cooling and Radiant Cooling).

Stress in this study is defined as the distance (in degrees) between ambient condition and the expected comfort temperature for an hour. **Opportunity** in this study is defined as the availability of cooling potential in a heat sink (in degrees), to achieve desired comfort temperature for an hour.

Table 1 summarizes the strategies, heat sinks, climatic variables and the heat sink measure from the literature.

Table 1: Climatic Variables associated with strategies

Strategy	Sink	Climatic variables	Heat Sink Measure
Night Ventilation	Air	DBT	Diurnal Variation
Comfort Ventilation	Air	DBT & Wind Speed	$T_{in} – T_{out}$ (or, DBT), when DBT<T_{in}
Radiative Cooling	Sky	DBT, T_{dp}, & cloud cover	Difference between DBT and T_{sky}
Ground Cooling	Earth	T_{ground} & DBT	Difference between T_{ground} & DBT
Evaporative Cooling	Air	DBT & RH,	WBD (or DBT – WBT)

Key Performance Indices

The potential of a strategy is determined based on its ability to provide required comfort temperature using the heat sink in the climate and is quantified using two indices, Thermal Autonomy (TA) and Discomfort Degree Hours (DDH). We remove the confounding variables such as building use characteristics, building physical characteristics, design approach, specific system design for a strategy and assumes the overall system efficiency at 100%; this enables us to calculate the maximum potential available for a strategy in a climate, and frees the building physics from keeping the calculations relevant to only a specific building or design condition. The results are to be applied to the climate and not to the performance of a specific building. If the objective is to measure the TA or the DDH for a given building or design, the same overall approach can be used after modifying the equations and applying appropriate system efficiencies.

We use the upper limit indoor operative temperature of an adaptive thermal comfort model; ASHRAE Std-55 or Indian Model for Adaptive (thermal) Comfort model (IMAC) as the base point to calculate thermal stress.

Thermal Autonomy (TA) is the ability to achieve comfort in a climate without the use of active systems. Thermal autonomy is achieved for an hour when stress is less than the opportunity as defined in Table 2. The summation of the number of hours for which TA is achieved out of 8760 hours gives the potential of a strategy in percentage.

TA = 1, if Stress < Opportunity for a given hour, otherwise *TA = 0*

DDH indicates the residual cooling required to achieve comfort after the application of a passive cooling strategy. It is calculated as the difference between stress and opportunity (in degrees), when thermal autonomy is not achieved for an hour. The summation of the DDH gives the total degree hours which indicates the residual cooling required.

DDH = Stress – Opportunity, when Stress is more than Opportunity

For example, in-case of evaporative cooling, for an hour the DBT is 37 °C, WBT is 35.44 °C and expected thermal comfort temperature is 30.57 °C, therefore the stress is (DBT -T_c) 6.43 °C and the opportunity is (DBT – WBT, i.e. WBD) 1.56 °C. Thus, Stress > Opportunity and hence TA is not achieved and DDH is (Stress – Opportunity) 4.86 °C.

Key steps to quantify Passive Cooling Design strategies

The key steps involved in the methodology are summarised in Figure 1 below.

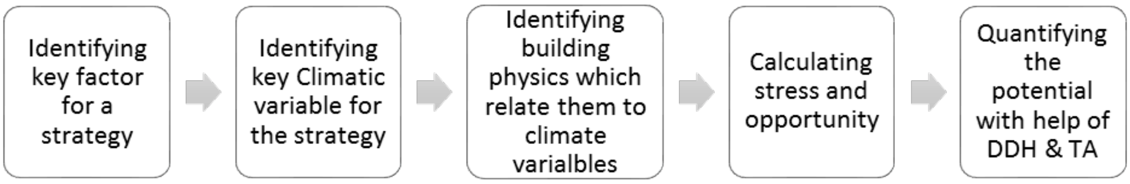

Figure 1: key steps involved in quantify potential for a strategy

Table 2: Stress and opportunity for strategies

Strategy	Key Climate Factors	Stress	Opportunity
Evaporative Cooling	Wet Bulb Depression	(DBT – T_c, when DBT> T_c)	DBT – WBT
Comfort Ventilation	Difference between T_{in} and T_{out} (DBT)	(T_{in} – T_c)	T_{in} – $\Delta\theta$[1]
Night Ventilation	Diurnal variation	(∑ (DBT- T_c), during daytime if DBT > T_c)	(∑ (DBT- T_c), during night when DBT < T_c)
Ground Cooling	Difference between T_{ground} and DBT	DBT – T_c	DBT – T_{ground}, when DBT>T_{ground}
Radiative Cooling	Difference between T_{sky} and DBT	T_{stag} – T_c	T_{stag} - DBT @ Night

Tool

A simple graphic user interface tool is developed with user inputs (selection) for the city (climate data), the passive strategy, and the desired thermal comfort model. The tool has the capability to show comparative results for different strategies and cities. The calculations for TA and DDH are done for all 8760 hours in a year for 59 Indian cities. The output shows the results for TA and DDH summarized at monthly and annual levels. The tool can also be used to understand the variation in the potential of a strategy across different cities, and to understand the potential for different strategies for an individual location.

The software used is Ms Excel™, Ms Power BI™ and VBA™. The TMY weather file for each city is loaded into an Excel template, and the climate variables relevant to the physics of each strategy (shown in Table 2) are filtered. The calculations are processed in Excel for all the cities and the thermal comfort models, and the results are transferred into an Excel database. MS Power BI™ is used for the visualisation of these results data. The user can compare the potential of strategies with the flexibility to choose the cities, strategies and the thermal comfort models.

The tool allows architects and designers in their early design stage to evaluate the potential of different passive design strategies, and for policy makers to evaluate the potential of a strategy and how it varies across various climates of India.

[1] $\Delta\theta = 2.319\, v_{air} + 0.4816$ (°C), It is the air temperature decrease, perceived by a person as the effect of air movement (v_{air}). Source: (Chiesa and Grosso, 2015)

Results

Comparison of Potential for all 5 Strategies for 1 City (Annual Summary)

Figure 2: Annual comparison of 5 strategies for one city

In Figure 2, The annual summary of TA and DDH is displayed for all the strategies for the selected city and selected thermal comfort condition. For Bhagalpur, Bihar (Composite Climate as per NBC) evaporative cooling has the highest potential followed by ground cooling, radiant cooling and night ventilation. Comfort ventilation has the lowest potential over a year.

Comparison of Potential for all 5 Strategies for 1 City (Monthly Summary)

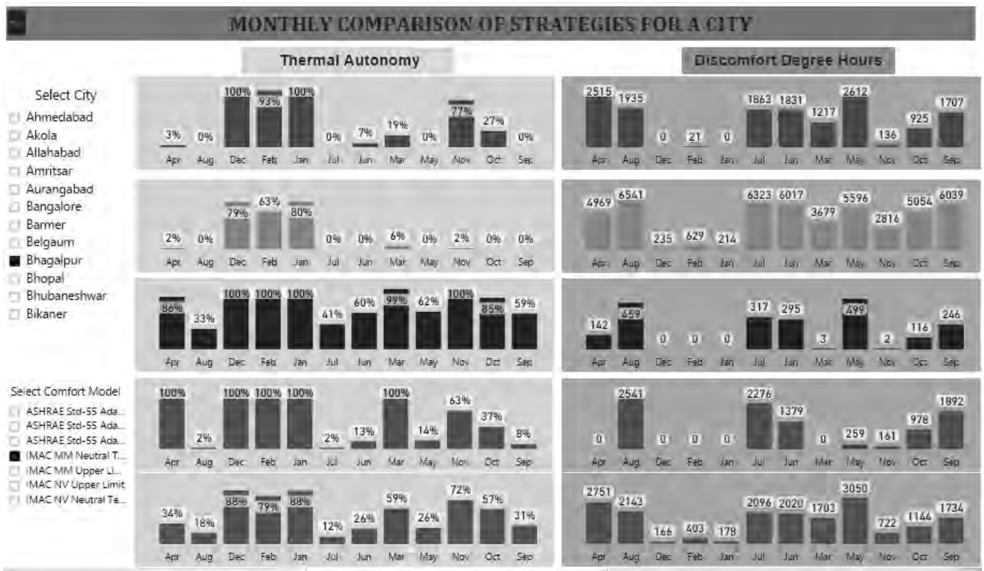

Figure 3: Monthly comparison of 5 strategies for one city

Figure 3 shows the monthly summary and provides a visualization of the variation over the year. The overlapping periods of applicability for the strategies can also be seen. For e.g. in the months of December, January and February all the strategies work well, however evaporative cooling, night cooling and ground cooling showing highest applicability. In this figure, though evaporative cooling has highest potential in Bhagalpur, it is less applicable for the months of May to September. Also in the month of June, evaporative cooling is the only strategy which will help to reduce DDH. Comfort ventilation only works for the months of December, January and February whereas night ventilation works only during November, December, January and February.

Comparison of Potential for all 5 Strategies between 2 Cities

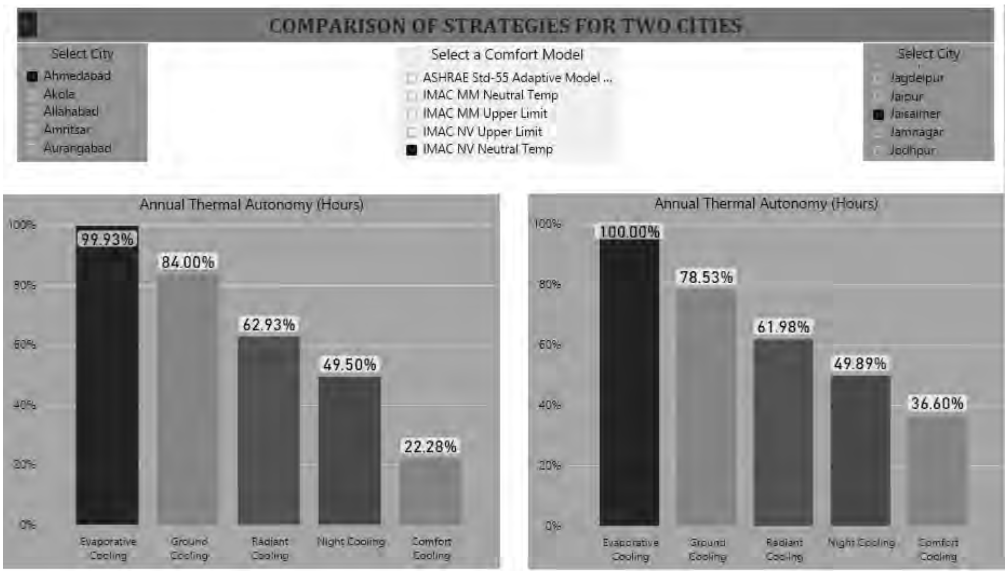

Figure 4: Comparison of TA of 5 strategies for two cities

In Figure 4, a thermal comfort condition is selected and two cities are selected for comparison. In this case, Ahmedabad and Jaisalmer show similar TA for all strategies except comfort ventilation and ground cooling. However, being in same climatic zone (hot and dry) as per National Building Code of India (NBC) (Bureau of Indian Standards (BIS), 2005), both cities shows different potential for comfort ventilation and ground cooling. Similar comparison is done for DDH also.

Comparison of Cities for a Strategy

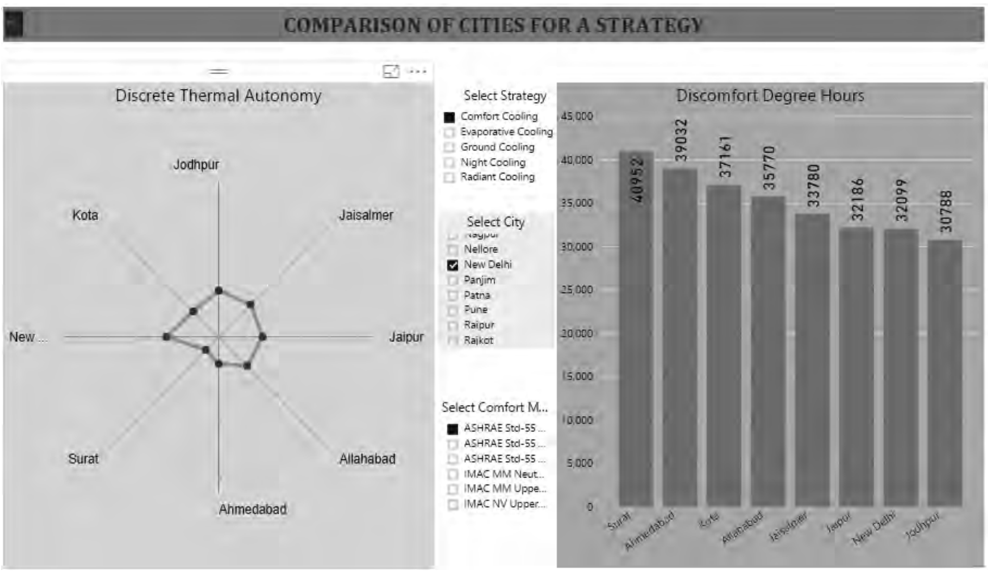

Figure 5: Comparison of Cities for a strategy

In Figure 5, a strategy and a thermal comfort condition are selected. Multiple cities can be selected for comparison. The spider graph on left shows the TA and bar graph on the right shows the DDH for selected cities. In this case, a significant variation in DDH can be seen for comfort ventilation across the selected cities. New Delhi (composite climate) shows higher DDH than Jodhpur (hot and dry climate). New Delhi has the highest TA (38%) for comfort ventilation followed by Jodhpur (33%).

Comparison of all cities (ranked) for a strategy

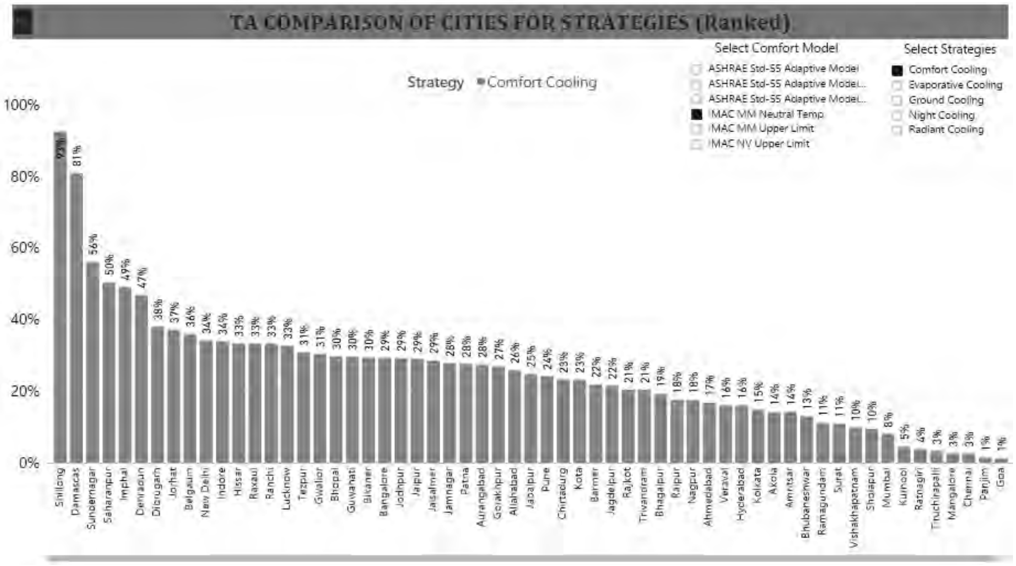

Figure 6: Comparison of 59 Indian Cities (Ranked) for a strategy

In Figure 6, the user selects a thermal comfort temperature and a strategy which is to be compared and all cities are ranked in decreasing order of TA. Cities that show a higher TA have higher potential for that strategy. A similar comparison may be done for DDH for all the cities.

Conclusions

This study uses Discomfort Degree Hours and Thermal Autonomy as two indices that can quantify the potential of a passive cooling strategy for a climate. This methodology and the indices developed allow comparison of cities for their potential for each strategy. It can compare the potential of strategies for cities at monthly and annual level. While some preliminary validation of the tool suggests that it shows expected trends, additional validation is needed before the methodology and its results can be used in design or policy-making. The results give an idea of the applicability of strategies in terms of Thermal Autonomy, and resultant intensity of use of AC in terms of Discomfort Degree Hours. The tool helps the user to identify the best strategy for a climate and the months when it is most applicable. This methodology can be used developing a TA and DDH map for each strategy for cities of India.

PLEA 2017 EDINBURGH
Design to Thrive

Procedural criteria for the design and construction of a low-cost solar greenhouse

Gian Luca Brunetti[1]

[1] Department of Architecture and Urban Studies (DAStU),
Polytechnic University of Milan, Milan, Italy. gianluca.brunetti@polimi.it.

Abstract: In this paper, the process followed for designing a low-cost botanical solar greenhouse in a river park in northern Italy is described with the aim of highlighting the strategies adopted to optimize it for robustness under peculiar site-specific constraints. The available design options were indeed substantially constrained by practical reasons deriving from the building site, the very tight budget, and the fact that the greenhouse had to be designed and finally self-built by the designers themselves: six student and two architects (the author included) in the short time (eighty hours) of a building workshop. Furthermore, the decision process had the requirement to be rational, due to the choice of basing each major decision step on a majority vote. The greenhouse has proved to be well-constructible. It will be used in the future for evaluating the correspondence between expected performances - as derived on the basis of thermal and lighting simulations - and recorded performances. The paper focuses on the peculiarities of the decision process that has been adopted, mainly derived from the necessity of "carving" the optimization process inside the reduced search space determined by the local constraints, and the choice of incorporating redundancy as desirable feature – a means for obtaining robustness at thermal and construction level. Some of the major constraints playing a role in the decision process, besides low cost, have been: the presence of a "C" shaped uninsulated concrete south-facing wall; the solar obstructions constituted by hills and deciduous trees; the necessity of avoiding construction delays due to the curing of mortars and concrete; the necessity of basing the control of solar shading devices and ventilation on seasonal, manual controls, so as to reduce the necessity of daily operations; and the necessity of adopting construction solutions suitable to forgive the low levels of precision of the builders.

Keywords: Greenhouses, passive solar gain, passive cooling, agriculture, self-construction

Introduction

Professional horticultural greenhouses are very seldom "bioclimatic". Their temperature is indeed usually governed by mechanical plants (Beytes, 2002; Taylor, 1999). But the main reason why bioclimatic design was not common for botanical greenhouses in the earlier past (the difficulty of succeeding in heating them passively - Hix, 1974) - is different from the present one: the present trend is mainly due to the higher construction costs of a solar greenhouse. Solar greenhouses indeed have to have a large winter solar aperture, and therefore a high height-to-depth ratio; which implies that they cover a small ground area per quantity of envelope used (Clegg and Watkins, 1978; McCullagh, 1978; Jones, McFarland, 1984). For that reason, solar greenhouses leaning to houses (Fisher and Yanda, 1976) in the last decades have had an overall greater success than independent solar greenhouses (Nearing and Nearing, 1977).

From a constructional viewpoint, wooden greenhouses are usually built with monolithic rafters and studs (Alward and Shapiro, 1980; Shapiro, 1984), which requires rather substantial quantities of wood for obtaining the load bearing resistance which is needed to resist the weight of the snow, but eases the construction process. (The required snow load in northern Italy is about 150 kg/sqm.)

In this paper, the process followed for designing and self-building a low-cost horticultural bioclimatic greenhouse in a river park in northern Italy is presented, and the outcomes of that process are discussed.

The design and construction activities in question have been carried out in eighty hours of a design workshop. The group of designer-builders was constituted by six master students (BS architects: Annalisa Banfi, Eva Cividini, Giovanni Di Fiore, Giacomo Lunghi, Federico Mira, Federico Monti) and two architects (Paolo Carlesso and Gian Luca Brunetti – who is writing this). In addition, academic colleagues of the author (prof. Remo Dorigati, with regards to the integration of the greenhouse into the site; prof. Carlotta Fontana and prof. Gianni Scudo, as co-ideators of the workshop) and the members of a local association hosting the project ("Contrada dei Calimali" - see acknowledgements and website) supported the design project with actions and ideas.

The construction site (coordinates: 45°39'59.70" N, 8°53'01.64" E) was owned by the association, which is active in the conservation of the landscape and in social activities in the zone of the Olona valley in the Lombardy region. The borders of the area including the design site are drawn in red in Figure 1 and the design site is signalled by an arrow.

Figure 1. The area owned by the association (in red) and the design area (see the white arrow).

The design area was square in shape, with edges of about 14 m; and the wall enclosing its north side seemed perfect for supporting a lean-to solar stand-alone solar greenhouse. The area was already being used as a vegetable garden and its horticultural use did not therefore have to change. The plot lay about 25 m near the Olona river, was about 5.5 m deep, and faced a chicken house and an orchard.

The precast concrete panels enclosing the plot (about 2 m high above ground and 2 wide) had originally been conceived for resisting horizontal forces and were therefore suitable for anchoring a light lean-to greenhouse and adding thermal mass to it.

The association agreed to have the greenhouse built on the vegetable garden in the context of a design and construction workshop, which was going to be structured in 10 session of 8 hours to be held twice a week (for a total of 80 hours). The wooden components needed for the construction activity were going to be donated by a sponsor. The other components were going to be bought.

The multiple purposes of the endeavour were that of minimizing the construction materials which were going to be used, making the greenhouses easy and quick to build and making its inner environmental conditions suitable for cultivation.

From constraints to decisions

Several constraints derived from the local conditions. The position of the greenhouse was already given, as well as the orientation of the back massive wall. So the length of the greenhouse and its shape in vertical transversal section were the main things to be defined by the design-builders. The back wall could clearly constitute and additional thermal mass for the greenhouse.

The original intention of the design-builders was to make the greenhouse small - a few meters thick and a few meters wide - and leave most of the available land in use as an open-air vegetable garden. But the wish expressed by the association was that of a longer, thicker, and higher greenhouse, stretched so as to "use" most of the available back wall, while keeping the greenhouse detached from the concrete walls enclosing the plot to the east and the west, so as to make possible entering the greenhouse from both sides. This last condition would have increased the thermal losses of the greenhouse during winter, but could decrease its thermal gains during summer, because of the shading action of the walls. And the increased size of the greenhouse in the making increased the importance of devising construction solutions which were efficient and easy to build.

Other design constraints derived from the micro-geographical context of the Olona river valley, which, in the given tract, is characterized by a stricture between hills, and runs with a north-south orientation. These conditions preserve the solar access into the valley during the central part of the day in all seasons, but disallow it during the summer mornings and afternoons; which is advantageous for reducing the likelihood of overheating during summers without reducing excessively the possibility of solar gains during winters.

Another important design constraint was constituted by the presence of a high deciduous tree to the south-south-west of the greenhouse site. The tree, besides shading the early-afternoon sun radiation during the summer, was likely to shade it also during spring and autumn.

Additional constraints were due to the very tight budget: about 1700 Euros were available in total. This encouraged the technical choice of using sawn wood components of small section (only 5 x 6 x 400 cm laths and 2.5 x 12 x 400 cm planks were used) and suggested to assemble them in truss configurations (for structural efficiency), discouraging the use of high-cost, high-impact glue-laminated wood. The economic constraints also encouraged the choice of alveolated polycarbonate glazing sheets in place of glass panels (the option of polyethylene foils was never an option, because the greenhouse had to be permanent), as well as the choice of anchoring them to the greenhouse with wooden "buttons" rather than wooden caps.

A further, considerable constraint was constituted by the lack of manual construction skills on part of the majority of the designer-builders. This encouraged the adoption of easy-to-execute construction solutions: for example, by opting for distributed connections by screwing rather than concentrated connections by bolting; and for connection configurations which didn't require a high dimensional precision - like lapped joints – rather than connections which required a medium level of precision - like butt joints.

The above constraints where combined with the requirement of making the greenhouse visually appealing, also considering that it had to host educational visits, and with a further condition self-administered by the design-builders: that of basing each design decision on a majority vote (which was of course possible because the team was small). That choice has had significant consequences on the design process, because it required that each designer-builder proposing a solution had to support it with reasonably sound reasons for convincing the colleagues. Which encouraged a rationalization of the decisions and made possible that many of them stemmed out from the design constraints.

It is also interesting to note that the described strategy for pursuing the design endeavour largely outlasted the design phase on paper (which took about two days) and prolonged itself well into the construction phase, in which the design and construction activities coexisted at the 1:1 scale.

Thermal design analyses

Due to the described constraints, the thermal analyses were mainly focused on determining the shape of the vertical transversal section of the greenhouse. The analyses took place in the periods between workshop days and were performed by the author in phases of increasing resolution. Before the decision was taken of filling almost completely the available plot space with the greenhouse, two batches of simulation-based explorations were performed. In both, the models – simulated by the means of the ESP-r simulation platform (see website) - were single-zone and had the glazing frames compacted in two symmetrical bulks at the sides (Figure 2, Figure 3).

These two former simulation batches were performed manually adopting shapes and materials which turned out to be not very corresponding to the solutions adopted afterwards. The greenhouse models in the first batch, in particular, were less thick and tall than those in the following batches, and featured operable openings also at the roof.

Moreover, in the first batch the solar obstructions constituted by the hills and the tree were not taken into account. They were taken into account only from the second batch onwards. Lastly, in the first batch, infiltration and ventilation rates were scheduled; whilst in the following batches mass-flow networks were used, built with the strategy of assigning the same pressure coefficient to all openings, so as to rule out from the calculations, as much as possible, the aerodynamic effects implied in the pressure coefficients, and include only the effect of thermal buoyancy.

The first simulation batch was overall devised so as to be very optimistic and let the designers perceive with clarity the “behavioural propensity” linked to the shape of each greenhouse section.

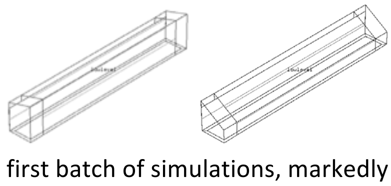

Figure 2. Some shapes tested in the first batch of simulations, markedly thinner than the one finally chosen.

The second simulation batch included the solar obstructions and was aimed to gain a feeling of the shading effects of the tree and of the thermal effects of the insulation of the back wall (at the outer face) and/or of the side walls.

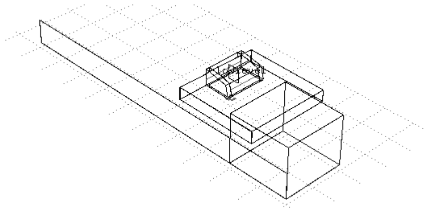

Figure 3. One of the models tested in the second batch of simulations, including the site solar obstructions and the ventilation nodal network. The greenhouse model is less wide and less thick the one finally built. The large boxed-shape obstruction represents a deciduous tree and was made partially transparent in winter. The site obstructions representing the hills are here still incompletely modelled.

The third simulation batch has been automated through the use of the Sim::OPT application (see website). It featured a larger volume (following the earlier stages of design decisions) and was aimed to evaluate comparatively and cumulatively the winter and summer thermal behaviour of the candidate greenhouse shapes. The performance ratings were carried out using indicators defined by the author on the basis of resultant temperatures.

The ventilation nodal network modelled for the task featured operable openings that were full-size on the front and back elevations, and were constituted by doors at the sides inserted in transparent walls. The ventilation openings were held closed in the simulations regarding winter (just the effect of the cracks was then in play) and 40% opened in the simulations regarding summer. Also, some of the evaporative effects of the vegetables were rudimentarily taken into account by including some wet surfaces in the models. The hypothesis of insulating the external surface of the concrete back wall with 15 cm of a plaster-like compound of straw, earth and lime was also taken into account.

In searching for a good shape for the greenhouse, three design parameters were taken into account: the height of the back top edge of the roof (which could assume 3 possible values), the height of the front top edge of the roof (which could assume 7 possible values), and the depth (y position) of the front top edge of the roof (which could assume 5 possible values).

The thermal indicators were obtained by defining a weighted indicator relative to heating and a weighted indicator relative to cooling for each winter month and for each summer month, and averaging the results. The months which were more likely to need both heat gain and heat dissipation (in the specific case, March and October) were taken into account with respect to both purposes, and as a result they had a double weight in the calculations; which is in line with the fact that for horticultural greenhouses the mid-season months are particularly important (usually, more than the seasonal extremes) for productivity.

More specifically, the indicator used for winter derived from the consideration that a high average temperatures combined with a small temperature swing (measured as the difference between monthly maxima and minima) was advantageous. Plants indeed do not like high daily swings (Shapiro, 1984). On that basis, the indicator was conceived as the sum of the average temperature and the difference between the highest monthly swing and the monthly swing of the case in question. That way, high average temperatures coupled with small temperature swings were given a higher score. The obtained score was then normalized (so as to be comprised between 1 and 0). In the same line, the indicator adopted for summer derived from the consideration that low average temperatures and a small temperature swing were advantageous. It was conceived as the difference of the average temperature and the difference between the highest monthly swing and the monthly swing of the case in question. That way, low average temperatures coupled with small temperature swings were given a higher score, then normalized.

The above indicators were devised so that no explicit weighting of objective functions was ever needed: nor in constructing the two indicators, nor in combining them.

The simulation results showed that heightening the greenhouse at the back increased its suitability for heating; and heightening it at the front increased its suitability for cooling. And with respect to the consequences of varying the depth (y position) of the top front edge, they showed that decreasing the greenhouse volume increased its suitability for heating, whilst increasing it increased its suitability for cooling (Figure 4).

Figure 4. Left: examples of shapes appropriate in winter. Right: examples of shapes appropriate in summer.

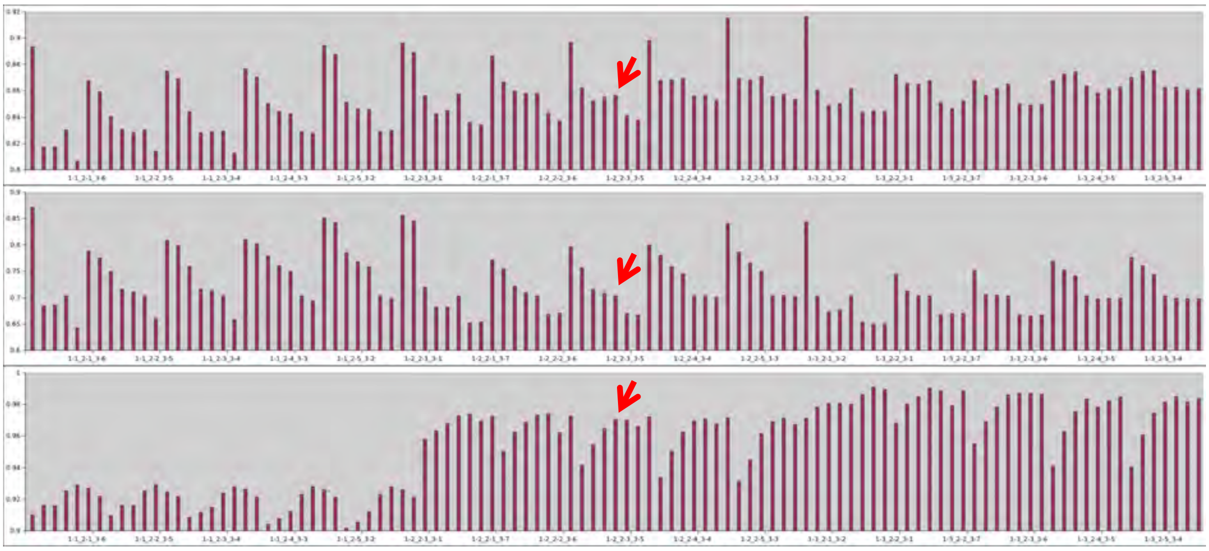

Figure 5. Rating of the simulated cases with respect to heating and cooling (top); to heating (middle); and to cooling (bottom). The higher the score, the more advantageous the option. The finally selected solution is signalled with a red arrow.

The greenhouse shapes which were selected for the project were, in the end, not the best performing; nor for winter, nor for summer, nor for the cumulated year; but it lay in the group of the “average” options (Figure 5). Indeed, constructional, usability and aesthetic consideration played an important role in the decisions.

A last batch of explorations was focused on the finally selected design option and aimed to determine the most advantageous seasonal arrangement of the openings. That batch also took into account the optional presence of shading nets on the roof. The response of those explorations was that in November, December, January and February the openings of the greenhouse should stay closed; that in March and October they should be kept a bit open (about 5%); that in April and September they should be kept wide open (about 60%); and that in the remaining summer months they should be kept wide open and additionally shaded at the roof by the means of a shading net (Fig. 6).

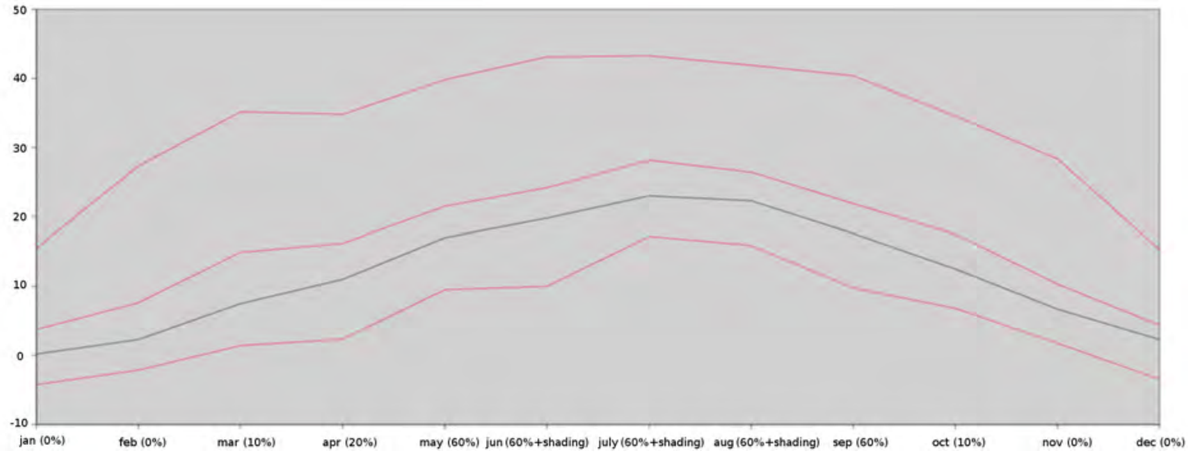

Figure 6. Predicted temperatures for the final design configuration in conditions of seasonal operation. In red: the resultant maximum, minimum and average monthly temperatures in the greenhouse (the percentage of ventilation openings and the use of shading devices is also signalled). In black: average ambient temperatures.

Construction decisions

The foundations of the greenhouse had to be constructed without waiting that any mortar-like materials set, so it was built dry, by digging a trench, half-filling it with gravel, then anchoring chestnut timbers to the ground with bent steel rods hammered diagonally into it. The greenhouse structure is characterized by the use of trussed asymmetrical portal frames spaced 2 m apart. All the portal frames have been built using almost only lapped joints. The structure has been conceived with the aim of providing redundancy, for robustness.

Figure 7. Progression of the construction phases and the outcome.

The openable frames have also been constructed with trussed configurations, for adding rigidity. In that case, butt joints were preferred over the more complex miter joints.
The horizontal bracing elements of the structure were hosted in a void layer inside the roof structure, so that both the diagonal elements, the top chords of the portals and the transversal rafters run uninterrupted (Figure 7).
The drainage of water was pursued by the means of internal flashings obtained by cutting a cheap fiberglass profiled sheet in strips (Figure 8).

Figure 8. Views of the operable openings.

Conclusions

The most distinctive construction solutions were that of using trussed structures not requiring high levels of precision and that of devising fully openable front and back facades for favouring ventilation. The results proved the constructional viability of both strategies.

With respect to the viability of the choices regarding the thermal behaviour and daylighting, the use of structured criteria for the exploration of the design options implying the indicators defined for the purpose allowed to support a rational decision process shared by the whole design-and-construction team.

Acknowledgements

The author would like to thank all the members of the Calimali's Association for the warm support; and among them, especially the persons who have given manual support during the construction phase!: Claudio Caccin (president), Giancarlo Favaro, Nevio Pavanello, Frando Restelli, Fiorito Siviero, Mr Bruno. The author would also like to thank the sponsor of the initiative - the "Valle Olona" carpentry of Fagnano Olona, which donated the wood for building the greenhouse - especially in the person of Arch. Pietro Stellini; and the Ge.A.S.C. municipal enterprise of Fagnano Olona.

ABSTRACT: The purpose of this research was to propose and build a sustainable, low-impact, optimized, modular lodge, to facilitate scientific studies in the Antarctic. Within this unique climate, this paper presents new environmental and sustainable approach for the extreme cold. The Polar Lodge was designed and built with a primary concern of proposing a zero carbon emission module. Other major concerns included that the proposal should be: modular; easy to transport and fast to assemble by a small team of non-experts (size and weight of parts was critical); resistant to wind; have minimum impact on the ecosystem; dry; warm; safe; physically and psychologically comfortable. The solution presented was inspired and adapted by the traditional Yurt. Scientific data was collected and analysed regarding the lodge´s performance in the extreme environmental conditions with the use of data loggers. The environmental comfort and thermal performance of the Antarctic yurt was tested for two consecutive days by the team of researchers in an isolated area on Collins Bay. Data was collected and the experience registered, substantiating environmental comfort on physiological, psychological grounds. Finally, this paper also intends to contribute to the scientific efforts of low energy building, within the concerns of climate change and sustainability.

Keywords: Low Tech, Energy Efficiency, Sustainable Architecture, Bioclimatic Dwelling, Cold Climates

Introduction

A vast body of knowledge has been produced on the problem of global warming over the last few decades. There are numerous publications on low-energy, sustainable, building design strategies for both European, U.S., and "developing world" contexts, resulting in an increasing awareness of the building sector that a change in paradigm is necessary. One can already find recent best-practice built examples of sustainable buildings, mostly in Northern Europe and the U.S. However, research into building designs for extreme cold climates such as the Antarctic is still at its infancy. Information is still necessary on a number of variables and, most of all, built examples of sustainable design, using low-energy strategies and eco-friendly materials, is required. This paper is based on the research and construction of such an example – a sustainable and self-sufficient building to lodge scientists during their field investigations in Antarctica. This research project, named Polar Lodge, is part of PROPOLAR, the Portuguese Polar program. It must be observed that there are huge ethical issues about any development in pristine areas such as Antarctica, often concerning waste disposal of the actual buildings themselves, and the local use of energy for heating. This constituted a motivating challenge, with positive impact in aspects of the long-term replicability of the solutions for other contexts, such as in cold climate regions in Europe.

This project is called Polar Lodge, and is a joint collaboration of the University of Lisbon (IST), the University of Cambridge, UniCEUB of Brasilia, and more recently the University of Bahrain. The project began in 2014, when a first two-week mission was carried out in the Antarctic Peninsula in order to assess both existing building typologies and occupants' expectations. A diverse variety of Antarctic Polar Stations were visited. Scientific data was collected and analysed regarding building performance in extreme environmental conditions, constructive characteristics of the existing pavilions, and energy and comfort performance of each building.

1. Field Work – Building of the Bioclimatic Antarctic Yurt

This paper investigates the building of a polar lodge in Antarctica. It was part of the initial objectives for the lodge to be modular, sustainable, reusable, easy to transport, and not energy consuming. The Mongolian Yurt, primitive yet efficient and environmentally friendly in its continental ambiance was the main case study due to the similarities of its characteristics with the proposed objectives for the polar lodge.

The initial intentions were to design and construct a sustainable prototype which allowed researchers moving in land to work away continuously from permanent bases in Antarctica with field work for up to two months (Antarctic summer time). For this a set of objectives were set:

- Be easily assembled by two people during an Antarctic summer day without any need of specialized training or skills for its assemblage;
- Reduced weight and dimensions to be carried by a zodiac (inflatable boat) or towed by ski motorbikes;
- Use of ecological and biodegradable materials;
- Ensure higher level of thermal comfort compared to tents;
- Ability to withstand wind gusts up to 120Km / h;
- Ensure acoustic and thermal comfort;
- Provide physical and psychological comfort.
- Allow the storage of modules on a permanent basis or in hangars during the Antarctic winter period;

The materials used in the construction of the Antarctic yurt were as follows: Base platform: plywood; Lattice structure: indented wood; Indoor finishing: two layers of natural wool with flameproof protection; Outdoor covering: waterproof biodegradable fabric;

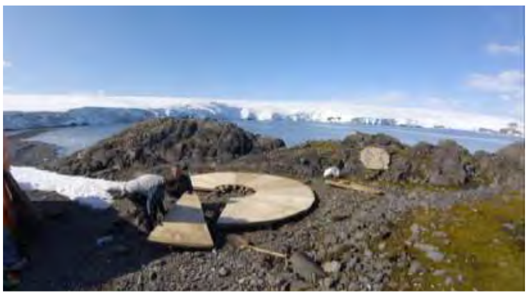
Figure 1: Site location in Collins bay, King George Island, Antarctica.

Figure 2: Collins bay, site for the Antarctic yurt

The assembly of the yurt took around 20 hours and was done in two days. There was a major concern in to adequate the terrain in the appropriate way, by levelling it and reinforcing the surroundings, therefore reinforcing the surroundings, therefore consuming more time than planned. Figures 3-15 illustrate how he 20 hours required for assembling the Yurt were divided:

Figures 3 and 4: Transferring the yurt materials from the zodiac boat to ashore (1 hour).

Figure 5. Levelling the terrain manually, where the yurt is to be implemented (4 hours).



Figures 6 and 7: Assembling the yurt´s wooden floor base (4 hours).

Figures 8 and 9: Installation of vertical trusses and application of its upper frame (4 hours).

Figures 10 and 11: Assembly of the multiple layers of thermal insulation (2 hours).

Figures 12 and13: Waterproof biodegradable membrane on the perimeter walls and roof (2hours).

Figures 14 and 15. Anchorage in 4 points, cable placement, fastening structure around the perimeter (3hours).

Figure 16 and 17: Assemblage completion of the Yurt.

2. Data Logger Measurements

After the yurt was assembled, it was prepared to be tested. Three data loggers were installed for registering measurements inside and outside of the yurt, on the 15th of January of 2016, and all three research team members slept in the yurt in isolation in front of Collins Glacier in Collins Bay. Given that the calibration, programming and activation of the 3 data loggers were done in advance still in Portugal, we must take into account the time zones – a four hours difference to the local time in Antarctica. The two data loggers called "inside 1" and "inside 2" are identified with the colours blue and green respectively in the graph, and were placed inside the yurt in opposite locations. The third data logger was denominated "outside" and labelled with the yellow colour on the chart. This data logger was placed on the outer face of the yurt, where to some extent it would benefit from the wind protection and thermal influence of the yurt indirectly.

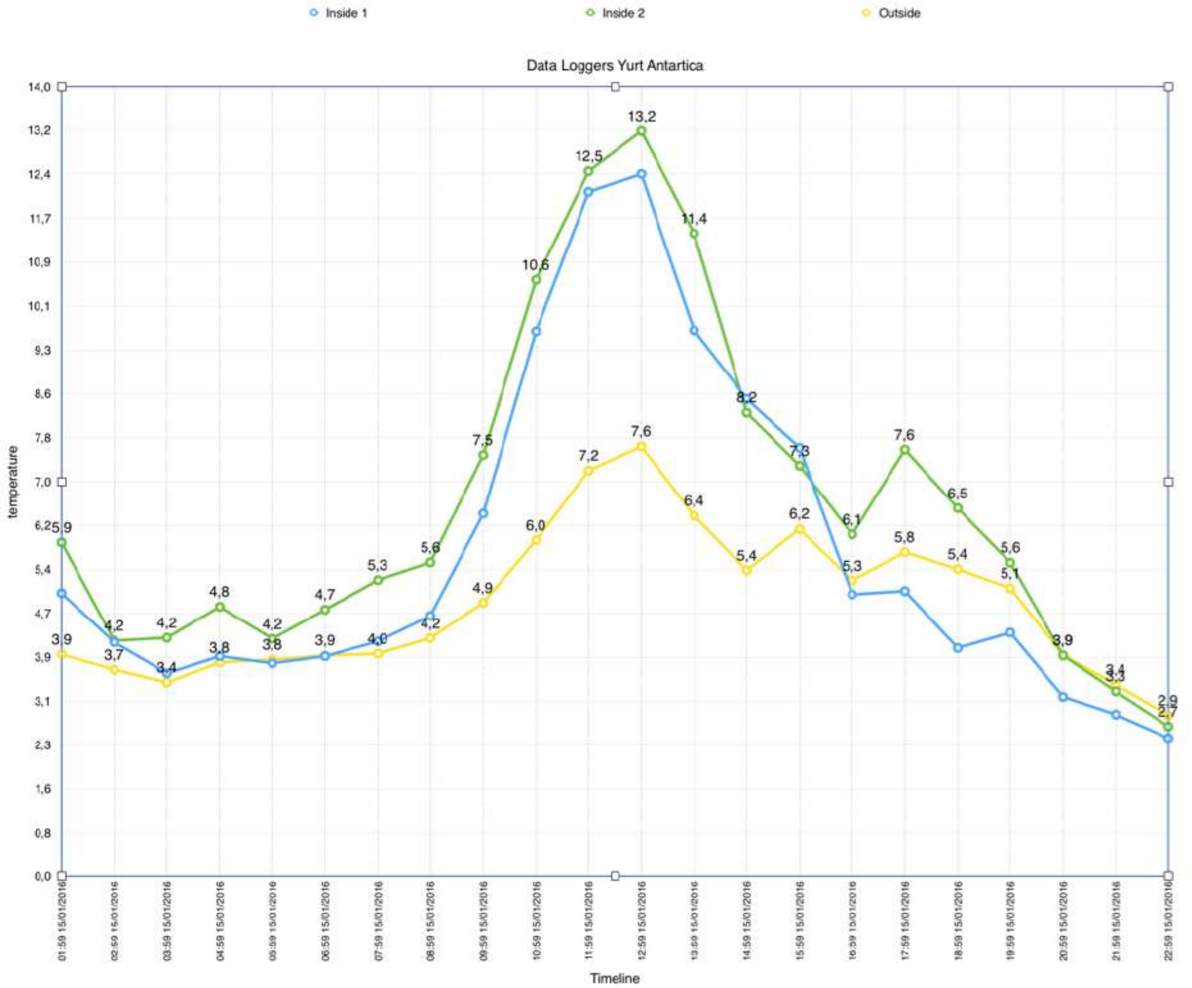


Figure 18: Graph showing the Data loggers' results in the yurt between the 15th and the 16th of January 2016.

The small difference in results between the two "inside" data loggers is due to their different locations inside the Yurt. "Inside 1" was positioned further away from the team members while the "inside 2" data logger was closer to the team members and the portable gas heater.

The research was done during January, the summer period in Antarctica and therefore with almost 24 hours sunshine. The first measurement was registered at 01:59 15/01/2016, corresponding to 21:59 local time, which is approximately the time at which the sun is at very low position and is blocked by the glacier wall near the site. Therefore from that time there is a lowering of the overall temperature in the absence of direct sunlight. The following four measurements (22:59, 23: 59, 0:59, and 01:59 hours local time) correspond to the completion of the assembly of the yurt's envelope, the mounting of the yurt camp beds in its interior, dinner preparation, and the firing a small portable gas heater air gas (figures 19 and 20). The yurt at this stage is starting to differentiate the internal and external temperatures and giving signs of high-energy performance with low technology.

Figures 19 and 20: images of the a portable low capacity gas heater

Seven of the following measurements (from 02:59 to 09:59 local time) correspond to the time when the team was at rest inside, and without leaving the yurt. Therefore at 10 am local time the average temperature difference between the internal and the external temperature was approximately 5.5 ° C, considering that the outside air temperature obtained was 7.6 degrees Celsius. However, it must be observed that the data logger denominated "outside" was located externally adjacent to the yurt and may have been influenced by the temperature increase inside the yurt, given the proximity of the data logger to the envelope. This observation is based on the fact that the average outside temperature was around 4.5 degrees, as registered at base camp. Furthermore, following the values of the Met station, the temperature difference between the inside and outside could have reached values greater than 9ºC, and close to double digits. In addition to help analyse the yurt's thermal efficiency, we used a FLIR thermal camera to obtain point readings of thermal performance of the interior and exterior. Images made it possible to prove the tightness of the envelope, the efficiency of the wool insulation, and identify thermal gaps as well as the range effectiveness of the heat source, as can be seen in Figures 21 to 23.

.

Figures 21, 22 and 23. Thermal performance of the Yurt's interior.

Figure 24: The yurt's interior

Data Analysis

The data collected was analysed and studied, leading to important observations. The numerical information was confronted with the sensorial information registered by experimenting the environmental comfort of the Antarctic yurt by sleeping there. It is necessary to stress the value of not only physical comfort but also psychological (Brager, 1998; Canter, 1975). These psychological aspects will be further discussed in a different opportunity and paper. From the design and measurements collected, the following observations were reached:

- The compact, round, yurt shape enables a good thermal performance, and in addition performs very well against the wind when it is undifferentiated and flows in different directions throughout the day;
- The Yurt insulation made of two layers of natural wool with fireproof protection, still ensured significant insulation from the exterior;
- The inner insulation proved to be an efficient thermal gap barrier;
- Significant temperature differences were observed with the data loggers, of up to 6°C.
- The innate acoustic characteristics of the wool used, allows users of the yurt to perceive a level of acoustic comfort and greater sense of shelter when compared to the usual common tents; it allows for a total detachment from external wind noises, providing a great sense of security
- The natural incoming zenital daylight, allows for a comforting sense of place;
- The high floor-to ceiling height of the yurt provides valuable ergonomic space, allowing the user to stand up, move freely, and perform naturally any task;
- The construction of the yurt is completely biodegradable and environmentally friendly, fully adapted to the current requirements in Antarctica.

Conclusions

In recent years, research stations in Antarctica have depended on technology to build and maintain safe, and comfortable spatial environments. This implicates in higher costs and dependency on powered energy systems. High tech materials and systems also translate in future waste potentials and consequent pollution magnets, as unfortunately already can be seen in Antarctica. Pollution is a word, which should not echo in such a pristine place like the white continent. On the other hand, sustainability should be the order word when proposing any interference in Antarctica. In a lower building scale level, researchers are dependent on shelter to collect data in different fronts and in different places of the continent. At the moment this is mainly done by mounting tents and camps, which are neither safe nor comfortable. With this scenario in mind the Polar Lodge project proposed the first flexible, modular, demountable, portable, and sustainable shelter in Antarctica. Consequently the Polar Lodge was successfully designed and built to be sustainable, self-sufficient, easy to transport and assemble. More importantly it is able to withstand freezing summer temperatures providing comfortable (both physically and psychologically), and safe spaces with minimum impact on the surroundings, and independent of fossil fuels or electricity, maximizing energy efficiency through the choice of materials, form and design. The Antarctic yurt has been used by different scientists, setting an example of low environmental impact, ecological, and sustainable design.

Future Studies

This paper discusses the results of fieldwork in Antarctica in light of designing sustainable and resilient buildings in harmony with an extreme climatic context and limited local resources. Studies may progress in looking into low technology but high energy efficiency design as means to attain a neo vernacular architecture, one which benefits from modern materials and structures but are rooted on passive building concepts. Future building design strategies also include the use of sun and wind power to be a building component for the Antarctic, aiming to be self-sufficient in terms of energy consumption, through the use of renewable energy systems, as well as an optimized environmental performance. Finally, the intention of this paper is to contribute to the scientific efforts that are being invested in the Antarctic within the concerns of climate change.

Abstract: This work explores three patterns of occupants' control of window blinds and the potential influence on daylight performance of an office room oriented to the East. In Natal city (5° S), Northeast coast area of Brazil, windows oriented to East are frequently obstructed by curtains, despite the daylighting and the exterior view. The daylight discomfort leads the occupant to close the blinds. The consequences are obstructed outside view, poor daylight quality and dependency on artificial lighting. This paper assesses the impact on available daylight using parametric analysis based on daylighting dynamic computer simulations run in Grasshopper and Daysim software, and the parameters assessed are window-to-wall ratio (40% and 80% WWR), sky view factor (small and large SVF) and occupant behavior (active, intermediate and passive users). The performance criteria combines Useful Daylight Illuminance (UDI500-5000lux) and illuminance uniformity distribution. Results confirm the role of user behavior on the daylighting performance. The combination of external shading devices, high Sky View Factor (SVF) and high window size can make daylighting user proof for 1/3 of the time, and can double the daylighting performance if combined with an active user.

Keywords: Daylighting, occupant behavior, fenestration systems.

Introduction

Occupant behavior plays a significant role on daylight performance of office buildings (Foster ,Oreszczyn, 2001; Mahdavi *et al.*, 2008; Fabi *et al.*, 2011; Yan *et al.*, 2015; D'oca *et al.*, 2016) which depends on presence, actions and occupancy profile (Rijal *et al.*, 2007, p. 824 e 825). The performance optimization emerges as a double challenge, which depends on technical and human requirements (Hong *et al.*, 2015; D'oca *et al.*, 2016).

Over the last few decades, many studies have focused on bridging the gap between the energy performance of predicted and real buildings, increasing the importance about the user behavior (Fabi *et al.*, 2011; Hong *et al.*, 2015). The complicating factor is the uncertainty of actual interaction and diversity of occupant profiles (Reinhart ,Voss, 2003), which includes passive and active users. Each occupant behavior pattern requires different technical solution for the building systems, which may affect the interactions between them (Yan *et al.*, 2015).

The behavioural models in building performance simulation often focus on the manual opening windows and lighting control, including the operation of shading devices. Hong *et al.* (2015) proposed a DNAs framework to formalize the modelling of energy-related occupant behavior, using four many components: *drivers*, *needs*, *actions* and *systems.* Reinhart *and Voss* (2003) present an approach that mimics manual lighting and blind control in private offices called *Lightswitch*. The algorithm is based on direct sunlight above 50W/m², witch induces the control when the occupant arrives or leaves the room.

External devices, including blinds, louvers and overhangs, are commonly indicated to tropical climates, due the excessive solar radiation (direct and diffuse) and overheating. When properly designed, can prevent glare and direct radiation (Stack,Goulding ,Lewis, 2000; Inkarojrit, 2005; Tzempelikos, 2005; Kirimtat *et al.*, 2016), decreasing the use of internal blinds, which are inefficient for external view, lighting and thermal performance.

Previous studies on daylighting evaluation for tropical climates (Carvalho, 2014; Moreno, 2015; Dias, 2016) show the importance of using shading devices to optimize the performance. The daylight performance can be expressed by the correlation between WWR and SVF. Models with small WWR (e.g. 20%) need a high SVF to have a daylight zone for the half of the room. Models with intermediate WWR (eg. 40-60%) must be totally shaded, with a small or intermediate SVF to achieve practically the entire room depth. Models with high WWR (e.g. 80%-90%) must be completely shaded, with a small SVF to reach the entire room depth.

Objective

This paper aims to assess the impact of occupants' control behavior on fenestration systems in daylight performance of office buildings in a tropical climate.

Methodology

The procedures consist in defining representative models, with simulation and parametric analysis of daylight performance (Figure 1). The models are based on local office buildings assessment, with a zone 5.00m large and 7.00m depth and a single window orientated to the East. The models varies in terms of without exterior shading (with horizontal overhang 1.5m depth and fixed external blinds), two sizes of windows (40 and 80% WWR), two sky visible factor (low and high SVF[1], **Error! Reference source not found.** and **Error! Reference source not found.**), and three user behaviors. The reflectivity properties of the internal surfaces (Table 1) were determined based on the Brazilian code (Abnt, 2013).

The three patterns of occupant interaction with window blinds are based on visual discomfort, and consist of:

- Passive user: the occupant ignores the daylighting turning the artificial light on and closing the blind when the room is uncomfortable. The occupant does not open the blinds anymore during the same day;
- Intermediate user: the occupant ignores the daylighting turning the artificial light on and closing the blind when the room is uncomfortable. The occupant does not open the blinds during that specific time period, and take the control action just when returns to the room.

[1] "portion of the sky visible at a given point (observer) and it depends the size of the source" (Leder, 2007)

- Active user: the occupant closes the blinds when the room is uncomfortable and opens the blinds when the available daylight does not cause discomfort. The control is similar to an automatic system.

The daylight criteria evalutation is:

- minimum illuminance of 500lux (Abnt, 2013);
- maximum illuminance of 5.000 lux;
- uniformity, with illuminance levels ratio less than 1/10 (maximum and minimum illuminance level ratio must be less than 0.1) (Abnt, 1992).

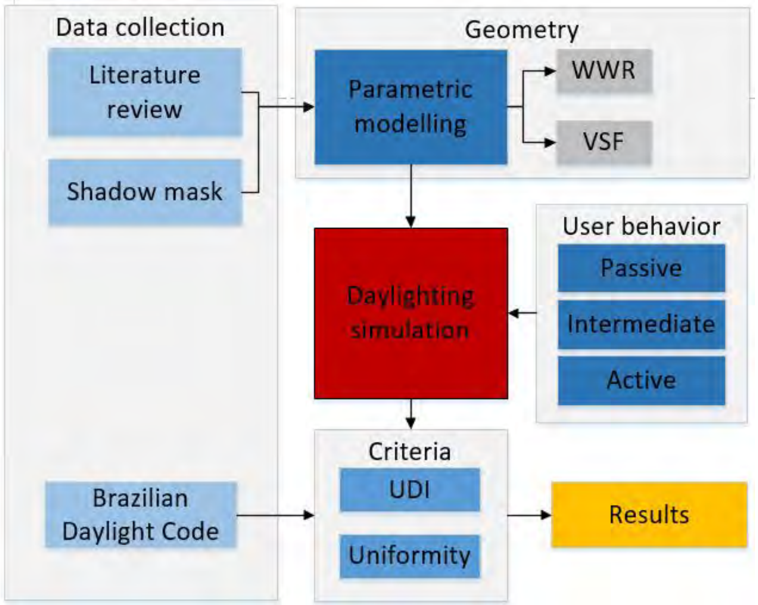

Figure 1. Procedures.

Table 1. Reflectivity of materials.

Elements	Light reflectance
ceiling	0.6 - 0.9
wall	0.3 – 0.8
work plane	0.2 – 0.6
floor	0.1 – 0.5

Source. (Abnt, 2013).

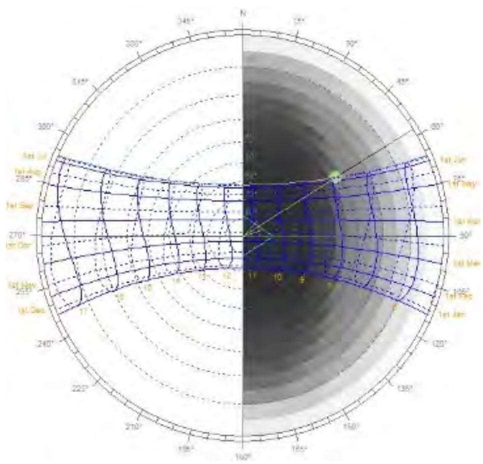

Figure 2. Low SVF.

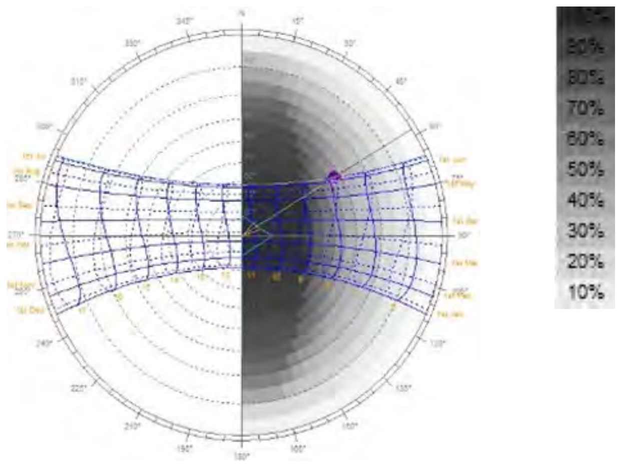

Figure 3. High SVF.

The combinations between window-to-wall ratio (WWR) and sky view factor were defined based on shadow masks simulated in Ecotect software (Marsh, 2011).

The geometry was parametrically modelled in Grasshopper/Rhinoceros (Rutten, 2015) and the models were simulated in Daysim (Reinhart, 2010). The input data of the simulation were geometric model, occupancy file, user behavior, sensors file, climate file and materials properties of the room surfaces.

The sensors distribution was designed according to Brazilian Code Standard (Abnt, 2005), which determines the identification and distance of the points (Figure 4 and Figure 5).

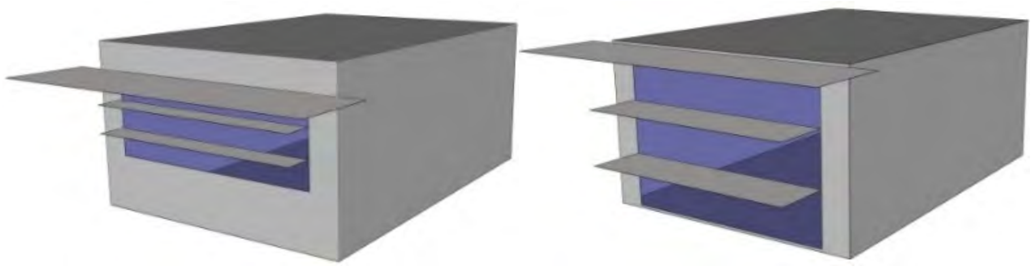

Figure 4. Exterior shading for 40% and 80% WWR.

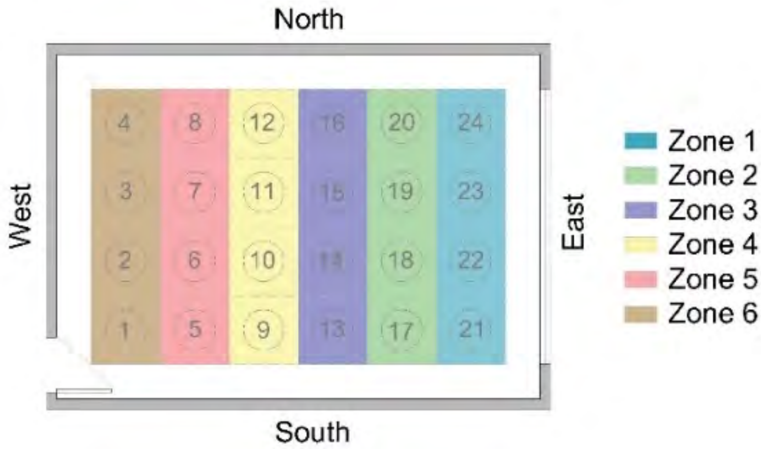

Figure 5. Sensors and zones distribution.

The performance parameter is an adapted Useful Daylight Illuminance (UDI) between 500-5000lux, with comfortable daylighting uniformity, calculated in electronic spreadsheets, and graphically organized in terms of zone depth for each WWR.

Results

The results show the almost complete lack of daylighting use for passive users, and the maximum daylight performance for active users of the room with high SVF, 40% (Figure 6) and 80% WWR (Figure 7), which can reach up to 55% and 85%, respectively, at the first and second zone depths.

Passive users blind the window since the early hours due to the penetration of direct solar radiation, causing high levels of illuminance and unsatisfactory uniformity for models without exterior shading (Figure 8 and Figure 9). Models with exterior shading and low WWR varies from lack of illuminance to unsatisfactory uniformity.

Results of intermediate user in rooms without shading indicate the potential use of daylighting at afternoon when the blinds are opened after lunch, with approximately 35% of occurrence for both window sizes, reaching the second zone depth for 40%WWR and third zone depth for 80%WWWR.

The difference between intermediate and active user for room without exterior shading is attributed to the available daylight at later morning hours, which can improve to approximately 10% of daily use.

In models with external shading, increasing the SVF, the performance increases more noticeable in 40%WWR models and 80%WWR models with active user. Increasing windows size and SVF also increases the zone depth performance.

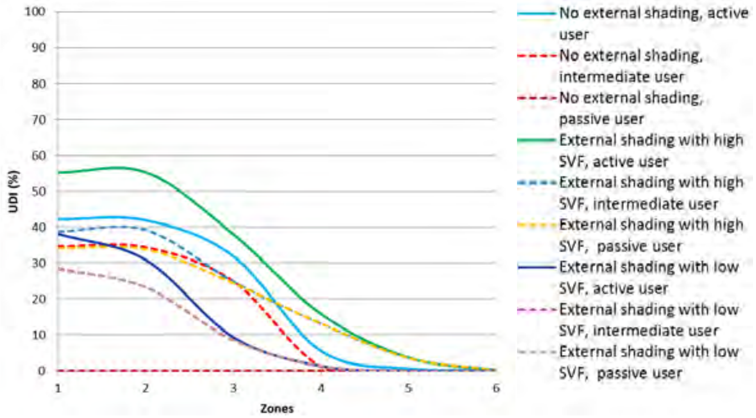

Figure 6. UDI for 40%WWR.

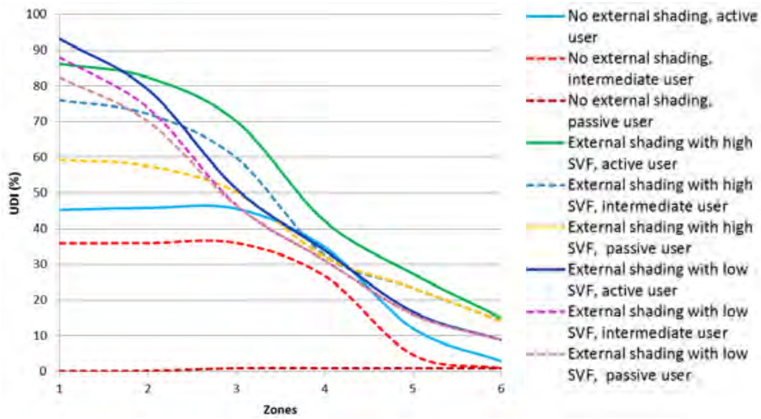

Figure 7. UDI for 80% WWR.

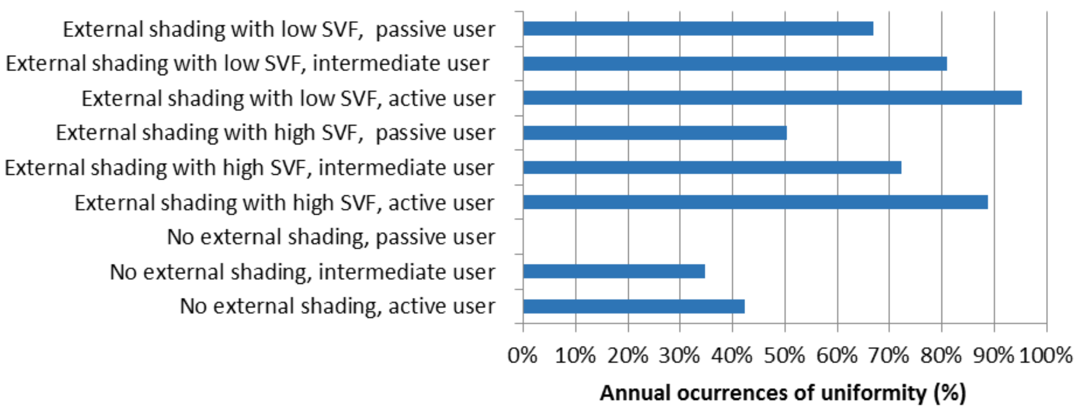

Figure 8. Occurrences of uniformity for 40% WWR.

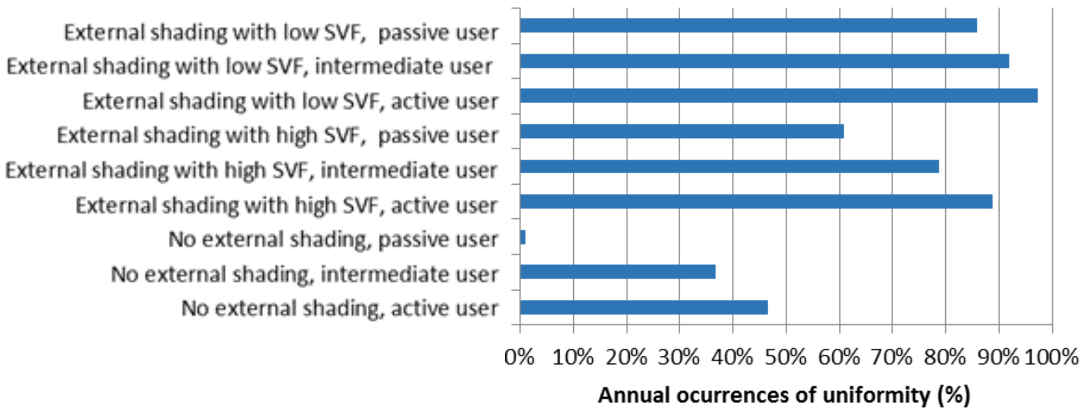

Figure 9. Occurrences of uniformity for 80% WWR.

The best-performing model at zone 1 has external shading with low VSF and active control, presenting an occurrence of uniformity of 95% for WWR 40% and 97% for WWR 80%. In this case, the impact of user behavior is more significant with a small WWR. Results show that the difference of occurrences of active and passive users is 30% with a WWR 40% (Figure 8) and 10% for WW 80% (Figure 9).

For the scenarios with high VSF, the influence of user behavior is already more noticeable. For WWR 40%, there is an occurrence of 88% for active users and 50% for passive users (Figure 8). For WWR 80%, active users promoted 88% of uniformity and passive users, 60% (Figure 9).

The procedures demonstrated limitations of the Grasshopper software:

- The component “read annual result” do not generate graphic results for the UDI determined by the design illuminance for dynamic shading.
- The component “EPWindow shade” do not generate user behavior interactions according to different comfort variables.

Conclusion

As expected, the use of daylight is highly influenced by the user behavior depending on the geographic localization. The unsatisfactory performance in the early hours demands adjustments that block the daylighting, leaving the user without further discomfort stimulus to make new adjustments to use daylight. The intermediate user could beneficiate from the lunch break to get a stimulus to open the blinds. The active user, more hypothetical than real, could represent someone very attentive and connected with the exterior. Nonetheless, these results also demonstrated the importance of a blind automatic control, which could result in daylight use for most of the time at the three zones close to the window.

The architectural characteristics of window size, external shading and SVF play a major influence on daylighting performance. In combination with an active user or automatic blind control, they can make daylighting useful for 2/3 of the time for the first half of the room.

The user behavior modelling requires more refinement in future developments, including glare perception and intermediate shading adjustments.

Abstract: In the past, the absence of in-depth investigation on the energy saving design of housing construction by designers and developers has resulted in unnecessary excessive energy consumption. Passive design strategies, which are considered easier to be realized in housing industry, are undoubtedly the most direct and efficient method to achieve energy saving in the vigorously promoted green building era in Taiwan. Natural ventilation is an efficient passive design means that integrates climate design to achieve building energy saving and create healthy environments for human habitat. To investigate the effect of utilizing natural ventilation on improving the residential indoor thermal environment in Taiwan, in-situ measurement of an apartment building, whose design followed the current Taiwanese green building guidelines, was conducted during seasons suitable for natural ventilation. Long-term indoor and outdoor ambient temperature and relative humidity were monitored. The indoor thermal environment was analysed against the measured data. The analytic results confirm the effectiveness of several utilized passive design strategies that followed the green building design guidelines to improve the indoor thermal comfort.

Keywords: thermal comfort, naturally ventilated residence, green building

Introduction

The time people spend indoors accounts for about 80% of their life time. With ever better living conditions, people have paid increasing attention to indoor thermal comfort. As far as indoor thermal comfort is concerned, the problem of indoor overheat can be solved with an air conditioner. Correspondingly, a survey shows that 85% of Taiwanese households have been equipped with an air conditioner. This indicates that most of Taiwanese residents who live in a humid and hot climate have becoming increasingly accustomed to creating a comfortable indoor environment. Nevertheless, such a solution would cause a heavier financial burden because of the increasing use of energy and is in consistent with the national objective of reducing the greenhouse gas emission from buildings. Worse still, installing an air conditioning system in houses will become a practice in the long run; consequently, the principle of passive building will disappear in the design of many residential buildings.

In the eco-friendly building mark accreditation, the way in which the issues about the indoor thermal comfort of natural ventilated buildings are handled is different from that of the buildings equipped with air conditioning where only one indoor environment assessment indicator can ensure the satisfaction of residents [Liang]. As for the former, miscellaneous indicators, including micro-climate and building, are used for the control and confirmation. Taking a house with the eco-friendly building market accreditation as the research subject, this paper described the design methods adopted by the research subject and conducted a measure-based experiment on the building, with the hope of demonstrating the effects of Taiwanese eco-friendly buildings in guaranteeing the thermal comfort of natural ventilated houses.

Methodology

The research subject was a residential building located in Taichung City in Taiwan, as is shown in Figure 1. Designed and constructed according to the principles of environment-coexisting buildings, it passed the accreditation for the Taiwanese eco-friendly building mark. According to the research objectives of this paper, only the technologies the building adopted to promote natural ventilation and reduce the use of air conditioning will be discussed.

Figure 1 Appearance of the Residential Building as the Research Subject

Planting as many trees as possible on the premises can increase the moisture content in the air and lower the air temperature to regulate the climate and create greater comfort [Ng]. Figure 2 shows the vegetation of the research subject, revealing that about 50% of the premises was covered by trees and that the trees scattered around the building. Aside from the ground vegetation, trees could also be found on the balconies of the floors and on the roof.

Figure 2 Layout of the Vegetation and Pools of the Research Subject

If premises have a stronger ability to retain moisture, they will have greater potential to reduce outdoor temperature through moisture evaporation, thus significantly alleviating a high outdoor temperature and increasing outdoor thermal comfort [Lin]. As is shown in Figure 2, the belt-shaped eco-ditches and ponds, along with an outdoor swimming pool, scattered around the building in the research subject. In particular, the water of the eco-ditches and ponds came from the rainwater recycling system.

As for the households, the higher houses had good wind speeds, so they were equipped with windows of appropriate sizing and location which could contribute to adequate cross ventilation and eliminate the heat generated indoors and the one transmitted into and stored in the room, thus maintaining the thermal comfort throughout the day. But as far as the public space on the ground floor was concerned, there weren't good wind speeds due to the trees around the building; therefore, the buoyancy driven stack ventilation must be adopted to solve the problem. In the research subject, a buoyancy driven stack ventilation system (see Figure 3) was installed in the rooms on the first floor, so that the outdoor cool and fresh air could flow towards the majority of the breathing zone.

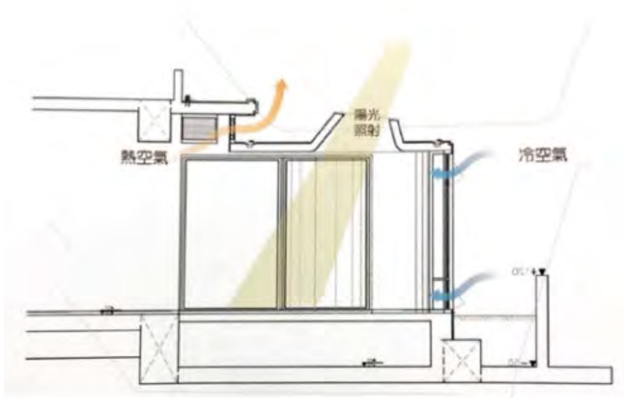

Figure 3 Diagram of the Buoyancy Driven Stack Ventilation System Installed in the Ground-level Public Space in the Research Space

Adequate window sizing was installed on the south side of the research subject so that the houses could have as much natural ventilation as possible. But the problem was that the building would face much solar radiation which would result in a high indoor temperature in warmer months. Studies [Hwang; Lyon; Chan] showed that solar radiation and the thermal performance of windows had great influence on the thermal comfort of the residents in the building's glazed perimeter zones. To avoid the problem, each house was equipped with an effective sunshade device and balcony to prevent solar radiation from entering the rooms through windows, as is shown in Figure 2. The trees lined around the building created adequate sunshade for the public space on the ground floor.

In this study, the survey was based on objective parameter measurement. The indoor parameters of the testing included air temperature and relative humidity. The measurement was conducted in the public space on the ground floor as well as in the sitting room and bedroom of a residential house on the 14th floor. The measurement lasted for two months, from October to December 2016. The period was in the season when natural ventilation was suitable for Taiwan. According to the schedule of the residents, the measurement in the public space started from 10:30 to 17:00; the one in the sitting room started from 09:00 to 19:00; the one in the bedroom started from 19:00 to 07:00. To facilitate the comparison with the indoor thermal comfort, the graphers were placed in three locations – the outdoor balcony on the 14th floor, the location outside the window of the public space on the ground floor, and the upwind outside the premises. These recorders measured the outdoor temperature during the period.

Results and discussion

Figure 4 is a comparative analysis of outdoor air temperature inside and outside the premises. The temperature difference, the horizontal ordinate of Figure 4, refers to the gap between the air temperature inside the premises and that outside the premises. As is shown in Figure 4, the vegetation and moisture retention design of the premises significantly lowered the air temperature outside the premises, so the air temperature inside the premises was always lower than that outside the premises during the measurement period. For 50% of the period, the temperature was lowered by more than 1.0℃, with an average of 1.1℃ and a maximum of 3℃.

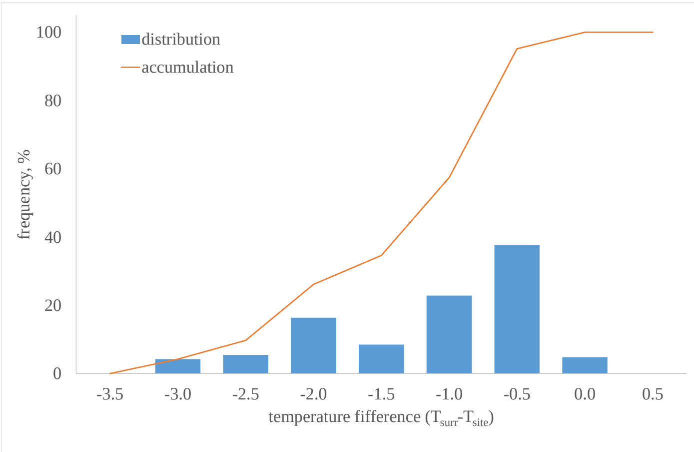

Figure 4 Comparative Analysis of Outdoor Air Temperature inside and Outside the Premises

Figure 5 shows the measurement results of the indoor temperature of the public space equipped with the buoyancy driven stack ventilation on the ground floor. According to Figure 5, the indoor temperature of the public space on the ground floor was the same with the outdoor temperature for 45% of the measurement period, and it happened after 14:00. This manifested that the buoyancy driven stack ventilation brought adequate natural ventilation to the space, so that the indoor space and the outdoor space shared the same temperature. Figure 5 also demonstrates that the indoor temperature was lower than the outdoor temperature for 55% of the measurement period. The comparison of the time of the temperature difference shows that it started from 10:30 to 14:00 and that the temperature difference was more significant in the earlier stage. The reason for the phenomenon was that the doors and windows of the space were closed before the measurement at 10:30 by which the low temperature in the previous night had not dissipated. In the public space on the ground floor, the combination of the thermal storage at night and the buoyancy driven stack ventilation during the day led to an average temperature reduction of 0.4℃ in the indoor temperature compared with the outdoor temperature in the premises.

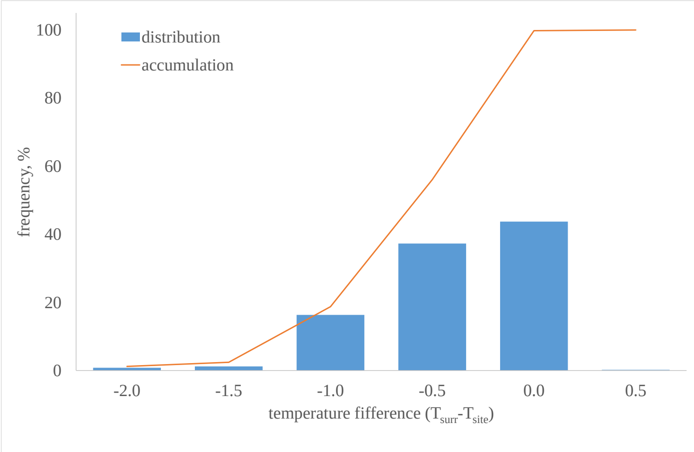

Figure 5 Comparative Analysis of the Indoor and Outdoor Temperature of the Public Space Installed with Buoyancy Driven Stack Ventilation on the Ground Floor

Figure 6 shows the results of the temperature measurement of the sitting room during the day. During the measurement, the French window of the sitting room was kept open. According to Figure 6, the temperature of the sitting room was the same with the outdoor temperature for 30% of the measurement period during the day when the French window was kept open, while there was a difference of -0.5~0.5℃ between the indoor and outdoor temperature for 67% of the measurement time during the day. Throughout the measurement period, the average temperature of the sitting room was 0.1℃ lower than the average outdoor temperature during the day.

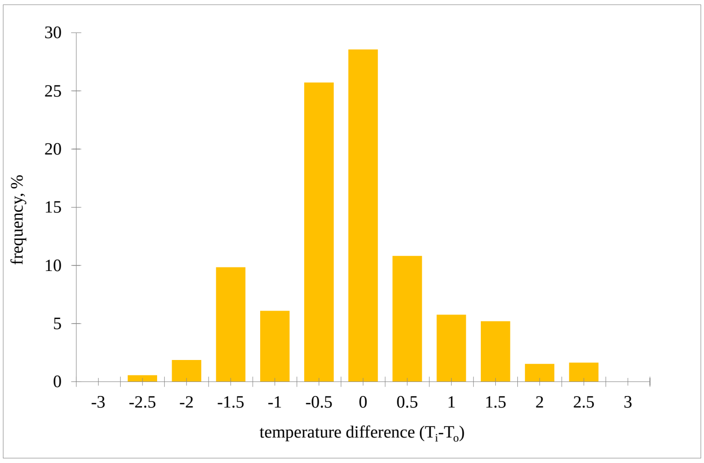

Figure 6 Distribution of the Difference between the Temperature of the Sitting Room and the Outdoor Temperature

Figure 7 shows the results of the temperature measurement of the bedroom at night. The temperature of the bedroom was the same with the outdoor temperature for 21% of the measurement period, and there was a difference of -0.5~0.5℃ between the indoor and outdoor temperature for 56% of the measurement period during the day. Throughout the measurement period, the average temperature of the bedroom was 0.1℃ lower than the average outdoor temperature.

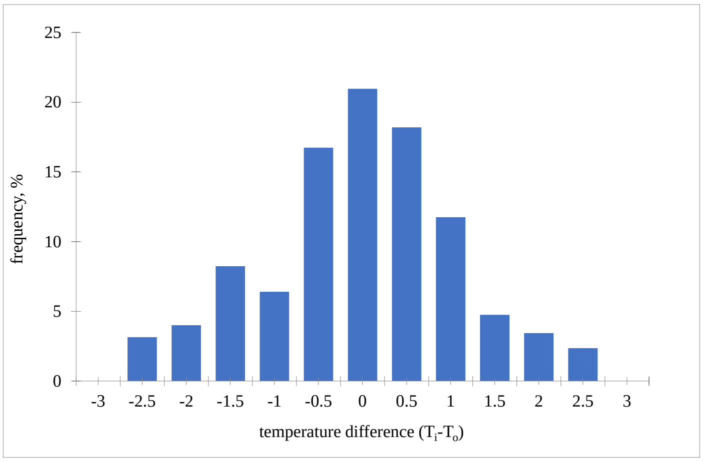

Figure 7 Distribution of the Difference between the Temperature of the Bedroom and the Outdoor Temperature

According to Figures 6 and 7, the cross ventilation design in the residential house could help maintain a temperature shared by the sitting room/bedroom and the outside environment. In other words, it is possible to maintain thermal comfort brought by cross ventilation to the indoor space of residential house in the season suitable for natural ventilation.

Conclusion

This study aims to find out if the residential houses which follow the design principles of eco-friendly buildings can meet the requirements on thermal comfort in the season suitable for natural ventilation. Through a measurement-based experiment on a building with the accreditation of eco-friendly building, this paper has demonstrated that a design featuring the combination of the vegetation and moisture retention design of the premises, the sunshade of the building, buoyancy driven stack ventilation and the cross ventilation can ensure thermal comfort in an indoor environment when the external conditions are suitable, thus reducing the use of air conditioning, energy consumption and carbon emission.

Abstract: Sky view factor (SVF) measures the openness of a point to the sky vault and as such, has been widely used in urban climatology and environmental design studies associated to various phenomena, including Urban Heat Island intensity and daylight availability. This study examines to what extent SVF can be also employed for predicting solar availability in the urban environment, with emphasis on building façades.
SVF and solar irradiance simulations were performed for vertical façades in 24 urban forms -of 500x500m area- in London; mean values were computed by urban form, and by façade orientation, considering 30 orientations at 12° azimuth intervals. The statistical analysis reveals a strong linear relationship (R^2>0.8) between SVF and annual global irradiance for all orientations. The models derived from linear regression tests were integrated into a graphical tool for predicting annual global irradiance on a façade in London as a function of its SVF and azimuth angle. Furthermore, the fact that SVF was found to correlate well with both major components of solar irradiation, namely direct and sky diffused irradiances, indicates that it can be used for predicting annual solar availability at latitudes similar to London, even for sunnier climates.

Keywords: solar potential, solar indicator, sky view factor, urban façades, orientation

Introduction

Solar energy is one of the renewable energy resources with the greatest potential; it is estimated that, upon certain conditions, solar energy could contribute to 27 per cent of the global electricity production by 2050 (IEA, 2014). Unlike other renewable energy technologies, photovoltaic (PV) systems can be relatively easily applied in the urban environment, integrated into new and existing buildings. A major advantage of exploiting building envelopes for harnessing solar radiation is the on-site production and use of energy which will be a requirement for all new buildings in the European Union after 2020 (EPBD, 2010).

Compared to façades, roofs are regarded more favourable for the implementation of photovoltaic systems as there they are generally less affected by overshadowing and intervene less with buildings' appearance and other functions served by façades (daylighting, natural ventilation, etc.). Nonetheless, with façades comprising the greatest part of urban buildings' surface, their solar irradiation represents a considerable percentage of cities' solar energy potential (Redweik et al., 2013) and hence, their exploitation becomes critical for the attainment of energy efficiency targets at building and urban scale. In response to this challenge, photovoltaics technology is advancing rapidly offering more possibilities for an improved architectural integration, aesthetically (colours, level of transparency, etc.) and functionally (e.g. providing solar and glare protection).

The potential for integration of PV systems on façades varies significantly in urban areas, as façades' insolation is highly sensitive to urban geometry, affected by orientation and degree of obstruction (Esclapés et al., 2014; Yun and Steemers, 2009). The orientation of an unobstructed façade determines its interaction with the solar geometry at a specific location and thus, its potential solar irradiation. However, urban façades are usually obstructed by surrounding buildings which limits their openness to the sky (related to the sky diffuse solar component) and solar exposure (related to the direct solar component). Past studies, employing statistical analysis, have shown a strong negative relationship between degree of sky obstruction, associated positively to built density, and façades' total solar irradiation (Chatzipoulka et al., 2016; Mohajeri et al., 2016). However, their findings refer to average values over entire urban areas, neglecting the orientation parameter.

This study explores the relationship between the degree of sky obstruction, expressed by sky view factor (SVF), and solar availability on building façades as a function of their orientation. Initially introduced by urban climatologists, sky view factor (SVF) is a measure of the openness of a point to the sky and thus its capability to emit and receive longwave radiation to and from the sky, respectively. In the literature, SVF is equally used as urban geometry variable, e.g. investigating its relationship with spatial variations of urban air and surface temperatures (Eliasson, 1996; Yamashita et al., 1986), and as performance indicator evaluating environmentally different urban forms (Project PREcis, 2000; Ratti et al., 2003). With respect to façades' performance, SVF is widely used as indicator of daylight availability (e.g. Cheng et al., 2006; Zhang et al., 2012), whereas its relation with solar availability is less established.

In the past, SVF measurements were feasible only in situ and at one point each time, using special equipment such as fish-eye cameras. Nowadays, an increasing number of urban solar and thermal analysis models perform accurate SVF calculations as part of their simulations, over entire urban surfaces and at different spatial resolutions. Compared to solar irradiance simulations, the calculation of SVF is faster and requires solely one input, namely the 3D urban geometry information. In this context, predicting solar availability in urban environments using SVF values would enable a quick evaluation of solar energy potential and facilitate the task of architects and urban designers for integration of efficient solar active strategies in new and existing buildings.

Methodology

Cases studies

This study is part of an on-going research and based on the analysis of twenty-four urban forms, of 500x500m area each, which have been selected from three areas of London. These areas represent urban environments of different built density with the studied urban forms covering values from 3 to 22, m^3/m^2 (total built volume within the site over site area). The results of their geometrical analysis as well as the criteria for their selection are presented analytically in Chatzipoulka et al. (2016). It is noted that the naming of the urban forms as appeared in Figure 1 is reserved for consistency between past and future publications: the letter denotes the area to which an urban form belongs (C, W, N for central, west, north area, respectively), while the number derives from its position in the area's map.

Figure 1. Ground maps of twenty-four urban forms considered in the analysis, in decreasing order of density.

SVF and solar irradiance simulations

Solar simulations have been performed in PPF software, a powerful tool which has been employed by several studies, so far (e.g. Chatzipoulka et al., 2016; Cheng et al., 2006; Project PREcis, 2000). PPF is based on the RADIANCE ray-tracing programme (Ward Larson and Shakespeare, 1998) and uses sky models which represent average radiance distributions of the sky vault for a given time period (Compagnon, 2004). Specifically, for the irradiation simulations, climatic data of London (hourly direct and diffuse irradiance values) were obtained from METEONORM software (Remund et al., 2015) and processed statistically in order to build up London's annual sky model (Fig. 2a). Only daytime hours were considered, i.e. hours between sunrise and sunset on a day, which are 4317 in total. It is worth to be mentioned that, considering the entire year, direct and diffuse horizontal irradiance for London are in a relative balance with the former being 102 and the latter 120, W/m^2.

The 3D digital models of the urban forms were reproduced in a CAD software, including the surrounding buildings, and inserted in PPF (Fig. 2b). Annual mean irradiances [W/m^2] and sky view factor (SVF) [-] values were computed on a grid of 2-meter spatial resolution, adjusted onto the surfaces of the models. Direct (*Id*), diffused from the sky (*Is*) and reflected by buildings (*Ib*) irradiances were computed separately; while global (*Ig*) irradiance is calculated as the sum of them, as described below:

$$Ig = Id + Is + Ib$$

SVF ranges from 0 to 1, denoting a totally obstructed and unobstructed point, respectively; however, façades' SVF value ranges from 0 to 0.5 as unobstructed vertical surfaces can be seen only by half of the sky vault.

The simulation results were processed in Matlab and mean values of four types of irradiances and SVF were computed, first by urban form, and next by orientation in each urban form. The relationships between mean SVF and irradiances were next explored performing linear regression analysis in the same programme.

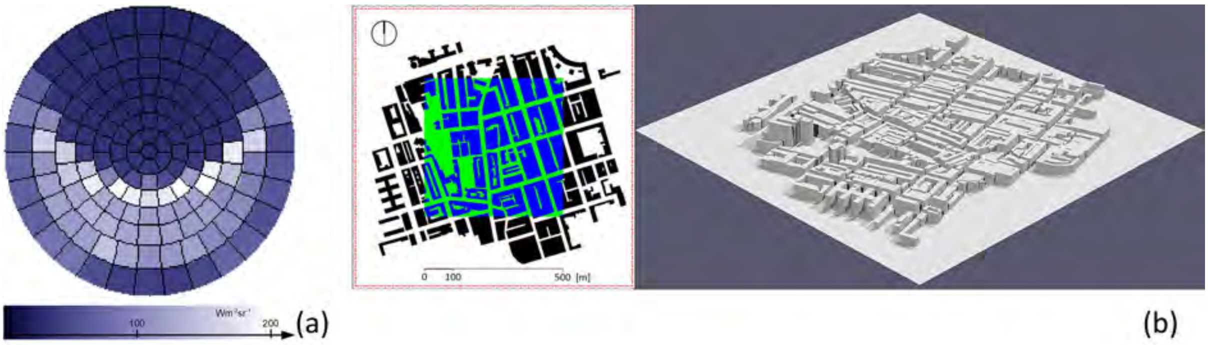

Figure 2: (a): Stereographic view of the sky vault representing London's annual sky model used for irradiance simulations. (b): Left, ground map of C2 urban form, in colour the simulated area and in black the surrounding buildings; right, its perspective view in PPF.

Results

Mean façade SVF and irradiances by urban form

Figure 3 illustrates annual mean irradiances and mean SVF values computed for each of the 24 urban forms, ranked (from left to right) in decreasing order of density. As implied by the line chart, the relationship between mean façade SVF and density is clearly negative with the coefficient of determination (R^2) being 0.92. The colour bars allow the comparison of the percentages in which annual global irradiance consists of direct, sky diffused and reflected irradiation. It is ascertained that, in all the urban forms, façades' annual global irradiance consists constantly of direct radiation by 42-43%, sky diffused by 44-45% and reflected by 13-14%. Hence, sky diffused radiation constitutes the greatest part of annual irradiation received by building façades in London, with direct solar contribution though being equally important.

The linear regression analysis revealed a particularly strong, positive correlation between SVF and all three irradiances comprising global irradiance (R^2>0.98) and so, not surprisingly, the relationship between SVF and global irradiance was found to be almost perfectly linear (R^2=0.99). It is pointed out that, since global irradiance expresses the sum of three irradiance components, its statistical relationship with SVF is determined by the relationship of each of its components with SVF, weighted by their percentages.

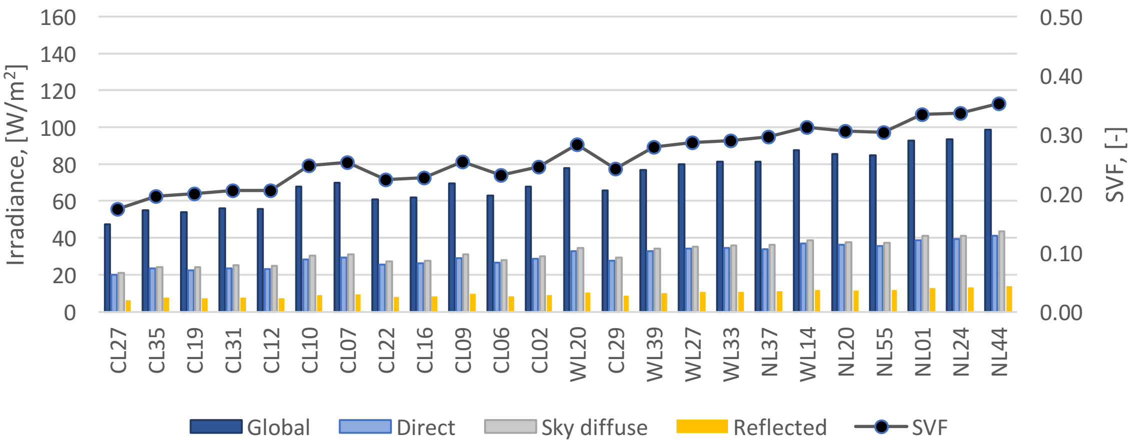

Figure 3. Mean façade SVF (dots, right vertical axis) and annual global, direct, sky diffused and reflected irradiance values (bars, left vertical axis) by urban form.

Mean façade SVF and irradiances by orientation

In the previous section, average façade SVF and irradiance values in the urban forms were found to correlate particularly highly, independently to type of irradiance. Nonetheless, solar availability on building façades and, especially the direct solar radiation received by them, is strongly affected by their orientation in relation to the sun path. Thus, the averaging of solar irradiance values over entire urban forms may suppress significant variations of the studied relationships occurring at different orientations. For this reason, the relationships between mean façade SVF and irradiances were also examined by orientation, considering 30 orientations at 12° azimuth intervals; these represent the patches into which the perimeter of the sky models is divided (see Fig. 2a). The numbering of the orientations starts from North (Orientation 1: -6 ≤ azimuth < 6) and counts clockwise.

Once mean SVF and irradiances were computed for all 30 orientations by urban form, the obtained values were classified by orientation. In total, 120 regression analysis tests, i.e. 30 orientations by four types of irradiance, were performed. For some orientations, the regression was based on less than 24 cases as some urban forms present very few points (<10) facing at specific orientations. In all cases though, the number of urban forms considered were not less than 20.

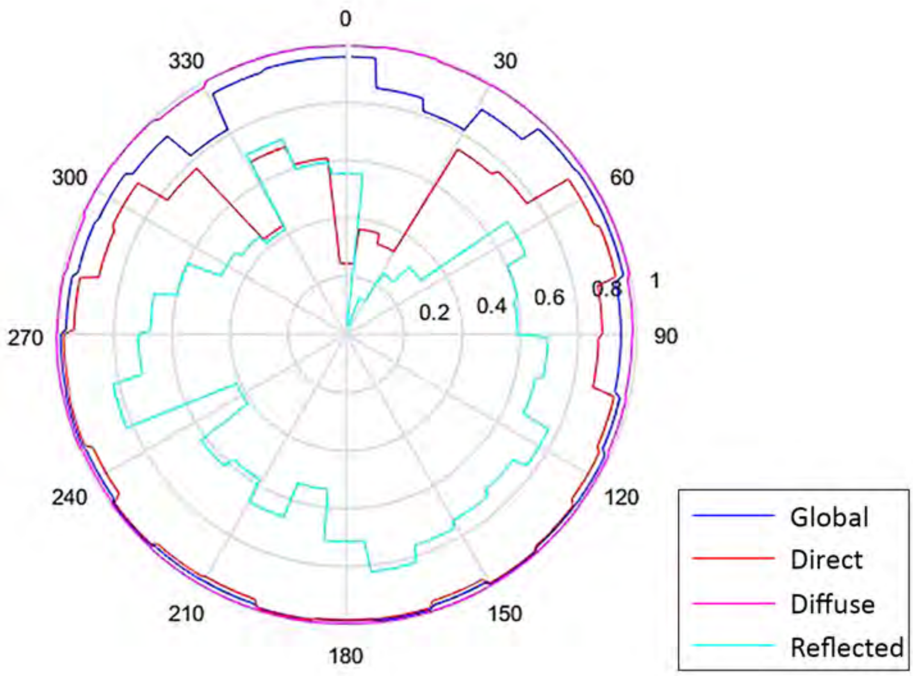

Figure 4. Variations of R^2 -measured from centre outwards- describing the linear relationship of SVF and annual mean irradiances, i.e. global, direct, diffuse, and reflected, by orientation.

The R^2 describing the strength of the relationship between mean SVF and annual irradiances are presented graphically in a polar chart in Figure 4, with the values being measured from the center outwards. As may be expected, the relationship between SVF and sky diffused irradiance is found to be almost perfectly linear for all orientations. Regarding direct irradiance though, the relationship is clearly affected by orientation: it is significantly strong (R^2>0.8) for façade azimuths between 60° and 300° (from East to West) whereas, for the remaining orientations, the R^2 values are reduced and vary unevenly. This may be partially attributed to low solar altitudes coinciding with north orientations (Chatzipoulka et al., 2015). On the other hand, the relationship between SVF and irradiance reflected by buildings appears to be independent to orientation as the R^2 fluctuates unevenly around different orientations. Finally, regarding global irradiance, it is of great interest that the R^2 value is constantly above 0.8. This is explained by the following: (i) the reflected part comprises a small percentage of the total irradiance received by building façades, and (ii) the solar irradiation of façades facing to north orientations is dominated by sky diffused radiation.

Predicting annual global irradiance on façades in London

Since mean façade SVF presents an almost perfectly linear relationship with annual mean global irradiance, independently to orientation, it is argued that SVF can be used as a good predictor of solar energy potential of façades. This section provides a graphical tool to architects and urban designers based in London for estimating annual global irradiance on a façade, as a function of its orientation and mean SVF. For this purpose, linear regression analysis was repeated setting intercept value to zero and 30 analytical models i.e. one for each orientation, were obtained; the beta coefficients (b) are presented in Table 1. As shown in Figure 5, which demonstrates the scatter plots and linear resolutions for six representative orientations, setting intercept to zero affects slightly the strength of the relationship with R^2 remaining significantly high.

The linear functions were next solved for 10 representative SVF values, from 0 to 0.5, at 0.05 intervals, and the (x, y) points are plotted on Cartesian axes as continuous curves. The relevant graph is presented in Figure 6; the suggested way of using it is as follows:

- identify the azimuth degree of the façade of interest on the horizontal axis;
- from that point, draw a normal line to intersect the curve representing SVF value closest to mean SVF of the façade;
- project the intersection point on the vertical axes to read the estimated annual mean global irradiance [W/m^2] (left) and solar irradiation [kWh/m^2] (right).

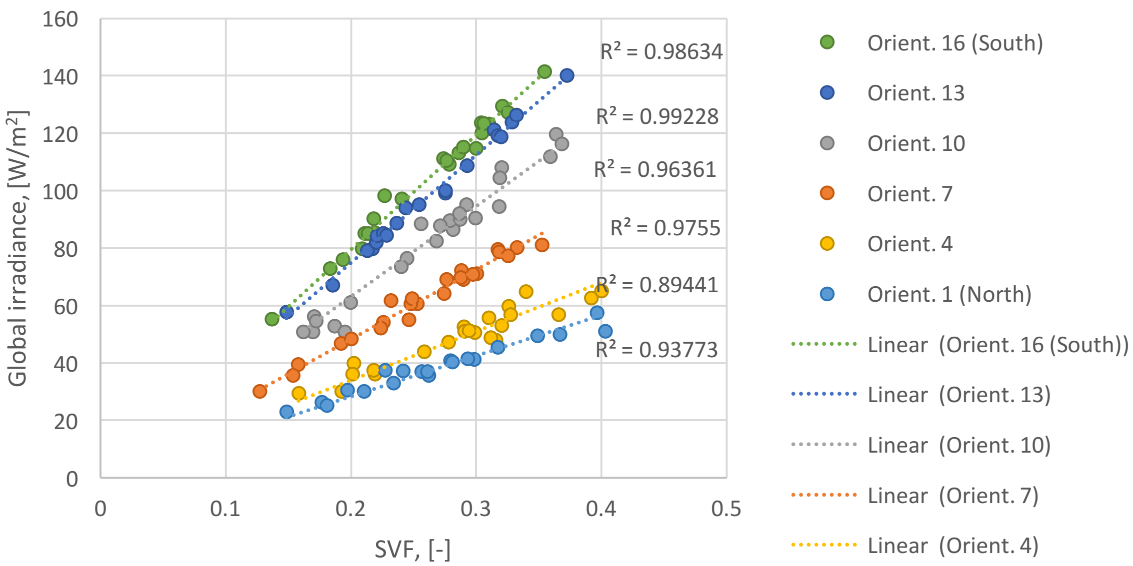

Figure 5. Mean global irradiance plotted against mean SVF values for six representative orientations, and their linear regression by setting intercept value to 0.

To test the validity of the prediction models, annual global irradiance was computed on the facades of a single, unobstructed building of triacontagonal plan (i.e. featuring 30 façades, pointing at the middle of orientation intervals). Comparing the results with values derived by solving the models for SVF equal to 0.5 - represented by the upper, light blue curve in Figure 6 -, it was found that the latter tend to slightly overestimate façades' annual global irradiance; however, there is still a very good agreement. Indicatively, the relative difference between values derived from the models and those simulated for the test is on average 3.7%, and the greatest differences, about 6.5%, are observed for façade orientations receiving annually more solar radiation, i.e. south orientations.

Conclusions and further research

Evaluating solar energy potential of façades using their SVF values would be of great relevance to professionals working in the field of urban environmental design. SVF is exclusively defined by urban geometry and thus its calculation is more straightforward compared to solar simulations. Using the case of London, the present study demonstrates that this is feasible since SVF was found to have a strong linear relationship with annual global irradiance, independently to façade orientation. To exemplify the usability of such a finding, the linear models obtained from regression analysis are integrated into a graphical tool for predicting annual solar irradiation of a façade surface, based on its SVF and azimuth angle.

Additionally, the fact that SVF was found to correlate well with both dominant components of solar irradiation, namely sky diffused radiation and direct radiation for major orientations (i.e. azimuths described by the annual sun path), indicates that SVF can be used as a predictor of annual solar availability at latitudes similar to London, even for sunnier climates. To test the sensitivity of the findings to other time periods and latitudes, the analysis has been extended to a winter month, January, and a summer month, July, considering two more European cities, Athens and Helsinki. Overall, the results confirm the strong relationship between SVF and solar irradiation of facades, and are reserved for a future publication.

Free-running High Rise Housing in Hot and Humid Climates – issues and solutions

Drin Chulakasyena[1] and Paula Cadima[2]

Abstract: Bangkok is one of the world's hottest and most humid cities. Its high rise residential developments currently depend on air conditioning to provide acceptable thermal comfort. This paper reports to the results of research carried out to establish guidelines towards free-running high rise buildings in this climate.
Fieldwork on existing buildings identified that opportunities for ventilation were commonly inadequate, with negative impacts on both temperature and humidity. Balconies were ubiquitous, but were little used due to design shortcomings. Examination of internal walls and divisions identified problems of inadequate soundproofing and insufficient separation of hot and odorous kitchens from other living spaces.
Solar control studies demonstrated that a combination of fixed horizontal and vertical shading devices and adaptive horizontal louvres could help address issues of excessive direct and diffuse solar radiation. Re-imagining building forms helped decreasing indoor temperature through improved cross ventilation. Further studies to assess the performance of an optimised model showed that a façade made of a combination of high thermal mass (concrete) in the living areas and lightweight material (timber) in the bedrooms improved thermal performance and users comfort. The combined results provide a basis for free-running designs for high rise residential buildings in the hot and humid Bangkok.

Keywords: free-running, hot and humid, solar control, cross ventilation, thermal mass.

Introduction

High rise developments in Bangkok are commonly designed with single aspect apartments and double load corridors, in either linear or L-shape, with large glazed areas, no shading devices and with a balcony inset into the façade of every unit. The potential for cross ventilation is very limited.

Most of this housing scheme replicates cold-climate models with sealed façades and relies very heavily on air conditioning engendering a wide range of environmental impacts. This is at odds with traditional living patterns in the tropics, where light winds, year-round mild weather, and fairly constant temperatures make outdoor living desirable. At the same time the obvious constraints of high rise construction, and of air pollution and noise in the city, limit the potential for the outdoor lifestyle that previous generations enjoyed. That said, there seems clear potential to design better performing buildings that would both improve environmental performance and work in better harmony with the climate.

Balconies are an almost omnipresent feature of high rise residential buildings in Bangkok and offer the greatest opportunity for connecting the occupants with the exterior environment. But recent research shows that the design of most existing balconies is such that they are little used other than for storage, drying clothes and as a location for installing air conditioning condenser units (Chulakasyena, 2016).

High demand and limited regulatory control can result in buildings whose design focus is on fast and low cost construction, often with lip service at best to environmental issues. As the market matures there is opportunity to promote the benefits of a greater focus on sustainable design, delivering not only better environmental performance but long term cost savings.

The aim of this paper is to establish design guidelines for achieving free running high-rise residential buildings in Bangkok, while maintaining or improving occupant's comfort and satisfaction within their dwellings.

Climate analysis and comfort band

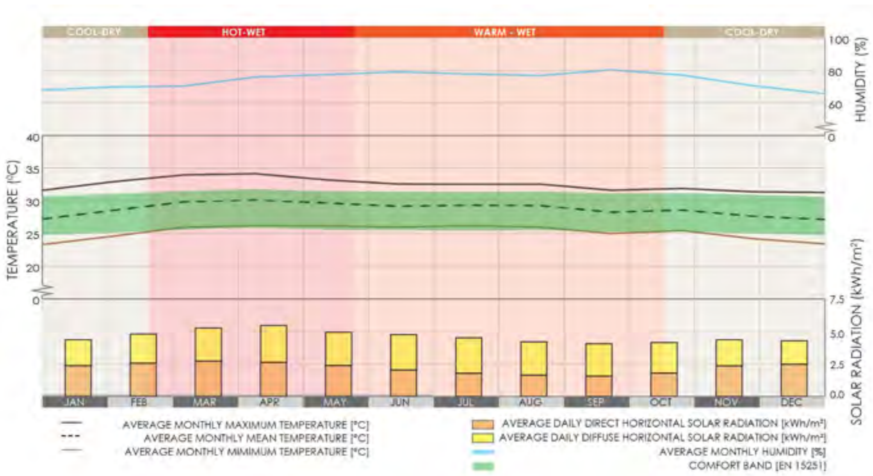

Fig. 1. Bangkok (Don-Muang airport) weather data with the EN 15251 comfort band (Source: Meteonorm 7.0)

Designing with the local climate highlights the need for enhancing ventilation and for reducing the impact of solar radiation, both direct and diffuse, while maintaining levels of daylight is desirable, (Fanger 1993, Koch-Nielsen 2002 and Givoni 1994). The thermal comfort criteria set out in EN 15251 correspond closely to those found in recent studies in Bangkok (Taweeken 2013, Jitkhajornwanich 2006) and will therefore be used for assessment purposes, Fig. 1.

Fieldwork

Fieldwork was carried out in two apartments, one at the *Rhythm* and another at the *U-Delight* building in Bangkok, (Chulakasyena, 2016). The *Rhythm* building has an enclosed, glazed lobby area, as is common in upmarket residential buildings, Fig. 2(a), while the *U-Delight* building has an open space that functions both as a lobby and playground area, Fig. 2(b). The fieldwork confirmed that ventilation in the apartments studied is inadequate. During the times visited there was a minimal air movement inside the lobby in the *Rhythm* building and a nearly consistent 1-2 m/s wind velocity within the ground floor of the *U-Delight* building.

Fig. 2. Lobby area in *Rhythm* building (a) and in *U-Delight* building (b).

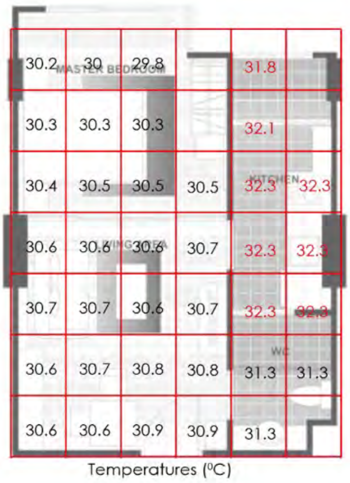

Fig. 3. spot measurements (temperature)

The indoor air temperature in the kitchen of a representative apartment was consistently almost 1.5K higher than in the bedroom and (linked) living room, Fig. 3. The higher temperature in the kitchen seemed likely to be due to the heat output of the refrigerator. This effect, together with the additional heat gain in the kitchen from cooking (and associated smells) suggested that separating kitchen and living areas is highly desirable.

In summary, the fieldwork studies confirmed practical issues related to the impact of solar radiation and poor potential for ventilation, and also drew attention to the internal layout, location of kitchens and usability of balconies.

Analytical work

Analytic work was carried out to assess the impacts of solar control, building form, natural ventilation, materiality and occupancy on environmental performance (visual and thermal), as well as of the balcony design in order to increase air movement. The base model, best thought to represent the typical construction and dimensions of a one-bedroom apartment in high-rise residential building in Bangkok, was assumed to be facing South with single glazing transmittance of 0.88. All other constructions details were considered to be identical with the fieldwork unit at the *U-delight* building to ensure a well calibrated model. *OpenStudio and*

Energy+ software were used for thermal simulations, *DIVA* for daylighting, *Autodesk Flow Design* for wind flow and *Grasshopper* for solar analysis.

Fixed Shading device

In order to help controlling solar radiation, a fixed horizontal shading device with 0.5m extension was tested. This is the maximum dimension allowed by National Regulations (regulation 55 section 43), therefore thought to better reflect the commercial realities of buildings in Bangkok, Fig. 4.

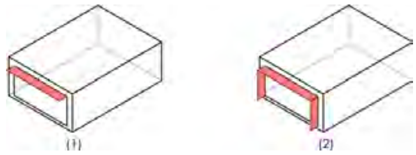

Fig. 4. 0.5m fixed shading devices – (1) Horizontal, (2) Combined Horizontal and Vertical

The analytic work showed that a fixed horizontal shading device on a South facing façade helped reducing around 80% of the direct solar radiation and almost 1.4K of the peak air temperature. On the East and West facing façades the reduction on direct solar radiation was around 25% and decreased by 0.9K the peak indoor air temperature. As expected, a fixed shading device on a North facing façade had very little effect on the air temperature (less than 0.1K).

The graph in Fig. 5 shows that adding a vertical shading to the East and West orientations reduces the incident direct solar radiation by approximately 5%, 13% to the South orientation and by 27% to the North orientation.

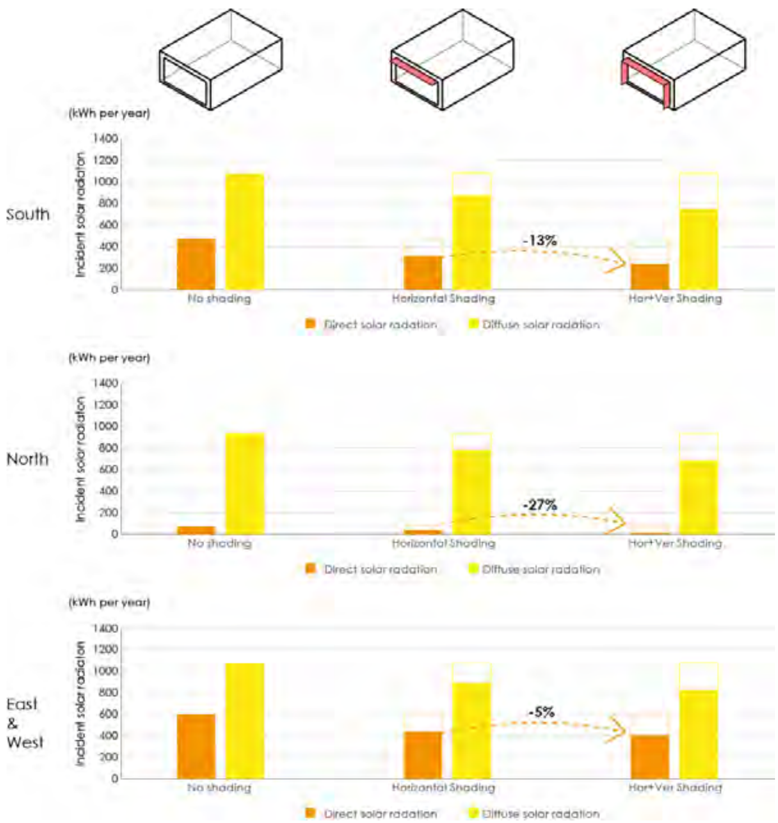

Fig. 5. Incident yearly solar radiation at various orientations with a fixed horizontal and a fixed horizontal + vertical shading devices.

Adaptive shading device

The effects on both thermal and daylighting performance of three different solar control design solutions were tested, Fig. 6: Vertical louvres (1), Horizontal louvres (2) and Combined vertical + horizontal louvres (3).

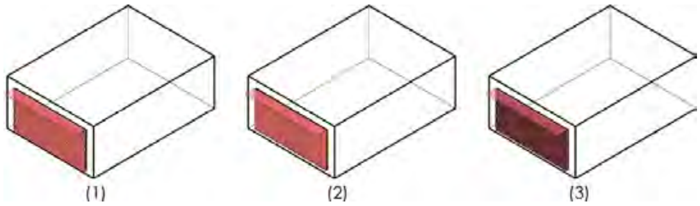

Fig. 6. Types of adaptive shading devices

Thermal Studies:
The amount of incident diffuse radiation on a South facing window is decreased by 33% with horizontal louvres and by 39% with vertical louvres, while combining horizontal and vertical louvres decreases 50%. Shading with any of these louvre types decreased by 0.3-0.4K the indoor air temperature. The studies show that on the East and West facing windows horizontal and combined horizontal with vertical louvres deliver the best performance, reducing both diffuse and direct radiation by up to 70% for East orientation and 61% for West orientation, while decreasing the indoor air temperature by almost 2K on a hot day.
The use of louvres on North facing windows is poorly justified as there is minimal reduction in the indoor air temperature. Nevertheless, this would help decreasing the diffuse solar radiation between 29% (horizontal) to 47% (combined).

Daylighting Studies:
In terms of visual performance, the combined solution is shown to deliver the best reduction in glare, although horizontal louvres provide the best results for daylighting distribution (for all orientations). Vertical louvres are the least advisable design strategy to control glare and provide a good daylighting distribution.

Building form

The climate analysis indicates that in Bangkok it is desirable to have building interior spaces coupled with outdoor temperature, as for most of the time the outdoor temperature is within the comfort band, especially during the night and rainy periods. The most efficient way to achieve this coupling is to provide cross-ventilation. This in turn requires openings on more than one façade. Three alternative forms were tested in models representing apartment unit with two, three and four external walls, respectively.

The typical construction materials used usually have low insulation properties (concrete wall), therefore increased external wall area and thus more exposure to the outdoor atmosphere will also help dissipate excess internal heat gain by convection.

Daytime temperatures drop by 1-2K for all variants (2, 3 and 4 external walls). Night time temperatures drop by 1-1.5K for 2 walls, 2.5-3K for 3 walls and 3-3.5K for 4 walls (the drop in night time temperature naturally has an impact on day time temperatures, as the starting temperature is lower). The tests exclude the effect of natural ventilation; so once that is factored; it would further reduce the air temperature in the models with 3 and 4 exposed walls, in particular during night time.

Natural ventilation

The matching square openings with an area of 1 m² allow ventilation rates of 5 to 40 ac/h. If the shape of the outlet were to be changed to a landscape rectangle with the same opening area made, there would be no meaningful difference.

The studies showed that providing larger openings of equal area provides the best results. With an enlarged inlet opening area to 3 m^2, the number of hours with ac/h above 15 increased by 47%. Enlarging both inlets and outlets to 3 m^2 the percentage of time with a rate of 15 ac/h or above can further increase by 75%.

Materials

Analytic results indicate that exposed high thermal mass combined with a ventilation rate of 15 ac/h, can help decreasing the daytime indoor temperature to within the comfort band. However, there is a slight temperature increase at night, a time during which lower temperatures are desirable for sleeping. This leads to the conclusion that the high mass strategy is appropriate for living areas used during the day, but lightweight materials perform better in the bedrooms, enabling the room temperature to couple more closely with the decreasing outdoor air temperature.

Occupancy

Predictably, the temperature rises both day and night with increased levels of occupancy, but by only around 0.1 - 0.2 K with four occupants. The high ventilation rate and the high thermal mass may help dissipating and to absorbing, respectively, the internal heat gains.

It was identified that the most effective strategy for lowering indoor temperatures when occupants are at work during the day is to leave the windows open all day. It was, however, also hypothesised that if occupants are present during the day they should close the windows when the outdoor temperature is above indoors. Results confirm that a reduction in daytime temperature of between 0.5-1.2K can be achieved this way, most prominent on the hottest day, Fig. 7. When the outdoor temperature exceeds the indoor temperature, the use of a fan providing air movement, can help further reducing the perceived temperature.

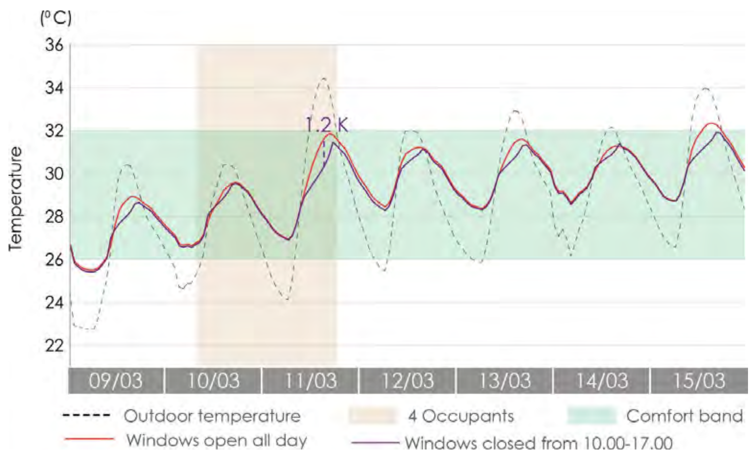

Fig. 7. Optimised model with windows open all day compared to windows closed from 10.00 – 17.00.

Balconies

The focus of this section is on enhancing ventilation on the inset type balcony, through the use of wing walls, Fig. 8, to create pressure differentials and thus increase air movement.

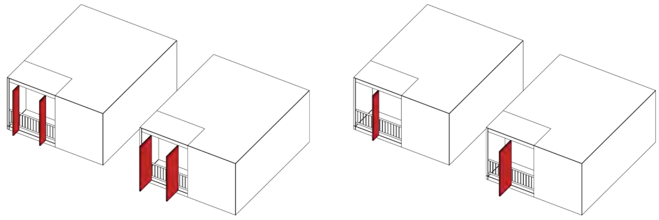

Fig. 8. Variations wing wall configurations.

Scenarios with the prevailing two wind directions in Bangkok were considered. These are perpendicular to the panels and at 45° to them. A wind velocity of 2.2 m/s was assumed, representing the average unobstructed wind flow in Bangkok.

The overall best performance is achieved by a 1m deep single panel. If this solution is excluded by regulatory considerations, the second best overall option is 0.5m deep twin panels. Limitations of the software and the real world variability in wind direction and velocity mean that the results must be viewed as indicative only, but they nonetheless helped identifying the most promising configurations of wing walls which can deliver enhanced ventilation to balconies.

Conclusion

Analytical work identified that fixed horizontal shading devices of 0.5m depth (which fall within regulatory limits) provide meaningful benefits on all building orientations, Fig. 9. Vertical shading on South and North facing windows is beneficial, although its benefits must be weighed against its potentially negative impact on lateral views, Fig. 9. Adaptive horizontal louvres can effectively address issues of excessive direct and diffuse solar radiation and daylighting in all orientations, Fig. 10.

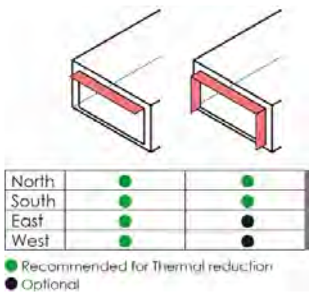

Fig. 9. Proposed fixed shading devices.

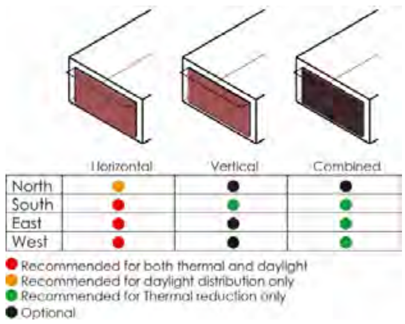

Fig. 10. proposed adjustable fixed shading devices.

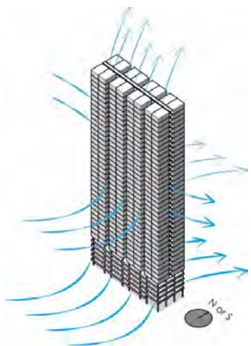

Fig. 11. Example of Proposed building form

Moving away from common monolithic building forms to apartments with three exposed walls was found to greatly increase the potential for cross ventilation, Fig. 11. Moreover, increased exposed surface also gives a greater flexibility for internal layout and openable glazing in kitchens, improving daylighting and the dissipation of indoor heat and odours.

Ventilation strategies are best with large and equal opening areas on both inlet and outlet sides.

Internally, exposed surfaces of high thermal mass were found to help reducing the air temperature in the living areas occupied during the day, while in bedrooms surfaces of low thermal mass were identified to work better, allowing a faster drop of the indoor temperature at night.

As expected, occupancy increased the internal temperature to rise, but the studies showed this to be minimal within the improved model, presumably as a consequence of the proposed ventilation strategy.

The installation of twin wing walls 0.5m deep on the balcony provides enhanced ventilation in real wind conditions and can further improve thermal comfort and its usability.

The optimised model combining all the strategies developed to drop the indoor air temperature showed a reduction on indoor temperature of up to 5.5K (on both the hottest day and night tested periods), indicating that the internal temperature can fall within the target comfort zone for all except the most extreme conditions. Even such exceptional conditions could be rendered acceptable by the use of electric fans, to create additional air movement and reduce the perceived temperature.

Overall, the study demonstrates that high rise apartments can be free-running in a hot and humid climate with simple strategies and a careful design.

Summer performance of certified passive houses In Temperate Maritime Climates

Shane Colclough#, Neil Hewitt, Philip Griffiths

Centre For Sustainable Technologies, Ulster University, Newtownabbey, Co Antrim, BT370QB, UK. # Correspondence email address - s.colclough@ulster.ac.uk

Abstract: The solar resource in Temperate Maritime Climates (TMC) can make a significant contribution to space heating demand given the relatively long space heating season, but is this at the cost of summer overheating? This paper reviews the recorded performance of the certified passive houses with contemporaneous houses built to the minimum building regulations in Northern Ireland. The metrics being gathered at five-minute intervals for the houses are analysed: a) occupancy profile; b) indoor air temperature; c) indoor relative humidity; d) indoor carbon dioxide concentrations; e) outdoor temperature; f) outdoor relative humidity; g) wind speed; h) barometric pressure; i) energy consumption. In addition “soft” data was also gathered on the inhabitants’ perception of indoor air quality, comfort levels, heating costs etc. for both the passive and non-passive houses. *Results & Conclusions.* The key metrics are reported upon. In addition to the higher recorded temperatures of the passive houses, it is also seen that the average carbon dioxide concentrations are more uniform in the passive houses compared with the houses complying with the minimum building regulations. Further investigation is needed, however the possibility of high CO_2 readings due to insufficient ventilation (compared with the forced ventilation system of passive houses) is targeted for further investigation as part of the ongoing monitoring project.

Keywords: Passive House, Passivhaus, overheating, IEQ, IAQ

Introduction

As the prevalence of low-energy and near Zero Energy Buildings (nZEB) (e.g. Anon 2012) increases, focus is turning to the potential for summer overheating (e.g. PHI, 2014, McGill et al 2015, 2017) and means of controlling overheating (e.g. Colclough 2011). This paper presents an assessment of four of the seven NI (Northern Ireland) certified newbuild Passive Houses (PH) (PHI, 2017) in addition to five houses built to comply with the minimum building regulations standard (B Regs). This represents a subset of the dwellings being monitored as part of a study of energy consumption and Indoor Environmental Quality (IEQ) of houses on the island of Ireland (see figure 1).

Installation of monitoring equipment in the living rooms and master bedrooms commenced in May 2016 for the nine Northern Ireland houses depicted in Table 1 and data is presented here for the period to March 2017. An analysis has been carried out to determine the performance of the passive houses (PH) compared with those complying with the minimum building regulations (B Regs) over the summer and winter period and this paper examines the performance of the Northern Ireland houses over the months of June, July and August 2016. While this report provides valuable insight into the performance of the house, the strength of the monitoring exercise being carried out by the Ulster University will be further enhanced by analysing the relative performance of the house compared with the other building regulations houses and passive houses being monitored at the same time, both in the Republic of Ireland and in Northern Ireland. This is the subject of a future paper.

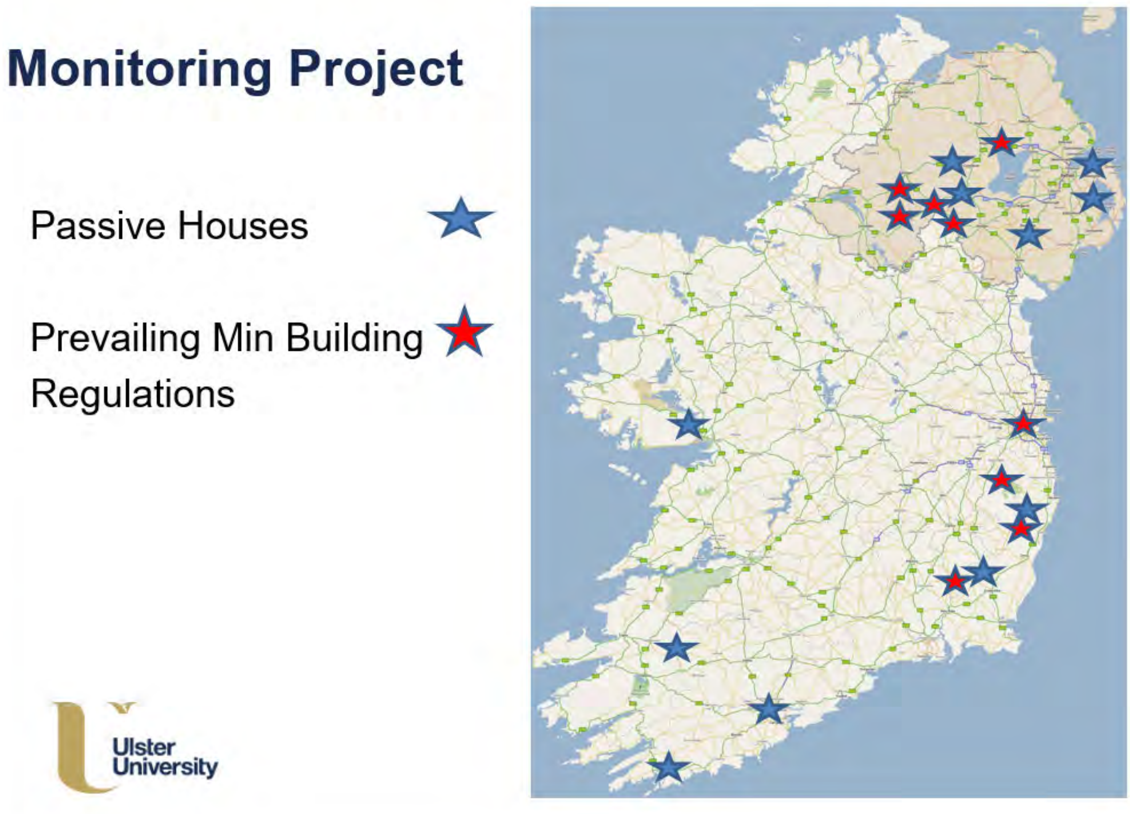

Figure 1 Locations of monitored passive houses and Building Regulations Houses

Table 1 Overview of the Monitored Houses

House	Building Type	Construction	Constructed	Size {m^2}
PH 1	2 storey Hse, Detached	TF	2014	158
PH 2	Bungalow, Detached	TF	2013	220
PH 3	Bungalow, Detached	TF	2011	145
PH 4	Detached	TF	2016	247
PH 5	Under construction	n/a	2017	n/a
BRegs 1	2 storey Hse, Detached	Block	2010	329
BRegs 2	2 story hose, Detached	TF	2014	294
BRegs 3	2 Storey, Detached	Block	2013	230
BRegs 4	2 Storey, Detached	block	2016	210
BRegs 5	2 storey Hse, Detached	Block	2015	246

The following metrics are being gathered at five-minute intervals for the nine houses currently being monitored:

a. occupancy profile

b. indoor air temperature
c. indoor relative humidity
d. indoor carbon dioxide concentrations
e. outdoor temperature
f. outdoor relative humidity
g. wind speed
h. barometric pressure
i. energy consumption

The monitoring unit is a commercially available unit with the following specification:
Temperature (indoor): Ranges from: 0°C to 50°C. Accuracy: ± 0.3°C
Temperature (outdoor): Ranges from: -40°C to 65°C. Accuracy: ± 0.3°C
Humidity (indoor and outdoor): Ranges from: 0 to 100%. Accuracy: ± 3%
CO_2 meter (indoor): Ranges from: 0 to 5000 ppm. Accuracy: ± 50 ppm or ± 5%
Sound meter: Ranges from: 35 dB to 120 dB

Calibration tests have been carried out on the devices and it has been found that some individual units unit did not perform to the stated specification with respect to carbon dioxide concentrations, and also relative humidity. It was found that the RH of a number of the units exhibited an offset (of up to 10%, i.e. instead of reading the correct 70%, the unit records and indicated 80%). For this reason the RH is not discussed in detail in this report. The unit uses an optical CO_2 sensor and automatically re-calibrates at fixed intervals. This calibration is carried out assuming that the minimum CO_2 level reaches 400 ppm. Wide bands for carbon dioxide concentrations have been used to allow for any inaccuracies in CO_2 measurements and follow-on measurements are planned with laboratory grade carbon dioxide sensors. All units have been found to perform within specifications regarding temperature.

Thresholds have been established for the key metrics being monitored and the percentage of time individual metrics exceed the thresholds are considered. Passive Houses are designed to have a uniform set temperature of 20°C throughout. A temperature threshold has therefore been set at 20°C. Thresholds have been defined to reflect the set temperatures in SAP at 21°C for the living room and 18°C for the other parts of the dwelling.

A set temperature of 24°C is required in SAP in the case of air-conditioned buildings, and the final threshold temperature of 25°C reflects the temperature that passive houses are allowed to exceed for no more than 10% of the time.

Results

Despite the small sample size of four passive houses and five building regulations houses, some clear trends are emerging in relation to the interior temperatures experienced in the dwellings. It is noted that summer temperature readings are not available in B Regs 4 and PH 5 and that limited readings are available in PH 5. An analysis has been carried out of the prevailing weather over the monitoring period, and it is noted that the summer of 2016 experienced similar temperatures to 2014 but higher temperatures than 2015 (by 1.1°C on average), but 30% less sunshine than the previous two years.

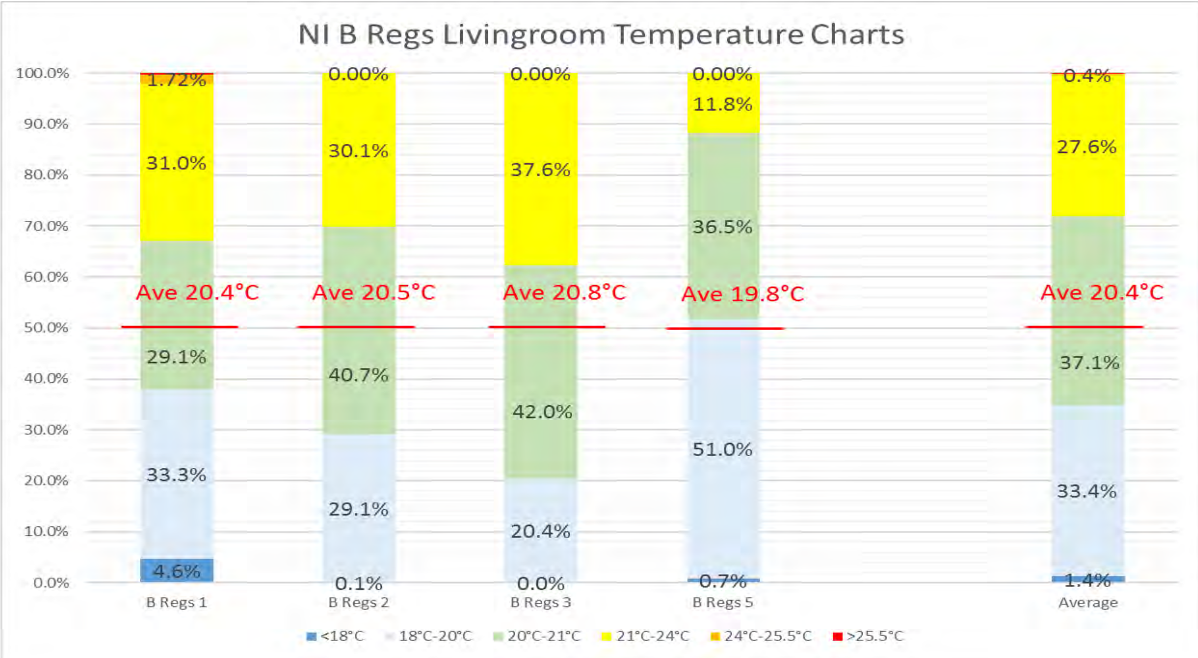

Figure 2 Average building regulations living room temps June, July, August 2016

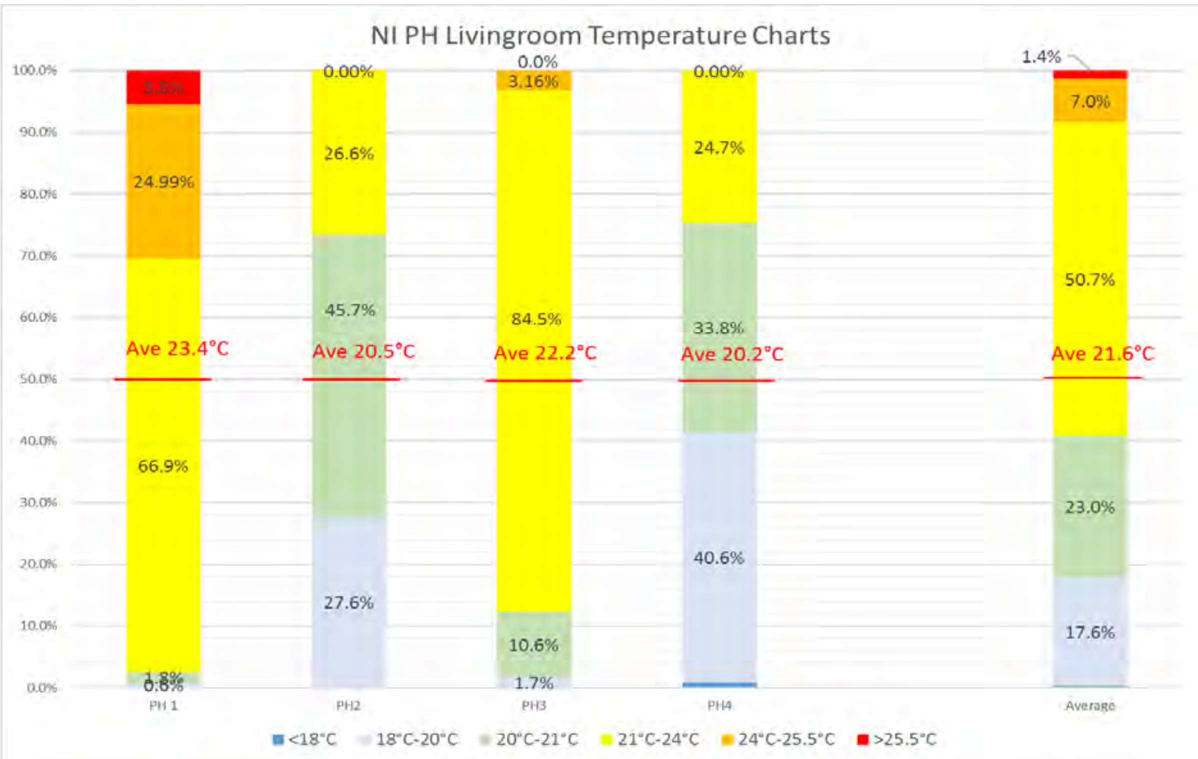

Figure 3 Chart of the NI Passive House living room temps, June July and August 2016

Figures 2, 3, 4 and 5 give the proportion of time that temperatures where experienced in the building regulations and passive houses both individually and as groups over the period broken down into the distinct temperature bands previously defined in addition to the average temperatures.

Living room temperatures

Figures 2 and 3 refer to the living room temperatures. The average temperature in the group of building regulations houses is 20.4°C and that in the Passive House group is 21.6°C. Thus the average summer temperature in the Passive Houses is 1.2°C above that in the buildings complying with the minimum building regulations.

In addition, the living room temperature in the houses complying with the minimum building regulations are at or above the building regulations set temperature of 21°C for 28% of the time, while the average Passive House temperature meets or exceeds the set temperature of 21°C more than twice as frequently at 59% of the time.

Considering the set temperature for passive houses (20°C), the Passive House living rooms on average are seen to meet or exceed this threshold for 82% of the time, while the building regulations houses meet or exceed the temperature threshold for 65% of the time.

Regarding overheating, the average of the building regulations house living room temperatures do not exceed the threshold of 24°C, while the Passive House exceeds the threshold for 8.4% of the time, and exceeds the Passive House threshold of 26°C for 1.4% of the time. While these figures are well within the limit of 26°C for 10% of the year specified by the Passive House Institute the living rooms of the Passive Houses are seen on average to have significantly higher temperatures during the summer period than the houses merely complying with the minimum building regulations.

Considering the individual houses, PH 1 is seen to exhibit the highest temperatures, with temperatures exceeding 25.5°C for 5.5% of the time. A retractable awning was installed over the southerly fenestration in September 2016, to reduce summer overheating.

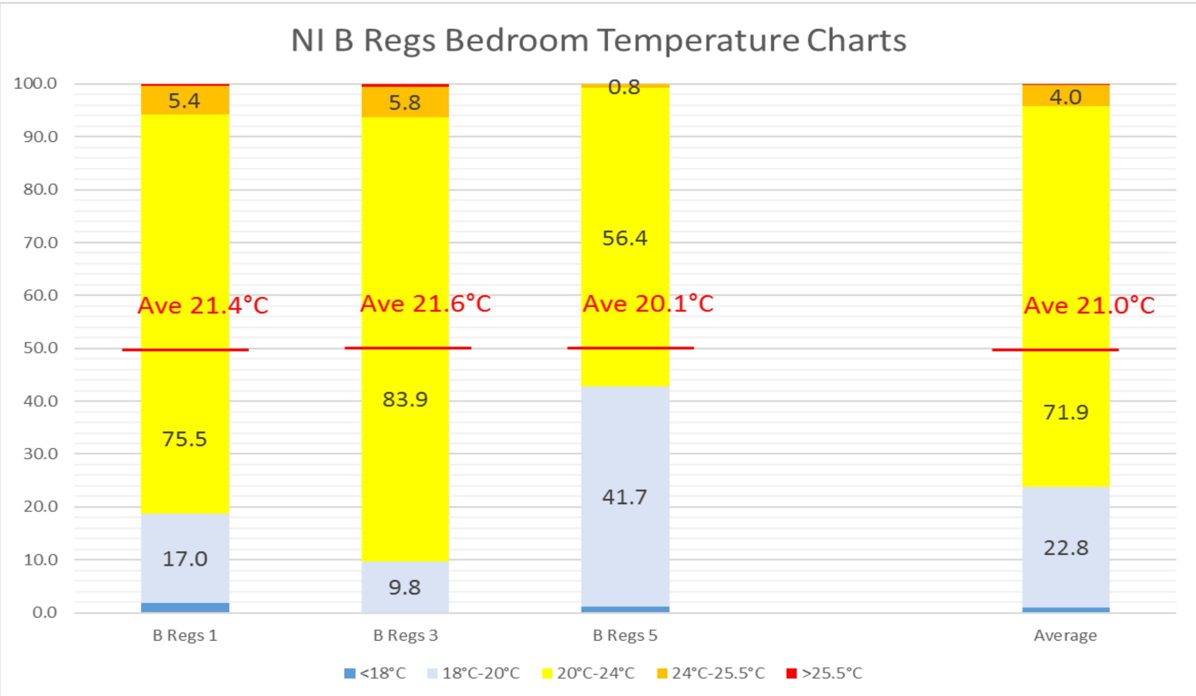

Figure 4 Chart giving the building regulations bedroom temps June, July, August 2016

Bedroom temperatures

Considering figures 4 and 5, it is seen that the trend of higher average temperatures continues in the passive house bedrooms, with the average temperature being 1.5°C higher in the passive houses (22.5°C compared with 21°C). During the summer period the temperature of the bedrooms in the passive houses and houses complying with the minimum building regulations consistently exceed the set temperature of 18°C required by the building regulations. Considering the Passive House standard set temperature of 20°C, the average temperature meets or exceeds this 95% of the time in passive houses and 76% of the time in houses complying with the minimum building regulations.

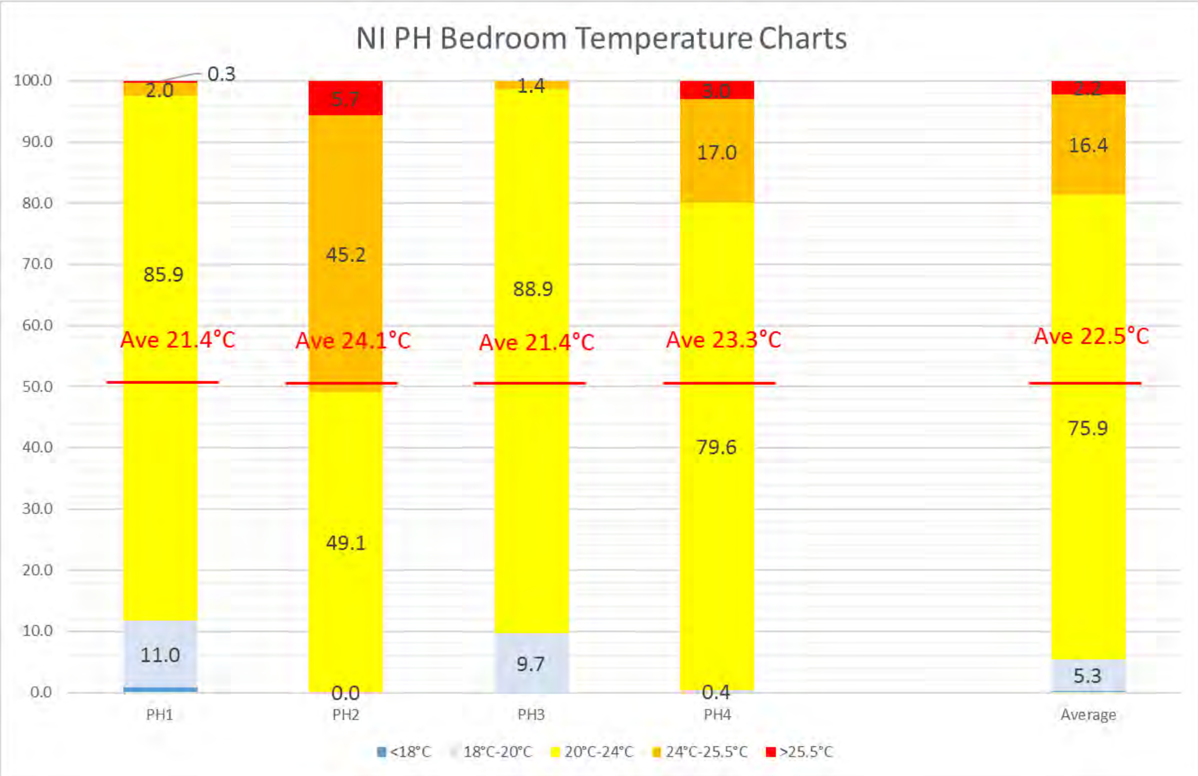

Figure 5 Chart giving the Passive House bedroom temperatures for June, July, August 2016

The temperatures in the Passive House bedrooms exceed the threshold of 24°C 18% of the time, and exceed the threshold of 26°C for 2.2% of the time. This compares with the building regulations bedrooms which exceeding the 24°C threshold only 4% of the time. Some passive houses are thus seen to record considerably higher temperatures than building regulations houses, whilst still operating within the Passive House maximum temperature limit of 26°C. It is noted that B Reg 1 and 2 had higher bedroom temperatures than PH 1 and 3, whilst experiencing slightly higher or similar average temperatures.

PH 2 is seen to exhibit the highest bedroom temperatures. The master bedroom is located on the second floor and opens onto a double height gallery which is directly over the living room. This is seen to contribute significantly to the high temperatures in the bedroom.

Qualitative assessment

In addition to the quantitative assessment reported above, the house owners were interviewed to assess their perception of Indoor Environmental Quality, along with a number of other questions in relation to their use of the property, overall satisfaction with the dwelling, costs and also the general suitability of the passive house standard for more widespread deployment. This information will be presented as part of another paper. Table 2 looks specifically at Indoor Environmental Quality aspect and shows the level of occupant satisfaction based on perceived overheating, stuffiness, dry throat and noise of the mechanical heat recovery and ventilation system, in addition to overall IEQ satisfaction. Scores are rated on a scale of one (best) to 7 (worst).

Table 2 Occupants Satisfaction Levels

House	Overall IEQ Satisfaction	Overheating (Summer)	Stuffy (Winter)	Stuffy (Summer)	Dry Throat?	MVHR Noise
PH 1	1	3	1	3	1	1
PH 2	2	5	1	5	1	1
PH 3	1	2	3	2	1	1
PH 4	2	1	1	2	1	1
B Regs 1	1	2	2	2	1	1
B Regs 2	2	4	2	4	1	n/a

All owners reported some level of lack of satisfaction with high summer temperatures or summer stuffiness. The highest perceived overheating occurred in PH 2, with the owner reporting significant dissatisfaction during the summer with overheating, and a sense of stuffiness. This predominantly related to the night-time bedroom temperatures, which recorded the highest levels of the four passive houses studied, related to the location of the bedroom over the double height living room. In addition, the owner of PH 1 reported summer overheating in relation to bedroom temperatures.

The owner of B Regs 4 also reported significant dissatisfaction with overheating during the summer.

The owner of PH 3 reported more overheating and stuffiness during the winter period with the summer due to issues related to regulating the stove output, and the sometimes large number of visitors. She reported that the temperature was regulated by opening the doors to other rooms.

It is noteworthy that the building regulations house owners also reported summer overheating.

Corbon Dioxide Concentrations

In addition to the findings of higher temperatures in the passive houses, the passive houses were also seen to exhibit more uniform average concentrations of carbon dioxide (619 ppm for the living rooms and 616 ppm for the bedrooms) compared with the houses complying with the minimum building regulations (514 ppm in the living rooms and 820 ppm in the bedroom).

Conclusions

Monitoring has been carried out of four NI passive houses and four “standard” houses (built to the minimum building regulations) over the months of June July and August 2016. Both quantitative and qualitative analysis has been carried out to determine the performance of the two groups of houses.

A key finding is that differences are emerging in terms of the interior temperatures with the group of Passive Houses recording on average a 1.6°C higher temperature in the living rooms and a 1.4°C higher temperature in the bedrooms compared with the building regulations reference houses.

On a quantitative basis neither the houses complying with the minimum building regulations nor the Passive House standard are seen to exhibit significant overheating. The passive houses are seen to experience more frequent breaches of the stipulated Passive House threshold of 26°C. All the passive houses complied with the requirement of not exceeding the 26°C threshold for more than 10% of the time. Despite operating within specifications, the majority of owners of the building regulations houses and passive houses perceived some level of overheating during the summer, and reported difficulty in regulating the temperature by opening the windows given the occasionally high outdoor night-time temperatures.

Abstract: The building sector accounts for a third of the worldwide energy consumption. With the continuous rise in global temperatures, reducing the cooling loads in buildings is one of the main strategies in mitigating climate change in the built environment. Passive energy efficient design in hot climates can lead to a significant reduction in energy use while promoting occupant comfort. This study analysed the performance of external shading devices applied to a typical office building in the Mediterranean climate of Cape Town, South Africa. Evidence from a critical review of global literature informed the development of a base model and seven shading device typologies. Experimental testing aimed to inform best practice by optimizing the internal daylighting, and reducing the energy consumption. Computer based simulations conducted through Revit and DesignBuilder analysed the daylighting levels, annual cooling demand and peak electricity consumption. The results show that the most efficient passive design features for the selected location are the horizontal louvres, inclined double louvered canopy and surrounding shade. As the climate and sun path in Western South Africa are similar to Central Chile and Southern Australia it could be concluded that the findings are applicable for office buildings in these locations.

Keywords: Shading devices, Low energy, Mediterranean climate, Sustainability, Passive cooling design

Introduction

The building sector accounts for 35% of the overall energy consumption worldwide, out of which commercial buildings are responsible for 55% (Hayter et al, 2000). High glazing use in office building façades necessitates control of solar radiation entering rooms (Carbonari et al, 2001). Furthermore, cooling accounts for 24−38% of the total energy consumption in Mediterranean climates (Kamal, 2010) such as Western South Africa. Passive design in hot climates can lead to a significant reduction in energy use while promoting occupant comfort (Roaf, 2009). These factors informed this study's focus on the commercial sector of the built environment, specifically energy efficient cooling strategies for non-domestic buildings, aiming to make the following contributions to the field:

- to evaluate the principles of passive cooling design in the South African context;
- to address a specific gap identified in the local literature;
- to serve as technical guidance for the construction industry;
- to propose further research and recommendations to be undertaken based on current outcomes.

The main research question is to evaluate the optimal design of external shading devices for non−domestic buildings in Mediterranean climates, using a case study office building design in Cape Town, South Africa as the focus of the research methodology. Evidence from a critical review of current literature, combined with practitioner experience in the field, informed the development of a base model and seven typical shading device typologies: horizontal canopy; inclined louvered canopy; vertical fins; surrounding shade; inclined double louvered canopy; and vertical and horizontal louvres. Experimental testing focused on energy use reductions for cooling, heating and lighting, but view performance was also considered. The main hypothesis is that the implementation of passive cooling strategies can provide improved occupant comfort and reduce energy consumption and CO_2 emissions.

Existing literature regarding the design of shading devices highlighted a number of challenges and solutions that have directly informed the research strategy for this study. Carbonari et al (2001) argued that the most efficient shading devices, including glare control, for the climate and sun path of Italy are the horizontal louvres with 45^o angle inclined slats. Li et al (2007) identified the most efficient length of a horizontal canopy is 0.9m. A key challenge identified by Ahsan (2009) is providing effective shading on the eastern and western facades, due to the low incident sun angles falling on these elevations. Ahsan (2009) argues heat gain can be reduced from these facades by minimizing the window−to−wall ratio or by orientating the longer axis of the buildings along the east−west direction. More recently, Mandalaki et al (2014) concluded the most efficient shading devices in the Mediterranean climate are: full−façade Brise−Soleil, the inclined double canopy, the louvered canopy and the surrounding shade.

The scope of the existing research spans over a variety of locations such as Greece (Mandalaki et al, 2014), Malaysia (Ossen et al, 2005), Bangladesh (Ahsan, 2009), Italy (Carbonari et al, 2001) and Korea (Kim and Kim, 2009). Other researchers, such as Ochoa et al (2012) compared multi−objective optimization criteria for reduced energy use and high visual performance. Frontini et al (2012) have analysed the impact of shading devices on mean radiant temperature in office buildings. Although several studies investigate the performance of shading devices in Mediterranean climates, there is a visible gap in the knowledge of local literature that focuses on the specific sun path of South Africa.

Passive design considerations affecting the study boundaries

Energy efficiency can be achieved either through passive design, such as orientation of the building, choice of materials or use of shading devices, or through active strategies, such as choice of HVAC systems, solar water heaters or rain harvesting systems. Passive design takes advantage of the local climate for maintaining a comfortable indoor temperature and reducing the need for auxiliary heating or cooling (Bellia et al, 2013). Indirect solar gain and thermal mass can contribute towards low- and zero-energy design (Martinez et al, 2012), but these factors have been excluded from the scope of experimental research for this study as typical office buildings in South Africa have a high percentage of glazing. Similarly, whilst high performance glazing can limit solar gain (Frontini et al, 2012), they are not the focus of the current study because high investment costs make these types of glazing configurations atypical. Furthermore the study focuses on fixed external shading devices such as canopies, fins or louvres that hinder the direct solar radiation from reaching the internal space. They are more efficient than internal shading devices such as blinds or curtains which dissipate the heat to the internal air adjacent to the glazing (Datta, 2001).

According to Rosencrantz (2005) both the cooling demand and the annual cooling load could be reduced by half by using external solar shading instead of internal shading devices, leading to 33% reduction in cooling energy use.

Although fixed shading systems have been shown to reduce the cooling load demand during summer, they could also be a source of increased energy use due to possible increased lighting energy and heating demand during the winter months (Mandalaki et al, 2014). Therefore it is necessary to evaluate the heating load reduction and interior luminance with the cooling load reduction. Daylight availability is important not just for physiological and psychological causes, but also for energy saving achieved through an optimal integration between natural and artificial light (Bellia et al, 2013). Research shows that particularly in commercial dwellings, with a high occupancy rate during daytime hours, daylight positively affects workers' satisfaction, performance and productivity (Nazzal, 2005).

South African context

In order to develop passive design strategies for this study it was important to identify the climate and sun path for the investigated location, the energy consumption patterns and sources, and the national standards and policies for the building sector in South Africa. This study looks in particular at the Western Cape Province of South Africa and especially Cape Town – located on the 33.9249°S latitude and 18.4241°E longitude. This coastal location is characterised by Mediterranean climate, with wet winters and hot dry summers.

Sustainable buildings are a necessary construction strategy in South Africa due to limited energy sources and increasing energy demand. South Africa's energy consumption accounts for more than 40% of Africa's total CO_2 emission and almost 2% of global emissions due the heavy reliance on coal for energy production. South Africa, rated as the 15th highest country globally for carbon emissions by the International Energy Agency (2010), has targeted reducing CO_2 emissions to 34% below 2010 levels by 2020 and 42% by 2025. The proportion of dwellings with access to electricity doubled between 1994 and 2003 (Winkler, 2007). Energy supply became too limited in 2011 to satisfy the increased number of residents with access to electricity and the increased life style of the developing country. Major aims for energy efficient buildings in South Africa are therefore both energy demand reduction and decreased CO_2 emissions, which can be coterminous, but not necessarily so (Parkin et al, 2016).

Methodology

In order to identify the optimal shading devices design, the following quantitative and qualitative data gathering strategies were undertaken: 3d modelling of shading devices (using Autodesk Revit Architecture Version 2016, in which typical building materials were assigned) and software simulations (using DesignBuilder, Version 4.7.0.022, in which relevant building and occupant variables were assigned and external shading devices simulated). These methodologies were used due to the integrated capabilities of software engines to perform complex analysis, including energy usage for cooling, heating and lighting, daylighting performance, system loads, temperature distribution and location specific weather data. In contrast to monitored building measurements, software simulations offer the ability to test and compare various shading devices under the same conditions (Maile et al, 2007). DesignBuilder uses Radiance backward ray tracer in order to calculate annual daylight availability – proven more efficient and reliable than split−flux methods used by other competitive programs such as Autodesk Ecotect (Mandalaki et al, 2014). DesignBuilder is also validated under the comparative Standard Method of Test for the Evaluation of Building Energy Analysis Computer Programs (ASHRAE, 2005).

Building variables

The modelled building was based on the findings of comparative analysis of typical office building typologies in South Africa. Data collection took into account the top floor of such a typical office building, simplifying the plan layout to an open office area and a central closed core that would include all the circulation components (staircase, elevators etc.) and utilities (plant room, ablutions etc.), as shown in Figure 1 below. All building materials complied with South African National Standard (SANS) 204 for the Western Cape zone.

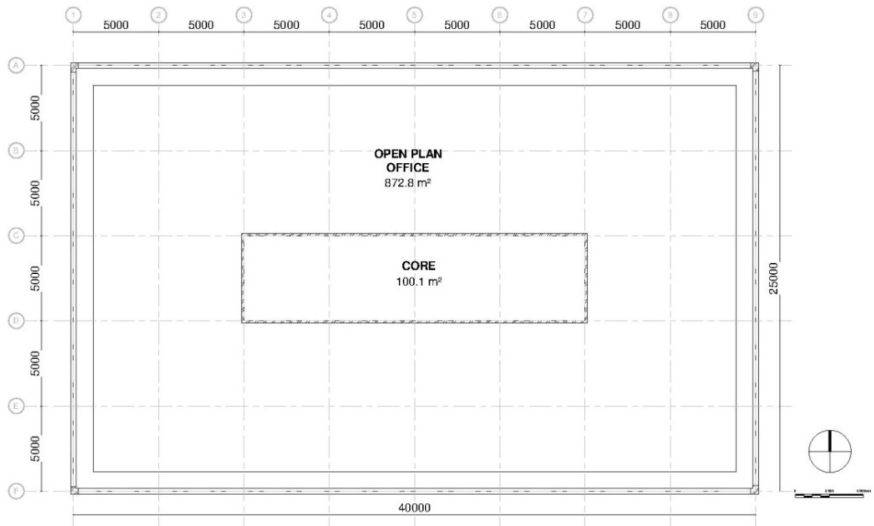

Figure 1. Typical simplified office building floor plan

The 1000m^2 footprint plan (40mx25m) was orientated along the east–west axis, as proposed by SANS 10400 XA, with a floor to ceiling height of 4m, external brick walls, with 2.5m high surrounding curtains walls (cill height at 1m), reinforced concrete surface bed/suspended slab, and a reinforced concrete flat roof. The floor is assumed as adiabatic, being situated above a zone with similar indoor thermal conditions. A wide variety of glazing materials and technologies are used in the industry, but 6mm single pane, clear glazing with a 70% visual transmittance and 10% aluminium frame ratio was chosen as a worst-case scenario permissible under SANS204. The software simulations were analysed comparatively against a base case with no shading, and all scenarios were modelled using the same building materials, so the choice of glazing will have no impact on the performance of the shading devices and the reduction in the energy consumption. All shading devices were modelled as aluminium – a wide spread practice due to the material's high reflectance of light and reduction of unwanted heat gain. Although heat transmittance of the materials is relevant for the annual energy consumption calculation, it will not affect a comparative study with identical conditions.

Occupancy variables and boundary conditions

Given the aim of the research was a comparative analysis of various shading devices, all other simulation variables were kept constant throughout all scenarios. Occupancy data and boundary conditions were very important factors for the reliability of the simulations and were therefore based on real buildings or building standards recommended by SANS. The metabolic rate, density of occupancy, efficiency of HVAC systems and the mechanical ventilation were in accordance with the national standards. The ventilation is completely mechanical, and the fuel used entirely electricity from the grid, as considered typical for an office building in the study context.

Scenarios

The modelled shading devices (shown in Figure 2) were based on an extensive literature review of passive cooling design. The findings from Kim and Kim (2009) have been used for the scenario 2 (horizontal canopy), scenario 3 (inclined louvered canopy) and scenario 6 (inclined double louvered canopy) to inform the optimal depth and angle of the overhangs. Due to a lack of academic literature on vertical fins (scenario 4), surrounding shade (scenario 5), and vertical (scenario 7) and horizontal louvre systems (scenario 8), these shading systems have been based on current architectural practice, comprising examples of external shading devices from a sample of South African commercial buildings.

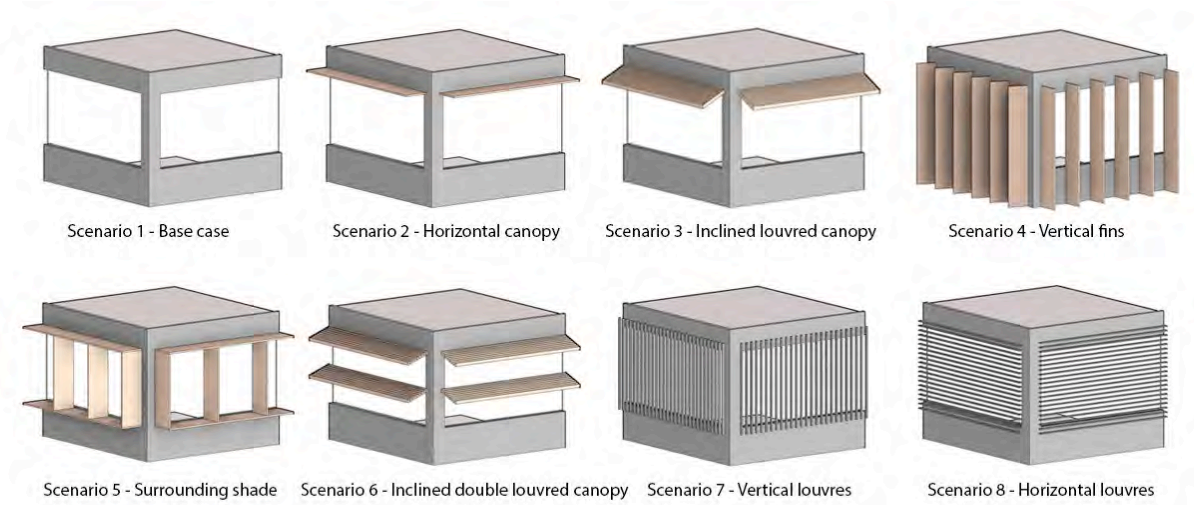

Figure 2. The 8 modelled and simulated scenarios

Simulations started with cooling design calculations undertaken for all scenarios in order to determine the required cooling load needs. Secondly, simulations were tested across an entire year, compiling both annual as well as monthly results, in order to collect the following data for all scenarios: internal gains (monthly and annual), system loads (annual), fuel breakdown (monthly and annual), thermal comfort (monthly) and temperature distribution (annual). Furthermore, daylighting simulation was particularly relevant for the current study as it shows the actual illuminance (lux) for each one of the scenarios. The current study does not take into account the glare which will account for the occupant's comfort ratio. Lastly, the view performance has been assessed by analysing the elevations of the façade from a visual permeability point of view.

Simulation results

The following Figure 3 below presents a summary of the findings, comparing visual permeability, radiant temperature (as a proxy for thermal comfort), daylighting (illuminance) and energy performance. The results show that the annual cooling demand is 74 293kWh for base study, 52 268kWh (30% reduction) for horizontal canopy, 47 973kWh (35% reduction) for inclined louvered canopy, 49 319kWh (33% reduction) for vertical fins, 42

500kWh (42% reduction) for surrounding shade, 36 136kWh (51% reduction) for inclined louvered double canopy, 38 098kWh (48% reduction) for vertical louvres and 39 055kWh (47% reduction) for horizontal louvres. By analysing the values in the graphs below, it can be seen that the latter three shading devices provide the highest energy reduction for cooling.

Shading device	Visual permea-bility	Radiant temperature (°C)	Daylighting (lux)	Annual cooling dem-and (kWh)	Peak elect-ricity cons-umption (kWh)	Solar gains exterior windows (kWh)
1. No shading	100%	20,25-27,89	218-4372	74293	16 000	185 080
2.Horizontal canopy	100%	19,71-26,50	155-2392	52268 (30% reducti-on)	13900 (13% redu-ction)	128 040 (30% reduc-tion)
3. Inclined louvred canopy	85%	19,36-26,18	136-2418	47973 (35% reduction)	13750 (14% redu-ction)	111 620 (39% reduc-tion)
4. Vertical fins	95%	19,32-26,91	90-1892	49319 (33% reduction)	14000 (12% redu-ction)	105 890 (42% reduc-tion)
5.Surrounding shade	97%	18,96-25,97	82-1534	42500 (42% reduction)	13100 (18% redu-ction)	85 057 (54% reduc-tion)
6. Inclined double canopy	70%	18,28-25,31	89-803	36136 (51% reduction)	12600 (21% redu-ction)	65 834 (64% redu-ction)
7. Vertical louvres	55%	19,50-26,20	6-314	38098 (48% reduction)	12 500 (21% redu-ction)	48 079 (74% redu-ction)
8.Horizontal louvres	60%	18,85-25,64	92-731	39055 (47% reduction)	12500 (21% redu-ction)	74 539 (60% redu-ction)

Figure 3. Summary of findings for the 8 simulated scenarios

The lowest electricity consumption is in June for the base case but in September for the rest of the buildings with shading devices. The peak electricity demand is in January, with a value of 16 000kWh for the base case, 13 900kWh (13% reduction) for the horizontal canopy, 13 750kWh (14% reduction) for the inclined louvered canopy, 14 000kWh (12% reduction) for the vertical fins, 13 100kWh (18% reduction) for the surrounding shade, 12 600kWh (21% reduction) for the inclined louvered double canopy, 12 500kWh (21% reduction) for the vertical louvres and 12 500kWh (21% reduction) for the horizontal louvres. The best performing shading devices for peak electricity consumption are the same as those for the annual overview of the energy demand.

Regarding the view performance the horizontal canopy provides significantly lower daylighting levels of 155lux to 2392lux with a 4m deep perimeter of 800lux−1700lux. This is also consequently high for a workplace. Therefore this shading device might need to be coupled with internal blinds or venetian blinds that can be manually or automatically adjusted according to the solar or heat gain. The third simulated scenario of inclined louvered canopy has similar daylighting levels of 136lux−2418lux. Furthermore tilting the slats by 20o would provide an equal distribution of light to the rear space through the reflection of the sunrays and bouncing on the white surface of a ceiling. The vertical fins provide a further decrease of light levels to 90lux−1892lux, with a perimeter of 600lux−1400lux. The surrounding shade provides similar daylighting levels of 82lux−1534lux, with a shallower perimeter zone of approx. 3m. Both the horizontal louvres as well as the inclined double canopy provide daylighting of approx. 90lux−750lux, with a perimeter of 300lux to 600lux, which is almost ideal for a workspace. The overlit zones are shown as spots, which could be individually analysed and corrected. The internal space around the utilities core provides a lux of under 250lux, which could be increased by the use of additional lighting or the design of the circulation around these zones. The vertical louvres provide the lowest but most uniform daylighting levels of 6lux to 314lux, which would require a very intensive use of artificial lighting.

The study aimed to gain an initial understanding of how a selection of external shading devices affects energy consumption and occupant comfort, which involved an overview of a range of typologies and characteristics rather than an in depth optimisation study. The software selected for the simulations had limitations that meant it was not possible to quantitatively test certain aspects of the scenarios' performance, such as effects of glare from the external shading devices on the occupant comfort and perceived radiant temperature across the floor plans. Further limitations of the study comprised not investigating the effects of building materials in detail, the depth of the shading devices and angles of the louvres on each of the particular orientations. Whether comparison measurements such as daylighting, fabric gains and radiant temperatures reflect the actual occupants' comfort in the current context is an ongoing research question. The model equations for simple geometrical configurations of shading devices have a degree of inaccuracy compared to real market products. Therefore, for more complicated geometrical models and orientation types (such as northwest facing facades) other types of research are required. The paper provides fresh empirical understanding of a sample of shading typologies typically used in practice in the study context, and hence passive cooling strategies, but it is acknowledged that each individual architectural project will have particular demands and solutions based on their specific context and occupants' needs.

Conclusion

The present research has shown to support the identified hypothesis that by implementing passive cooling design strategies it is possible to reduce the cooling demand of the typical office buildings studied in Cape Town, South Africa and thus reduce the total energy consumption and CO_2 emissions and enhance the internal comfort that would benefit the health, well−being and productivity of the occupants. The primary aims that were achieved are: identifying principles of passive cooling techniques, providing an overview of South African regulations and future targets, providing a technical guidance for the construction industry, filling in a gap in the local academic literature, proposing further research to be undertaken based on the current findings.

As the solar path is dependent on the latitude of the countries, when designing a shading device, it is necessary to refer to a specific location (Corrado et al, 2004). The Mediterranean climate can be found in: California, Central Chile, Mediterranean Basin, Western Cape of South Africa and Western and South Australia. Most of the countries in the specific climate zone have a wide range of sun angles, except Central Chile, Western South Africa and Southern Australia. The implication of this finding is the applicability of the current research not only for Western South Africa but also for Central Chile and Southern Australia. The next emerging question seeks to overcome the barriers of implementing the design features in practice. It is relevant at this point to have an overview at the triggers and trends in the sustainable building sector. As perceived high initial costs is one of the biggest hindrance to the adoption of energy efficient features (Dodge Data and Analytics, 2016), it should be understood that both the architects and consultants, as well as the developers, owners and tenants, play important roles in achieving sustainable buildings.

Design to Thrive

Validation of Wladimiro Acosta´s Helios System

Florencia Collo[1] and Simos Yannas[1]

[1] Architectural Association, School of Architecture, London, United Kingdom

Abstract: Wladimiro Acosta s architectural practice shows him to have been a pioneer of passive design back in 1930, but his work is little known and has remained unstudied by the environmental research community. His approach to designing with climate is described in his book "Dwelling and the City" published in 1936. It introduces Acosta's "Helios System", a design method for architectural solar control that precedes Olgyay's by some 20 years. It allows designers to size vertical and horizontal building elements providing solar protection in combination with design strategies for window sizing and operability. The paper presents a critical review of Acosta's system using current computational tools to assess his solar control devices for two buildings he designed in Buenos Aires. Computer models were assessed by hourly simulations of incident solar radiation on windows and sun penetration indoors. The results are compared to Acosta's original criteria and designs. The analysis shows that the principles established by Acosta are still valid for Buenos Aires. His climatic assessment was accurate and informative. The Helios System is well-founded and compares with the tools we have today. On close examination Acosta's designs are well informed.

Keywords: Wladimiro Acosta, Helios System, Solar Control, Environmental pioneer

Introduction

Wladimiro Acosta was a pioneer in the use of meteorological science for architectural purposes. He was a Russian architect who emigrated to Argentina in 1920's. At his arrival, modern architecture was starting to spread in Latin America. He valued the functionality and scientific approach of modernity, but was critical of replicating it without local adequacy. Instead, he analysed vernacular architecture of Buenos Aires –old colonial buildings- as examples of efficiency and comfort. He considered that to do a proper design he needed to "study the physical and human geography of the place, its characteristics, its technology, its construction techniques, the indigenous ways of living, and find an architecture that belongs to the place." He did research on solar studies, Buenos Aires climate, and the incipient comfort theories which he used to inform his practice. Acosta's approach to designing with climate is described in his book "Dwelling and the City" (1936). It introduces his "Helios System", a design method for architectural solar control that precedes Victor and Aladar Olgyays' "Solar Control and Shading Devices" by some 20 years.

The climate

Buenos Aires 's climate, according to the Koppen-Geiger classification is temperate or sub-tropical, moist all seasons (average ranges from 43 to 91%) with mild winters, and hot summers. The annual average temperature is of 17.6^{o}C, with predominant winds coming from N, NE, and E. Over the warm period, cloud coverage is low, whereas in the cold period days are mostly cloudy. Rainfall is fairly distributed along the year with a mean possibility of 30%.

Methodology

Both Acosta's theory and application will be reviewed in this paper. His principles will be offset by contemporary authors, whereas his application will be tested through simulations comparing his intentions with actual performance. Solar radiation, shadow masks, and shadow studies were conducted using Ladybug for Grasshopper.

Fundamentals of the Helios System: the scientific approach

Climate and comfort research

Acosta used historical weather data supplied by the Direction of Meteorology. In his essay Urban Climate (Acosta, 1936), he details the concept of the Urban Heat Island in Buenos Aires. His findings were supported by studies performed by Goldmerstein and Stodieck (Acosta, 1936), with similar concepts as the ones explained by Gartland in Heat Islands (Gartland, 2008). This phenomenon was confirmed locally by Figuerola-Mazzeo only in 1997. Also, Acosta points out the necessity to account for trees and green spaces inside the city to mitigate UHI, later confirmed by the LA studies of Akbari (2001). He based his design consideration on his notion of thermal comfort which included air and radiant temperature, humidity and air movement, introducing a topic that Fanger developed only 34 year later (Fanger, 1970). Also, he was well aware of the notion of comfort band and the scarcity of means to quantify it there were at that time. He followed the state-of-the-art of the studies performed by several scientists of the epoch (Acosta).

Acosta´s thorough studies of climate, its influence on the city and architecture, and consequently on human comfort prove that his vision of the topic was not only accurate but also well ahead of his time as it compares to the contemporary approach of environmental design.

Solar studies

Acosta acknowledges the sun as the main source of energy, and solar studies as a starting point to initiate a building design. With the geographical positioning of Buenos Aires (34° South), he derived the most relevant solar angles that would inform his architecture (Figure 1). Also, he tempted to create a way to represent them in 2d, preceding Hand's charts (1948) mentioned by Olgyay by some 16 years.

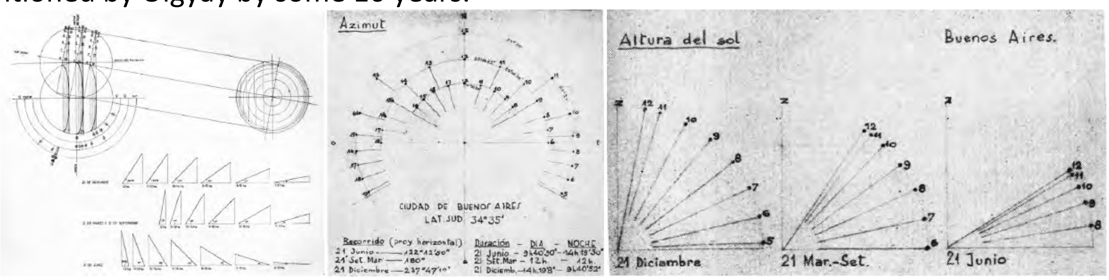

Figure 1. Solar angles' studies (source: La Arquitectura Helios, Acosta)

For Acosta knowing accurately the path of the sun was essential to deciding on the orientation of a building. He advanced many effects of the contemporary building physics such as solar radiation, radiant temperature, and heat transfer. He evaluates solar contribution for the climate of Buenos Aires as "detrimental during summer, since it adds to the hot atmosphere, and beneficial during winter, because it can compensate the cold from the exterior", demonstrating a perfect understanding of the physical implications. Recognising the importance of solar control, and knowing the right angles at a set time of the year, Acosta investigated several systems of regulation depicted in Figure 2a, before reaching the optimal which he called the Helios System (Figure 2b). Also, he used solar angles to test his designs (Figure 2c) and show the operation of the system, preceding Olgyay's "Solar Control & Shading Devices" by some 30 years. Acosta understood the relevance of solar control, studied it scientifically and made it the leitmotif of his architectural practice.

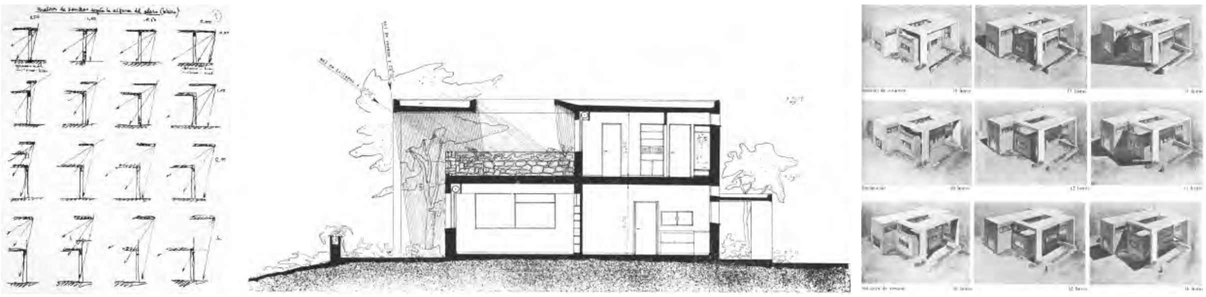

Figure 2. Solar studies on architecture (source: Vivienda y Clima, 1936)

The scientific approach to design is completed with the post occupancies studies he did, taking photographs of the buildings after completion to confirm his theory, verify sun angles and building use at different times of the day and year (Figure 5). He used these images as a way of explaining his work.

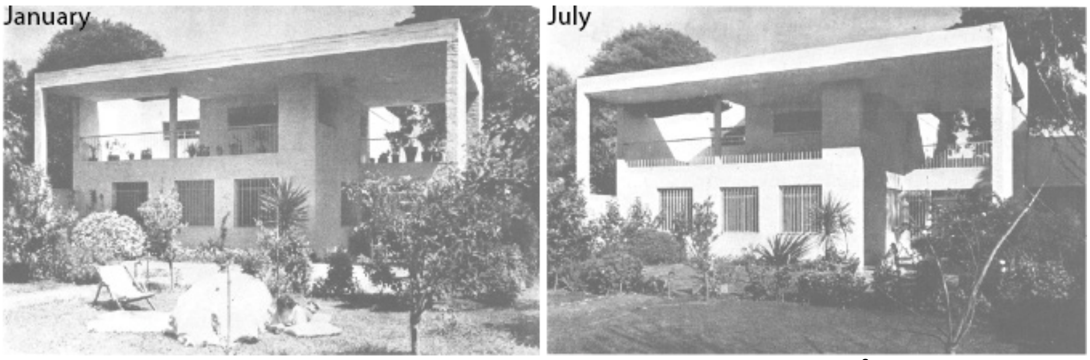

Figure 3. Documentation of built work (source: Nuestra Arquitectura n° 202, 1946)

Helios System

The main points of the system are summarised in Figure 4.

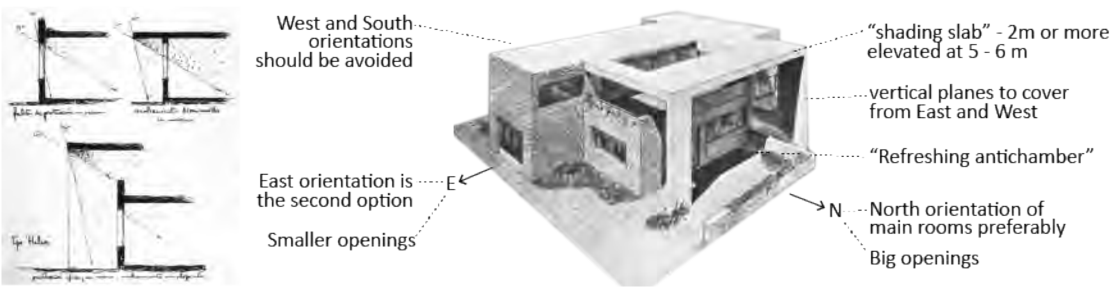

Figure 4. Helios System (source: Nuestra Arquitectura n°168)

The starting point is the orientation of the building for which the decision is subject to solar access, breeze capture, and moisture regulation. He recognises North as the most advantageous orientation for its solar properties, and the predominance of NE winds in Buenos Aires. Following, he marks a difference between East and West. East receives breeze and morning sun, which he considers "excellent in winter and bearable in summer". However, West orientation should be avoided as it "receives afternoon sun when the atmosphere is already hot" (Acosta, 1936). Acosta realises that although the amount of incident radiation is even, the earlier exposure weighs for East. Regarding moisture, he mentions North orientation is still the most advantageous because high levels of humidity can be dried by the sun.

The fixed shading devices, which he calls “shading slab” are the most recognisable feature of the system. The best solution is to protect both walls and windows already north oriented with a “combination of large projecting slabs of 2m or more, elevated at a double height of 4,50 to 6m, and vertical protections N-S oriented”. This creates a “refreshing antechamber”: a transitional space used as protected entrance, shading device and as an element for architectural composition. A shading mask was performed (Figure 4b) overlapped with the overheated period, considered when the monthly mean temperature is higher than the lower comfort limit (Szokolay, 1996). If the room is facing due north, the system entirely covers the overheated period, and lets the sun in the entire winter. However, if the facade starts to deviate (Figure 4c), the overhang lets the sun in near midday and covers either early in the morning or late in the afternoon during winter. For the system to work, the maximum acceptable deviation from due north is 20°.

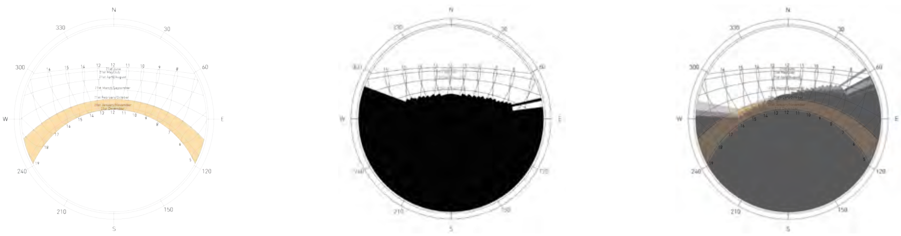

Figure 5. Helios System shading masks

With reference to the openings, Acosta points out the necessity of adjusting the size according to orientation for the purpose of solar control, maximising openings to the north and minimising them to the south and west. Also, he acknowledges that different shapes and positions can modify daylight distribution, and points out that the higher the window, the further the light enters the room. Finally, suggests that all the windows should have an operable upper part for ventilation purposes.

With regards to adapting to a denser urban situation, where orientation is conditioned by narrow plots, Acosta states that solutions are reduced beforehand, and that the architect can only “remedy the adverse circumstances”. Therefore, the system is intended to relatively open areas where choice can be made, and does not specify how to deal with more unfavourable conditions.

Acosta put the well-being of the users at the centre of his design procedure, considering all the aspects to establish a design methodology for Buenos Aires. His theory compares with the contemporary approach of environmental design.

System’s application: 2 case studies

The design and direct application of the system will be reviewed in this section in two case studies: a detached house, and a high-rise building. Solar control will be assessed by the system’s capacity to limit solar loads and to protect against direct irradiation (Kuhn, 2000).

Case study 1: Helios House in Villa del Parque

This is a detached house on a large plot with very few constraints to design with. The proposal is fully designed according to environmental principles.

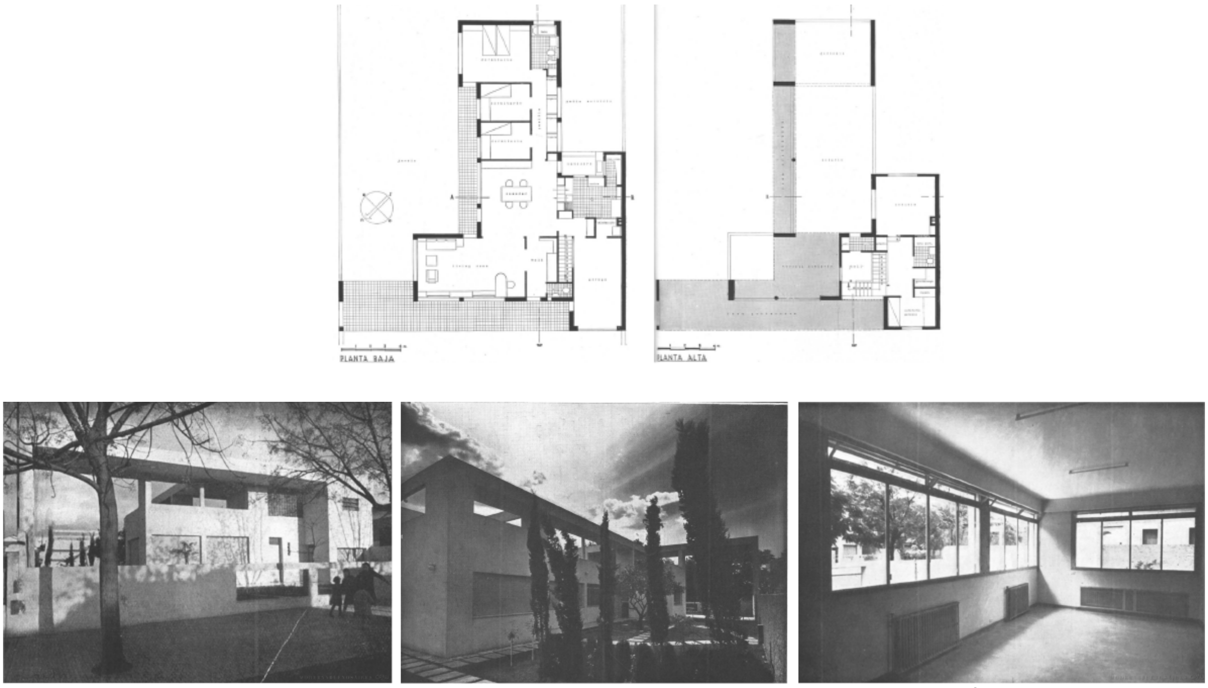

Figure 6. Helios House in Villa del Parque (source: Nuestra Arquitectura n°122)

The overall layout is clearly designed to optimise interior comfort. The main functions are located on the ground floor, where temperature is more stable and the system of overhangs is intended to work, leaving service functions -atelier, service room, gymnasium- on the top floor (Figure 6). Bedrooms, dining room and living room are NE oriented, which Acosta considered optimal, with big windows overlooking the garden. Special attention is given to the solar control of the windows, as the main feature of the Helios System. Overhangs –"shading slab"- are a fixed component, dimensioned to guarantee protection and allowance of the sun when needed. Also, there is a range of adaptive opportunities provided: night shutters, interior curtains, and an operable upper part for ventilation. Kitchen, garage, toilets and storage are SW oriented, with small unprotected windows, only intended for daylight and ventilation purposes with their corresponding mechanisms. However, the living room is facing both NE and NW, with windows on both sides.

summer solstice
equinox
winter solstice

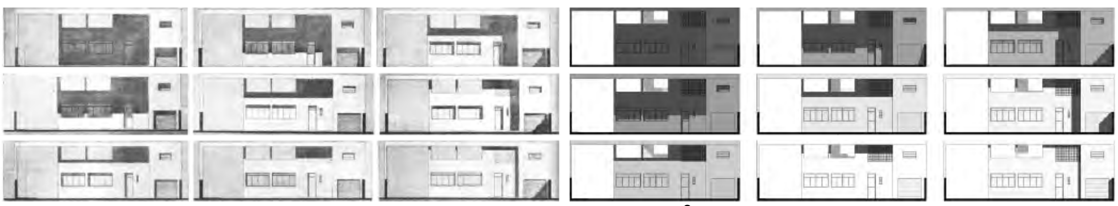

Figure 7. Shadow studies by Acosta (source: Nuestra Arquitectura n°122) and contemporary simulations

Figure 8. Pictures by Acosta of sun movement in 1939 (source: Nuestra Arquitectura n°122)

Acosta performed shadow studies as a design tool (Figure 7a) and as a post occupancy study. Both the simulations (Figure 7b) and the pictures he took prove that he could exactly predict the position of the sun at a set hour and design with this input in order to regulate the indoor thermal environment. Even if the size of the overhangs varies for the NE and NW orientations, they remain insufficient to serve the front facade. The architect foresaw this deficiency and offset it with tree shadow (Figure 8).

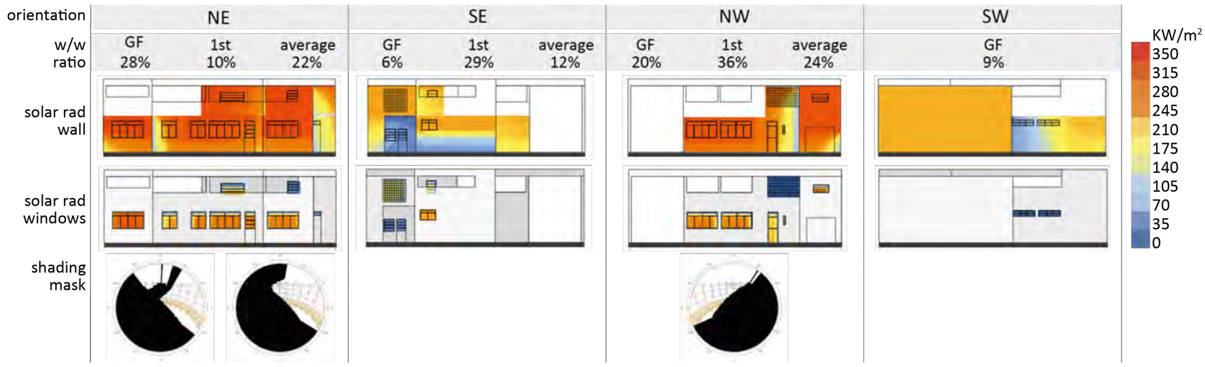

Figure 9. Validation of the solar control of the Helios House in Villa del Parque

As predicted in the previous section, the deviation from due north is greater than 20%, and the shading device leaves an excessive period of overheated hours unprotected. The front facade -NW- lets the sun in all the afternoon during the whole year. Regarding the solar load, results confirm that all the facades remain exposed and the shading system does not reduce significantly the quantity of solar radiation hitting the windows -from 320 to 280 KWh/m^2 , as an average- .

The disposition of the rooms in plan and section, size of openings, adaptive opportunities, and shading are planned in line with solar principles, which is remarkably advanced for the time. Nevertheless, the system of overhangs is applied here as if the orientation was due north, causing to reduce the performance. Acosta fully understood the fundamentals but did not adapt them properly for this orientation.

Case study 2: Rent House in Palermo Chico

This rent house was the only high rise building Acosta completed (1943). The plot was surrounded by large parks that have remained until today, with high potential for views. The typical plan is asymmetrical, T shaped, covering less than 2/3 of the plot.

The entire design optimises conditions for the comfort of the users. The main rooms -living and bedrooms- are located facing NE with very big windows (72% w/w) and very large balconies (2.2m). Maximum adaptive opportunities are provided, having guaranteed the performance with the use of the fixed balcony – “shading slab”-. Rooms are naturally ventilated through sliding panels and an operable upper part in all the openings. Bedrooms are provided with night shutters, and living rooms with a system of operable venetian blinds. Acosta took care of every mean for the users to regulate their thermal environment. He made such an emphasis on these devices that he showed special detailed pictures of them in publications (Figure 10).

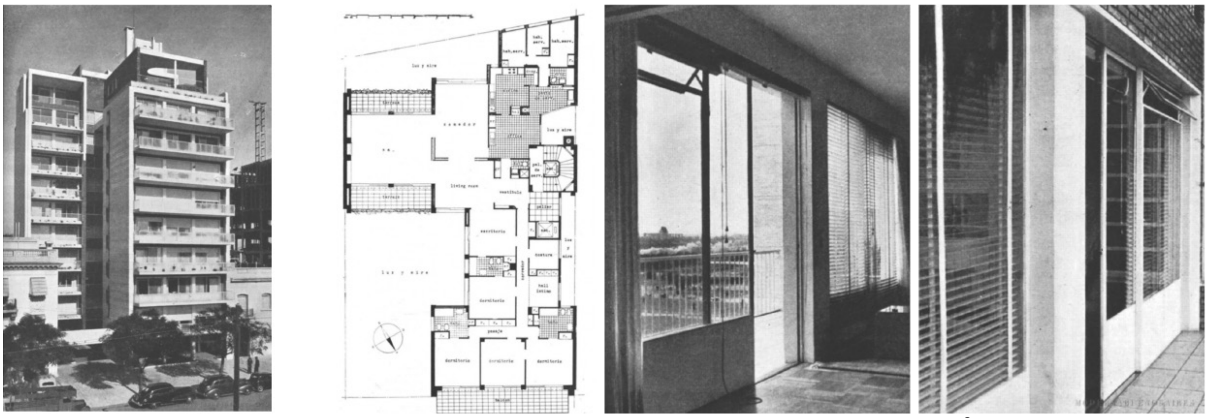

Figure 10. Rent house in Palermo Chico (source: Nuestra Arquitectura n°168)

Secondary rooms are facing SE and located in the centre, protected through the rest of the rooms. All the service functions of the dwelling are located facing SW and NW and sheltering the main rooms from the afternoon sun.

Acosta mentions that if the neighbour construction is built on the whole party wall, it would be a “hygienic and economic catastrophe since the air-and-light yards would become holes, and the rooms would not have any sun nor light”.

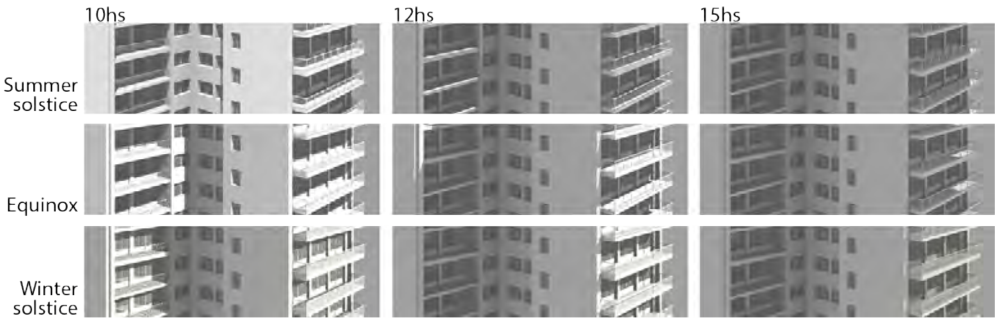

Figure 11. Shadow studies

Shadow studies (Figure 11) prove that the size of the balcony is perfectly calibrated. During the warm period, the sun barely reaches the balcony at all times and spares the window completely, preventing the interior from overheating. During the cold period, the sun reaches both the balcony and the interior, acting as a source of heat gain. At the equinox, the run rays reach the balcony, but not the glazing area, preventing the interior from excessive gains, but creating an enjoyable outdoor space. Results from the solar load analysis (Figure 12) confirm the adequacy of the overhangs for its significant contribution to reducing the amount of solar radiation: from 280 to 80 KWh/m^2. It is to be noted that SW orientation has larger windows than expected -56% w/w-, to enable views to the park.

Figure 12. Solar control assessment

Discussion

Although Acosta's studies of the vernacular architecture of Buenos Aires are highly relevant to learn from its considerations, his most meaningful contribution was to approach climate as a scientific tool that could inform his designs. He developed his theory in the 30's, which is still factual today. All his meteorological studies are useful, and briefly explained to reach a wide audience. The solar studies he carried out are also valid today. The principles of the Helios System for Buenos Aires are accurate and suited as guidelines. Furthermore, the identification of a system of shading devices as the key element design in the mentioned climate is instrumental as a starting point. Both case studies confirm that the application of the system was precise, and encompassing all the aspects of environmental design as we understand it nowadays. However, Acosta utilised the scheme that was intended for due North in rotated angles, as for the Helios House in Villa del Parque, which weakened the performance of the entire system. Comparing the two cases, the high-rise building shows a better performance than the detached house due to a lower deviation angle from due North. The guidelines Acosta provides are most relevant when choice can be made, but fails to explain how to cope with other situations.

Conclusion

Wladimiro Acosta was a pioneer in addressing environmental design scientifically, as he understood all the topics we cover today through the latest scientific research of his time. It is very likely that he was the first to use meteorological science as a mean to inform architecture. The Helios System is well-founded and seems to be a reasonable starting point to design in Buenos Aires, highlighting solar control with overhangs. His suggestions may be of a reduced application in today's urban context, though his thorough studies and principles are still solid and will remain a valid reference for Argentinian architects.

The 6*Zs* Refugee Shelter

Marwa Dabaieh[1]

[1] Department of Urban studies, Malmö University, Sweden.
marwa.dabaieh@mah.se

Abstract: Various natural and man-made disasters force the affected population to flee from their homes to other safe places. Providing these affected people with quick and cost-efficient shelters is always a challenge. Recently, issues regarding the supply of energy to refugee camps have been a main concern given the crises of displaced populations and the problem of how to supply energy to the camps. This study has the purpose of discussing the design of an eco-cycle refugee emergency shelter with the aim to reach a six '*Z*' target (i.e. '6*Zs*'), meaning zero emissions, zero energy, zero waste, zero cost, zero indoor air pollutants and zero impact on the environment after the shelter demolition. The key idea of this eco-cycle shelter is to reach a net 6*Zs* during all stages: material extraction, building construction, operation and maintenance until the shelter's end of life, which depends on plant-based row materials are brought in from the surrounding area to the building site. The study will discuss the design concepts involved and draw conclusions on the feasibility of achieving the 6*Zs* target through the modelling and simulation of the shelter's energy consumption, thermal performance and net carbon emissions. The beneficiaries of this project include not only refugees but also the majority of the world's urban poor. The shelter is designed for the cold Swedish climate, but the method can be adjusted to other climates or geographical contexts.

Keywords: Zero emission, Refugee shelter, Plant-based construction, Eco-cycle design

Introduction

Forced migration is not a new phenomenon. Throughout time, human beings have moved from one place to another to escape poverty, conflict or environmental dilapidation (Castles et al., 2014). During 2015–2016, Sweden experienced a strong wave of refugees from Syria as asylum-seekers due their circumstances of civil war and conflict. Sweden initially had an open-door policy, which put pressure on various Swedish institutions to act accordingly and quickly accommodate thousands of refugees. Sweden welcomed more than 160,000 asylum-seekers in 2015, with nearly 40,000 arriving in October alone. For a country of fewer than 10 million, this was equal to a population gain of almost two percent in one year. Setting up temporary camp hostels was one quick solution to house both families and individuals for several months, and in many cases, the refugees ended up staying there for two years until they were relocated once again in temporary housing. During this time in temporary housing, refugees suffered from difficulties like accessing washing and cooking facilities, as these are shared with others. In addition to privacy concerns, gender separation caused much inconvenience and tension inside the refugee camps.

Normally, temporary refugee housing is built to last one or two decades at the most, but sometimes, they are demolished after only two or three years. However, even during such a short lifetime, each housing unit utilises a wide range of resources in an energy-intensive construction and building process – from raw material extraction and production to construction and operation all the way to the end of the shelter life and consequent disposal. In addition, despite this short life span, the impacts of operations like annual heating and cooling energy as well as maintenance have a significant economic cost and environmental impact. In-depth studies are needed to assess the impact of such temporary structures and determine how their environmental burden can be lessened. The destruction of the refugees' previous houses during war and the effects of destructive weapons have taken their toll. This inspired the main concept of this project in November 2016 with the notion to design a low-cost and low-impact refugee shelter that could also be built quickly. This study discusses a design proposal for a 37m² eco-cycle refugee shelter from plant-based and earth materials. It aims at reaching six 'zero' (6*Zs*) goals: zero energy, zero emissions, zero waste, zero cost, zero indoor air pollutants and zero impact on the environment after the shelter's end of life. The methodology followed in this project is an experimental, participatory action research for designing and constructing a physical prototype as proof of concept in a living lab environment. In this paper, the design intentions and the theoretical notions for achieving the 6*Zs* concepts assessed by simulation verification will be discussed. In later stages of this project, more detailed calculations and numerical analyses will also be conducted followed by a proof of concept of the full-scale model. The project will be located in Brunnshög, Lund, which is in the Scania region of southern Sweden (Skåne), and the area acted as a test bed for the proof of concept of the physical model.

Literature review

There are few assessments of the impact of humanitarian shelters and construction especially in regard to emissions and their carbon footprint. Moreover, in the discourse, limited research tackles the issue of energy efficiency and thermal comfort for emergency shelters. Kuittinen and Winter (2015) show in their study that construction materials have a major impact on the carbon footprint of humanitarian temporary shelters. From the sample shelters they researched, they found that the shelters made from bio-natural materials are those with the least impact compared to others made from industrial materials (i.e. metal-intensive structures). In another study, Cornaro et al. (2015) analysed the thermal performance of tents equipped with photovoltaic systems in two different Italian climatic contexts. Their study showed a decrease in energy demand for heating of almost half and improved indoor comfort conditions in summer without the need for mechanical cooling. Here, they mainly used aerogel pads as high-insulation material in an easy retrofit solution to the original design of the tents.

Recently, other researchers have also started looking at the lifecycle energy and cost analysis for temporary, post-disaster housing. Atmaca and Atmaca (2016) compared the impact and cost efficiency of both prefabricated and temporary container housing in the Turkish context. Their study revealed that prefabricated housing is better in terms of cost and energy consumption over a 15-year period. This falls in line with the same outcome in the study by Islam et al. (2016) which calculated the carbon footprint lifecycle environmental impacts of shipping containers in Australia. This showed that the operation phase has the greatest impact. This later study can inform other research work in regard to using shipping containers as temporary shelters given their abundance and the fact that they have a lifetime of up to 60 years.

Applying passive solutions to humanitarian shelters is always one of the biggest challenges in a cold climate. A building simulation study by Crawford et al. (2005) evaluated the thermal behaviour of humanitarian shelters in cold climates with the goal of delivering design solutions and materials for quick and low cost deployment. In their study, many factors were considered, but the most important were moisture content and vapour production. They simulated two models in three different cold climates using calibrated data from environmental chamber tests. The study results showed that it is not feasible in all cold climates to depend solely on solar passive heat gains to attain the optimal indoor climate. Yu et al. (2016) constructed three bamboo-wood test cell models and monitored their thermal performance in a lab environment for the cold, Chinese climate. They tested different roof coverings and thermal insulation materials, and the results were compared to the data from monitoring being carried out on existing bamboo-wood shelters in Lushan, China. They also came up with different scenarios for combining low-cost thermal insulation materials with low-tech and affordable roof structures that can resist wind in winter and allow ventilation in summer. One of their suggestions was to use polypropylene sheets for walls, cardboard and air-bubble polythene sheets for roof thermal insulation, and fiberglass cement as a roof covering. Manfield (2000) compared some vernacular solutions and purpose-built shelters for cold climate practice, looking at several criteria like cost, weight, packing volume, delivery time, and most important, the thermal comfort. He suggested in his work that a tent environment that depends solely on casual gains from occupants could eliminate the need for fuel-burning stoves for heating. While other research was mainly focusing on acclimatization measure for temporary refugee tents and how to enhance indoor thermal comfort using inspiration from traditional Bedouin tents (Dabaieh and Borham, 2015).

In regard to energy supply, Lehne et al. (2016) concluded from their investigative research on energy access in refugee camps that 7 million displaced people in camps have access to electricity for only less than four hours a day. They showed with economical calculations that improved stoves for cooking and solar lamps could save $303 million a year in fuel costs. They highlighted that the issue of energy is an important concern and a crucial challenge to be solved within the humanitarian field. Dabaieh, (2016) suggested a plus energy refugee earthen prototype using solar and wind energy for self-sufficient energy supply. More studies are still needed in the area of energy efficiency and energy performance for refugee shelters. This present study attempts to add to the pool of existing literature by adding more applications for design prototypes with minimal impact on the environment, especially in terms of energy consumption and a comfortable indoor climate for the occupants.

Methodology

Eco-cycle design proposal

The shelter eco-design concept was based on in-depth interviews with 50 refugees based on stratified sampling in seven different camps located in the Scania region of Sweden. These interviews were conducted to learn more about the refugees' needs, the challenges they face in their temporary refugee camps in Sweden, and their future aspirations. The refugees were consulted for their opinion of the shelter design, and their comments were integrated in the design development proposal. This step took place in parallel with a literature study and technical meetings. The literature search was meant to look at similar research work investigating the environmental impacts, thermal performance, and cost efficiency of temporary refugee shelters for cold climates in particular. The technical meetings with researchers, architects, engineers and planners, both as individuals and companies (working with eco-cycle, passive, pre-fabricated home concepts) were meant to discuss the feasibility of the design proposal and have an estimated figure for the cost in the Swedish market based on the suggested site for construction. All of these aspects informed the final design proposal to achieve the 6*Zs* target.

Building Simulation for the 6Zs target

The 6*Zs* ideas were then simulated using DesignBuilder software. All the six zero targets were designed from a cradle-to-cradle perspective, from the material production to the building construction until operation and maintenance, and lastly, the demolition state after the shelter's end of life. Several parametric modifications were made for the passive design solutions to reach passive house premium standards as a benchmark. The outcome from the simulation is analysed to evaluate the performance of the passive solutions proposed, in particular, regarding passive heating and daylight as the main challenges in Sweden. Due to the limited size of this paper, only the final outcome of the simulation is discussed.

Results and discussion

The project design concept

The key idea of this eco-cycle shelter is to reach a net zero level of emissions, waste and energy during material extraction, building construction, operation and after end of life. The main wall skeleton is an earth-mix recipe together with reeds and straw. The earthen construction technique is based on the nature and properties of the local building site soil, so that no additives are imported from outside the building site except lime to be used for walls plastering. The Scania region is known to have good soil that is suitable for earth-building techniques and abundance of reeds and straw. It is a known fact that the earth gives off no harmful emissions, and it can be used again as soil or for rebuilding another house, as no chemicals or industrial materials are involved (Snell and Callahan, 2009). According to (King, 1996), earth buildings can last for over 90 years if properly built and according to Jones, (2015) straw bale houses can last for 200 years. The straw and reeds are natural, plant-based materials and used to enhance the earth mix's tensile strength. Both materials are also agents for absorbing CO_2. The plants absorb CO_2 during their growth process, and this continues when mixed with wet clay and decomposed partially into cellulose, which acts as a binding agent. The lime takes in CO_2 during treatment throughout the construction process and building operation with the increase in the indoor air humidity.

Regarding structural aspects, especially the straw bale and rammed-earth techniques, they are both stable for bearing wall structure systems. A standard 40cm-thick, rammed-earth walls can be used for load-bearing in buildings up to four stories high (Boltshauser and Rauch, 2011). Earth is non-flammable, so walls made of earth have the added advantage of being fireproof. The straw and reeds are used as infill for the rammed-earth structure. Also, a traditional final layer of plaster consisting of casein, beeswax and linseed oil is used to protect the facades from rain. Lime is also added to the walls' and roof's external plastering, as a water-resistant agent, in particular, in the erosion lines earth mix of the rammed earth exterior walls. The roof will be made of locally available wood, straw and reed boards and the built-in furniture (bed, sofa and wall cabins) is made from rammed earth and reeds, which will also help reduce the final building costs. In addition, the building can be extended easily if the need arises, and the size can be adjusted according to the number of occupants.

Figure 1 shows the shelter design concept as an outcome of the design meetings with the refugees. Several other technical installations, such as a natural earth refrigerator (8 degrees), so the occupants can store their food for daily use with zero energy consumption in addition to a waterless and manually driven washing machine. PV LED lamps will be installed and other installations will be chosen based on their energy efficiency. A green roof will be used to reduce water runoff, heat loss during the winter and heat gain during the summer from the roof surface. All the technical solutions shown are the outcome of the focus group technical meetings.

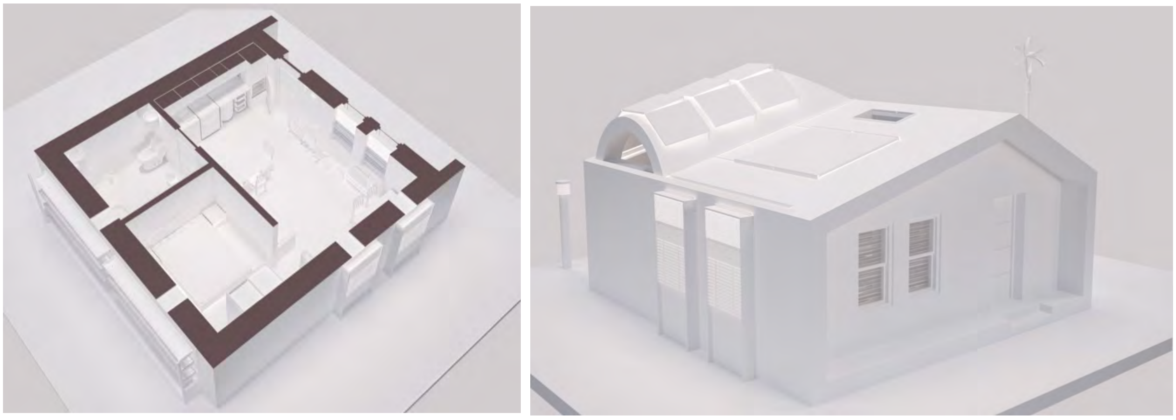

Figure 1. The concept for the refugee shelter, to the left is the 3D model showing the passive and the renewable active systems used and to the right is the plan showing the shelter zones.

eco-cycle design application towards the 6Zs goals

The goal of *net zero carbon* is achieved through using plant-based building materials (straw, reed and wood) through low-tech production and construction with a short transportation distance from building site. Using a green wall and a green roof act as carbon offset to achieve the net carbon target. The electricity is produced using renewable resources; however, the embodied carbon in the PV and wind turbines production is outside the boundaries of this study. The total carbon emissions calculation from manufacturing, construction, operation and demolition of the shelter was 0.02 kg CO2 e/m3.

The goal of *net zero energy* is attained through using hybrid renewable energy systems (Solar PV and Wind) shown in figure 2 for renewable energy production with an extra energy surplus to be utilised for other purposes like charging stations for e-bikes and e-cars or for street lighting. The preliminary simulation results for the shelter's yearly energy performance showed a total annual consumption of 28 kWh/m² and energy production is calculated to be round 120 kWh/m² year. These results were only for electrical appliances, night lighting, and heating during approximately seven weeks in winter. Passive heating and cooling solutions like Trombe wall and earth pipes are used to reduce the heating and cooling loads thus reducing the overall energy consumption of the building. The energy needed for cooking is mainly fuelled by bio-gas produced from household and neighbouring farm lands organic waste.

Net zero cost will be achieved through using renewable sources for electricity production calculated for a short payback during the shelter's complete lifetime of 15 years. The extra surplus of energy to be produced and sold to the neighbouring greenhouse which during the 15-year lifetime will cover the other building material and construction costs. The labour cost is also waved because the refugees will build the houses themselves. They will be paid incentives as motivation for their participation. Net zero waste is an important goal as the waste products will be either reused or recycled. The organic waste from the kitchen and the faeces from separating toilets will be used as bio-gas for the cooking stove. The urine will be used as fertilizers for the green wall and green roof. The grey water will be used for irrigation. The entire house structure will go back to soil after end of life or can be recycled again as building materials such as compressed earth blocks. Figure 2 shows the waste and water cycle.

Zero indoor air pollutants will be achieved through using plants like English ivy, Boston fern, snake plant and others as a natural air filtering solutions. They absorb chemicals and particles in the air and purify the indoor air. Some plants even produce O_2 during the night, and that will reduce the CO_2 concentration during sleeping periods. Figure 4 and 5 shows the integration of air purifying plants in the Trombe wall and green wall systems. A zero impact on the environment is yet another important goal. The main construction materials are natural, plant-based materials and can be recycled again or go back to nature as compost or soil. Earth, wood, reeds and straw constructions are not only environmentally friendly, but also represent a return to nature after the building end of life or demolition.

As for the thermal performance, the simulation found that the highest indoor temperature during summer was 23.5°C and the lowest in the winter was 14.5°C. In regard to humidity, the preliminary simulation showed that the annual maximum was 74.3%, and the minimum was 43.8%. Passive concepts in heating, cooling and daylighting are the key design aspects that reduce energy consumption during the building operation. These passive solutions include the earth pipes, a high thermal mass double wall, window-to-wall ratio, orientation, shading, Trombe wall, green wall and the cool roof. In order to decrease the dependency on artificial light during cloudy winter days, light shelves were used to reflect daylight into the shelter's interior. Figures 4,5 and 6 show the Trombe wall, green wall, and the earth pipes' passive solutions.

Conclusion

This paper discusses the theoretical background along with the design concept and expected performance of an eco-cycle refugee shelter by using building simulation. Refugee families or even individuals usually have a limited, low income and a lack of resources, and thus, they depend on support. By applying this project prototype, they will not need to worry about the high cost of energy in Sweden. As the proposed prototype is virtually independent of fossil sources of energy and is fully supplied with renewable energy, the low energy requirement for the operation is sufficient to provide a constant supply of energy all year long, even during overcast and muggy days. Living in a shelter house that has a minimal carbon footprint can bring about other changes in the refugees' lifestyle that also have a positive impact on the environment, including growing their own food. In addition, raising children in a passive and low carbon house will also bring about positive change for the next generation whose lives are expected to improve even more. The holistic idea of this shelter design notion is to benefit from living in a passive, zero energy and zero carbon house which also provides high levels of overall comfort without compromising the environment and with a lower cost of living than conventional houses. All results obtained from the simulation were based on the assumption that the passive solutions are utilised at the correct time of the day and night in different seasons. Therefore, training should be conducted as a pre-occupancy strategy and monitoring will be made during the post-occupancy period. More accurate results and testing for the feasibility of this project will be retrieved during the test-cell proof of concept phase.

Design to Thrive

Climatic comfort in outdoor spaces and its effect on residential complex in the hot and humid climate, case study bushehr, iran

Mahboubeh Engali Dehnavi [1], Mansoureh Tahbaz [2]

[1] Faculty of Architecture and Urban Planning, Shahid Beheshti University, Tehran, Iran,mahboubeh.dehnavi@yahoo.com
[2] Faculty of Architecture and Urban Planning, Shahid Beheshti University, Tehran, Iran,shtahbaz@yahoo.com

Abstract: Architects are seeking the best climatic condition in their designs nowadays. To achieve this goal, the open spaces around buildings as the primary factor in thermal condition, must be considered. The design of open spaces, affects inside thermal comfort and furthermore encourages residents to use open and public spaces. The aim of this article is creating a proper microclimate for the hot and humid city of Bushehr by some thermal outdoor indexes such as humidity, temperature, sun radiation , wind and analysing them by WBGT (Wet bulb global temperature) and TSI (Tropical summer index) index. In the following section, by studying the historic fabric of the city, main criteria related to climatic design is identified. Finally, designing a residential complex in the city of Bushehr is provided based on two criteria: first the climatic condition in the microclimate level and second the historic fabric of the city. Increasing shadows and wind as the main climatic modification obtained from the study have been applied in the proposed design aiming at thermal comfort in open spaces.

Keywords: thermal comfort, outdoor space, residential complex, WBGT, TSI, microclimate.

Introduction

Because of the constant presence of people in residential complexes, climatic design and construction of them is important. Thermal comfort of complexes are affected by climatic conditions of the surrounding open spaces. Thermal comfort in open spaces and creating a suitable microclimate depends on many factors. Climatic parameters such as the wind, solar radiation, temperature, and humidity will effect on the form, shape, and height of the buildings and spacing between them. The shade amount, a limited sky view angle and human factors such as activity, clothing and adapting to climate are other important aspects.

Because of its proximity to the Persian Gulf, low elevation above sea level and low latitude, the city of Bushehr has a hot and humid climate. In this study by analyzing climatic data in one hand and historic fabric of Bushehr (as a valuable pattern of climatic architecture) in the other hand, some principles for designing a residential complex are achieved.

Bushehr Climate data analysis

Bushehr city with Geographic Coordinates Latitude 28° 91’ N, 50° 83' E and 18 meters Elevation above sea level is located along the north coastal region of Persian Gulf in south west of Iran with warm semi-arid climate. The data of the Bushehr weather station during 1985-2005 is being considered for analysing the climate of the city. Temperature, humidity, wind and radiation are the main factors among these data for our analysis.

The Ave. lowest and Ave. highest annual temperature are 11 ° C in December and 38 ° C in August respectively. The Maximum summer temperature during the day is 35.8 ° C and during night is 30.2° C. Two months of the year the temperature is below 18°C, and in the half of the year it's greater than 21°C that crosses from comfort range (18-21°C). Considering Relative humidity comfort range (30%-60%) at 6 o'clock in two months and at 12 o'clock throughout the year, it has a sultry (www.bushehrmet.ir).

Wet Bulb Globe Temperature (WBGT)

The prominent and well-known heat stress index, The Wet Bulb Globe Temperature (WBGT) (ISO 7243, 1982) is a function of important environmental factors in hot condition: air temperature, radiant temperature, and air humidity. WBGT is adjusted for usual work uniform of long-sleeved shirt and pants with and without solar load (Tahbaz, 2011). According to Temperature and humidity data of each month, the following results is obtained. (Figure 2: right), (table1)

Tropical Summer Index (TSI)

TSI is appropriate for hot-dry and warm humid conditions (Sharma, 1986) when the radiant flux is not excessively high, and the subjects have sufficient air motion for any visible perspiration to evaporate off (Tahbaz, 2011).Results obtained from this indicator are shown in (Figure 2: left) and (table 2). Environmental stipulations of TSI are taken by people fully acclimatized, over a duration of consecutive summer seasons (Sharma, 1986).

The results of the data analysis of the weather station and climate indices reveal that Bushehr has relatively short and slightly cold winters and very long and hot summers. As a conclusion, utilizing air flows and shadow to avoid direct radiation, play the main role to create a suitable microclimate in outdoor and indoor spaces. According to TSI Chart that is provided for local people show that for people who are adapted to this climate, critical situation does not exist and better thermal conditions in hot months will be provided with proper design.

April ,May, June early, late September, October	25-30° C (Comfortable)
Late June, July August , September early	30-34° C (slightly warm)

Analysis of wind data

In Bushehr as a Peninsula, winds often blow from the sea. According to the wind chart of Bushehr (Figure 2), the prevailing and strongest wind blows from the North West mostly in the afternoon. In the warmest months - July, August, September- wind blow from the West, North West and South West which can be used to create efficient airflow.

Figure 2.Windrose diagram of Bushehr. (www.bushehrmet.ir presented by a local software).

The wind flow in passages

The wind flow condition plays a key role in urban designing, and its climate changes. Designing urban elements such as street orientation, height, and density of the buildings, change wind speed significantly. Urban wind conditions on the street level have a direct effect on human thermal comfort, energy consumption, heating, and cooling (Ranbar et al, 2010). When Distance between the buildings is high, airflows behind of buildings will not effect on one another but in compact construction, formed secondary flows causes turbulence that is essential in Hot and humid climate (Dekay et al, 2013).

Solar radiation and its control methods

Radiation in the form of solar and environmental radiation is another influencing climatic Phenomenon on human comfort (Razjooyan, 2010). The Sunshine duration is one of the factors affect solar radiation .In Bushehr, the least and highest amount of sunshine hours are 61.64% and 82.85%. It's over 60% in cold seasons and 70% in warm seasons.

There is two main controlling factors of radiation at a surface: 1-the amount of solar radiations received at the surface 2-the area on the object subjected to the sunshine. The received radiation at the surface explore in three poses. First, flat areas, second, built areas with low-density, third-built areas with high-density. In the flat ground, reflected solar radiation from the Earth's surface after absorption return to the sky with a long wavelength. In built areas with low-density, the major part of the reflected radiation impacts other buildings and absorb near the surface of the ground (Besharati zadeh, 2011). Figure3

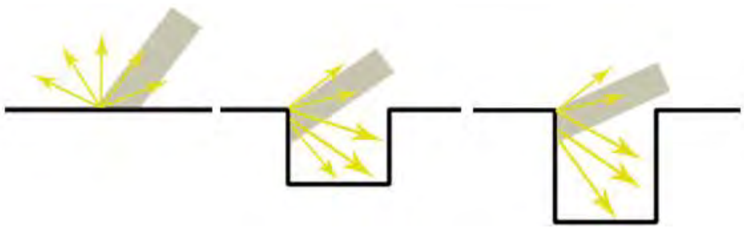

Figure3. Change of closeness and its effect on the sun reflection)Givoni,1998).

To adjust sunlight or shaded areas and surfaces, architects are able to control the sky view factor(SVF) by using settlement regulation such as mass and space and height of the buildings, passage orientation, perspective and proportion (Tahbaz, 2013). Using heat sink materials such as vegetation, water, wood and so on is another solution to decrease surface temperature of the environment (Besharati zadeh, 2011). In Bushehr to decrease the environment temperature it is common to use prominent and adjunct heat sink materials such as wood (shanashir) in the façade of the buildings.

The historic fabric of Bushehr

in The historic fabric of Bushehr, Courtyards in combination with open spaces have formed a balanced combination of mass and space. Passages, lead the wind into the fabric, and open spaces distribute the wind. For achieving maximum wind flow, building blocks as a single or multi-houses are surrounded by intersecting passages. The most important factor in shaping the street network is the wind direction that is affected by sea location in bushehr, By choosing suitable aspect ratios ,passages stay in the shade most hours of the day (Ranjbar et al, 2010). Many crossings passages with open spaces provide the maximum exchange between the building and wind. Main passages are built toward the seaside to take the maximum wind (Figure4). Passages are constructed narrow with an aspect ration of 1/2 to 1/6 width to height for creating more shadow and improving ventilation (Figure5). Edge of the buildings does not comply with the passages, and in the second floor, have over hangs like shanashil to increase the wind flow into indoor spaces (Nikghadam, 2012).

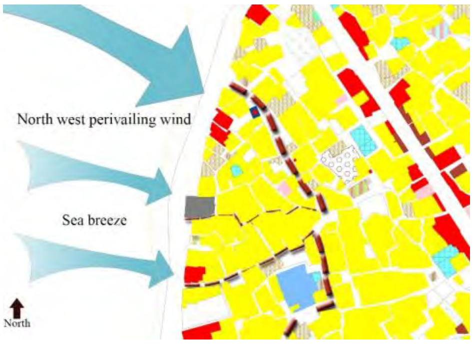

Figure 4. building and passage's orientation with considering the wind direction

Figure 5. An instance of the historical fabric's alleys

Design recommendation

By analyzing climatic data and study of historic fabric, certain criteria defines for thermal comfort design. In this part, some recommendation for the designing and choosing the orientation of passages, buildings, and their placement by considering the wind direction and producing shaded area is specified. Increasing the wind flow, and shaded area, are the main realized criteria in hot and humid climate.

Wind flow

Designed passages to the prevailing wind directions, increase wind flow in the city. For this goal, directions of boulevards and main streets can take 20 to 30 degrees deviation to the prevailing summer winds direction (Dekay et al, 2013). Figure6

To decrease wind shadow in the leeward areas the constructed buildings have porous texture. this placement, helps adjacent building's ventilation. Also, the air in porous fabricate flows through the buildings (Dekay et al, 2013). Figure7

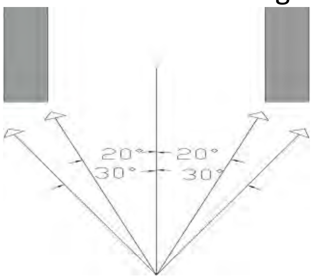

Figure 6. Orientated pathway from the Wind direction.

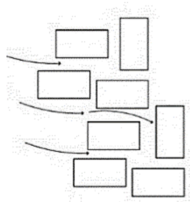

Figure 7. Creation porous texture

Shadows

Buildings can be made in such a way to create overshadow on the adjacent outside spaces and each other (Dekay et al, 2013). Figure8.

The temperature and heat absorbed from the shaded side of a building is low. With less heat radiation in shaded streets in hot climate, the thermal comfort of the pedestrians in open spaces would be improved. Sheltered walk ways and other types of the canopy can be used in the east-west streets which normally take a small shadow (Dekay et al, 2013). Figure9, 11, 12

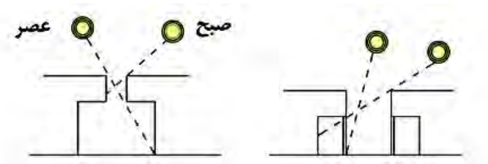

Figure 8. creating overshadow)Besharati Zadeh 2011).

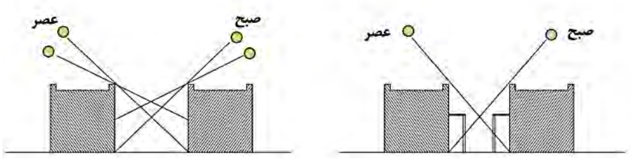

Figure 9.passage with horizontal awning and without awning.

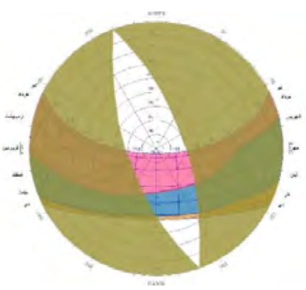

Figure 10.shadow mask for building with Awning

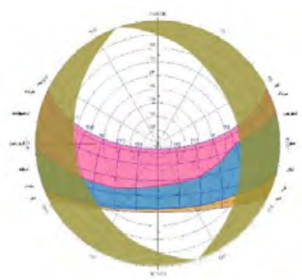

Figure 11.shadow mask for building without Awning

***Vegetation*:**

Vegetation reduces the temperature of adjacent air and surface by 6 to 8 °C due to a combination of evaporation, reflection and shading. Vegetation in dense urban areas creates a local air circulation. The warm air of this area rises and cool air substitutes by reduced pressure on the ground surface (Dekay et al, 2013).

In hot and humid climate shading of trees decrease the radiation flux and as a result the globe temperature (Dekay et al, 2013).

A strip surrounded by low-density trees act as a source of cool air (Dekay et al, 2013).

Proposal design of a residential complex:

The site of the project is located on the east side of Bushehr to design a residential complex for 250 houses (Figure12). Weather factors affecting the site are the prevailing wind from the West North and sea breeze from the beach. In this project, 20 to 30 degrees deviation of passages direction from the prevailing wind direction increases the wind flow. Turning to the South East in this climate reduces radiant heat on the building's wall (Figure13). The blocks Placement by considering design solutions shown in (Figure14). Using central courtyard, creating porous and dense texture, shading for buildings, changing passage's orientation, using covered walkways and vegetation to create the wind flow and shading for complex design are shown in figures15-19.

Figure 12-Site location.

Conclusion

Creating the proper microclimate, and comfortable thermal conditions in open spaces requires a precise study of the climatic parameters such as temperature, humidity, radiation, the wind and other associated indicator. In this article, by studying climatic factors and historical fabric of Bushehr, solutions to create a proper microclimate around the buildings and thermal comfort in open spaces are recommend. Defining specific layout and direction of the streets by considering the prevailing wind flow, shadings on the building's facade, utilizing shaded and covered passages and walkways in open spaces, using vegetation, creating a central courtyard for shading on the buildings and conducting the wind are the considered solutions for this case study design.

Abstract: Passive design strategies in Architecture are highly sensible to local climatic conditions, so techniques that work in some climatic context may be inefficient in another one, as it is the case of cool roofs for passive cooling. Cool roofs can be useful in climates with a large number of sunshine hours and thus with a high solar radiation throughout the year as it is usual in Southern Spain. In some other areas of the Iberian Peninsula, the energy efficiency of this kind of roofs for passive cooling is not clear. In this work, the thermodynamic behavior of a cool roof is analyzed in three typical climatic context of the Iberian Peninsula: Mediterranean climate in the south, Continental climate in the center and Atlantic climate in the north, during a whole typical climatic year. The thermodynamic balance of the cool roof was compared with the balance for a standard tiled roof. We conclude that the analysed cool roof provides substantial energy savings in the Mediterranean climatic context when compared to a standard roof, but its use in areas of colder climatology should be evaluated with caution due to the heat gain penalty that cool roofs produce during the heating season.

Keywords: *Energy efficiency, passive cooling, cool roofs, Finite Element, fluid dynamic*

Introduction

Over the last years, interest in the development of passive systems for heating and cooling has experienced a remarkable rise because of the need to decrease the energetic costs in the thermal conditioning of buildings. This way, extensive research in the field of energy efficiency has focused in the use of techniques that take advantage of environmental and climatic resources in a suitable form.

In hot climates, the high energy consumption needed to get internal comfort in buildings during the hot season poses a major problem. Hence the convenience of implementing techniques that minimize the cooling load. Among the various existing passive cooling techniques, in the present work we focus on a specific case of Cool Roof. A Cool Roof is a roofing system able to reject solar heat and keep roof surfaces cooler even with sunny weather. Last is possible because the properties of the used materials, which reflect the solar radiation and release the heat energy they have absorbed.

Usually a Cool Roof is a roof system with a low absorptivity coefficient for short-wave radiation from solar origin and a large infrared emittance coefficient. This way a remarkable reduction in the temperature of the roof surface is achieved, thereby decreasing the heat flow into the building.

This effect is achieved thanks to the properties of the so-called "cold materials" characterized by high solar reflectance and high emissivity for longwave radiation. In the roof studied in this work, the cold effect is achieved by applying on the roof external surface a white elastomer layer with the aforementioned radiative properties.

Since the influence of the Cool Roof affects basically the part of the building directly under it, its efficiency for tall buildings is limited to upper floors. However, the usefulness of Cool Roofs for low-rise housing and more collective use buildings, schools, office buildings, libraries, etc., is evident in the case studies included in the report "Cool Roof case studies in EU level" from the European Cool Roofs Council (Zinzi and Romeo, 2010), and in a large number of recent publications such as those of Synnefa et al. (2012) and Pisello and Cotana (2014).

In this paper the energy efficiency of the considered Cool Roof is analyzed in three locations in Spain that cover the most common climates on the peninsula: mediterranean climate (southern Spain, namely Seville city), continentalized mediterranean (center Spain, namely Madrid city) and oceanic (northern Spain, namely Santander city). Although the Iberian peninsula has other climatic zones, for brevity, only the mentioned zones are studied here because they are those that comprise a greater fraction of territory.

Due to the high levels of solar radiation and high temperatures frequent in southern Spain, the use of Cool Roofs in this area might turn out to be suitable to decrease the cooling load. However, its use penalizes the solar heat gain during the cold season since the amount of solar radiation reflected by the cover. Therefore its use should be assessed with the greatest possible precision in order to determine its suitability.

For the considered Madrid climate, the cloud cover and so the solar irradiation along the year, follow similar patterns that in Sevilla, but winters are much more cold and summer are less hot than in southern Spain, so the annual energy balance for the Cool Roofs are less favourable than the obtained for the Mediterranean climate.

Finally, in the north, the weather is often cloudy and characterized by mild temperatures with lower annual oscillations and lower levels of direct solar radiation throughout the year. This entails that the diffuse solar radiation and the flow of longwave radiation from the sky are quite high when compared to direct solar radiation. This determines the behaviour of the Cool Roof, resulting in an intermediate global energy balance when compared whit the others studied locations.

In this paper, by using computational numerical simulation techniques applied to the air fluid thermal dynamic, to the heat transfer through the roof and to the radiative exchanges, we draw conclusions about the patterns displayed by the thermodynamic behaviour of the considered Cool Roof when compared with a standard ceramic tiles roof in the analysed geographic and climatic contexts.

Case studies

For our study a detached house with two floors has been considered. The studied roofs are flat type and have the same configuration, which complies with the specifications of the Spanish Technical Code Ref. Such a configuration is described in Table 1 in which dimensioning and thermophysical characteristics of the various components of the roofs are described.

For the outer surface of ceramic tiles it is considered an absorptivity solar radiation coefficient of 0.75, while the emissivity coefficient of this layer is taken as equal to 0.83, as referenced by Gozalbo et al. (2008).

Table 1. Thermophysical characteristics of the roofs

Layer	Description	Thickness (m)	Density (kg/m^3)	Specific Heat $(J/kg\ K)$	Conductivity $(W/m\ K)$
1(Ext)	Ceramic Tiles	0.01	2000	800	1.00
2	Mortar	0.02	2000	1000	1.40
3	Protective Layer	0.02	1900	1000	1.80
4	Waterproofing (Bitominous Layer)	0.003	2100	1000	0,7
5	Separating Layer	0.02	1900	1000	1.80
6	Insulation (Extruded Polystyrene)	0.05	35	1400	0.038
7	Lightweight Concrete	0.15	1200	1000	0.57
8	Ceramic Pieces	0.30	650	1000	1.58
9 (Int)	Plastering	0.015	1000	1000	0.57

In order to transform the roof in a Cool Roof, it has been deemed the application of a white elastomer layer on the surface of the outer layer of the roof. On its technical specifications this layer provides a solar reflectance coefficient equal to 0.85 and an emissivity in the range of infrared radiation equal to 0.85.

The constructive section of the roofs are showed in Figure 1.

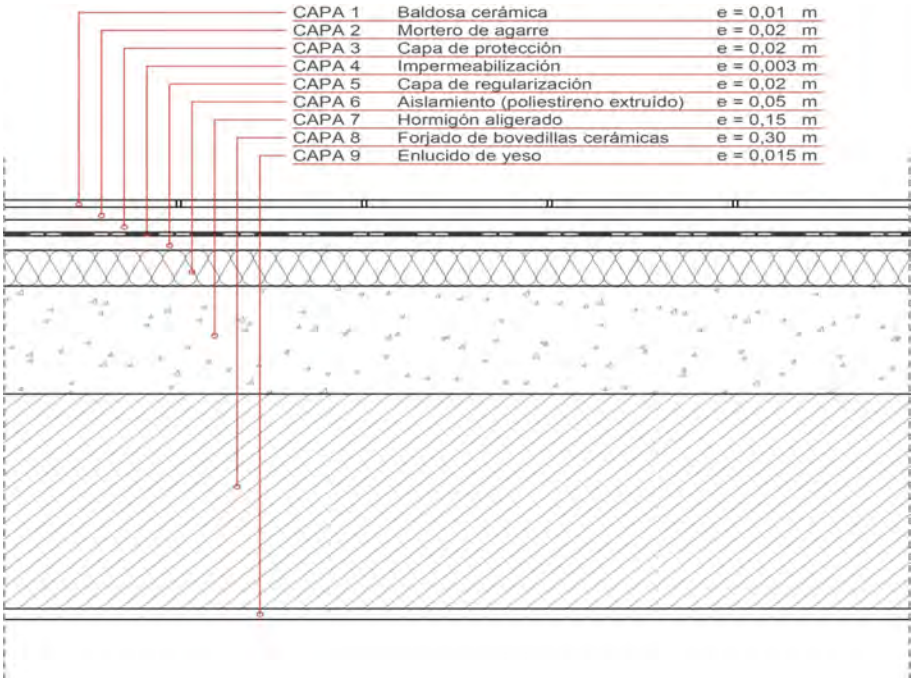

Figure 1. Constructive Section of Roofs.

Climatic Conditions

As mentioned above, passive systems are highly sensitive to local environmental conditions. In Southern Spain, and specifically in the city of Seville, clime is determined by a high seasonality. In summer daytime temperatures often reach high values, while in winter the values are significantly lower but moderate for what is common in central and northern Europe. respect it is considered usual in Europe. Solar radiation is quite high the whole year, but specially strong in summer. Meanwhile downwelling radiation is quite uniform all over the year but with a higher daily range of variation in summer which allows for nocturnal radiative cooling. Madrid has a similar seasonal behaviour but with temperatures colder in winter and summer. The solar radiation is lower than in Seville although it reaches high values the whole year and the downwelling radiation is the lowest of the three studied locations, although in summer the values of these radiation are very similar.

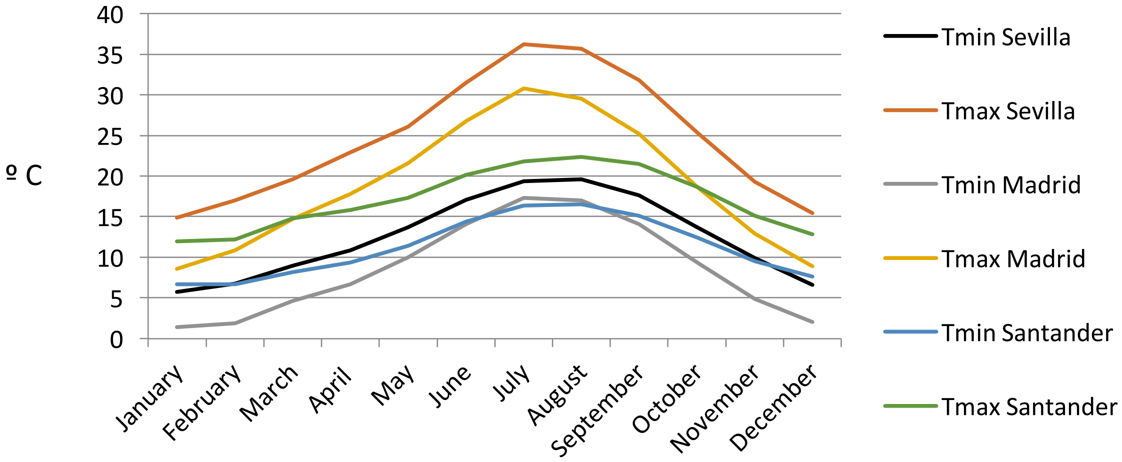

Figure 2. Averages of maximum and minimum temperatures

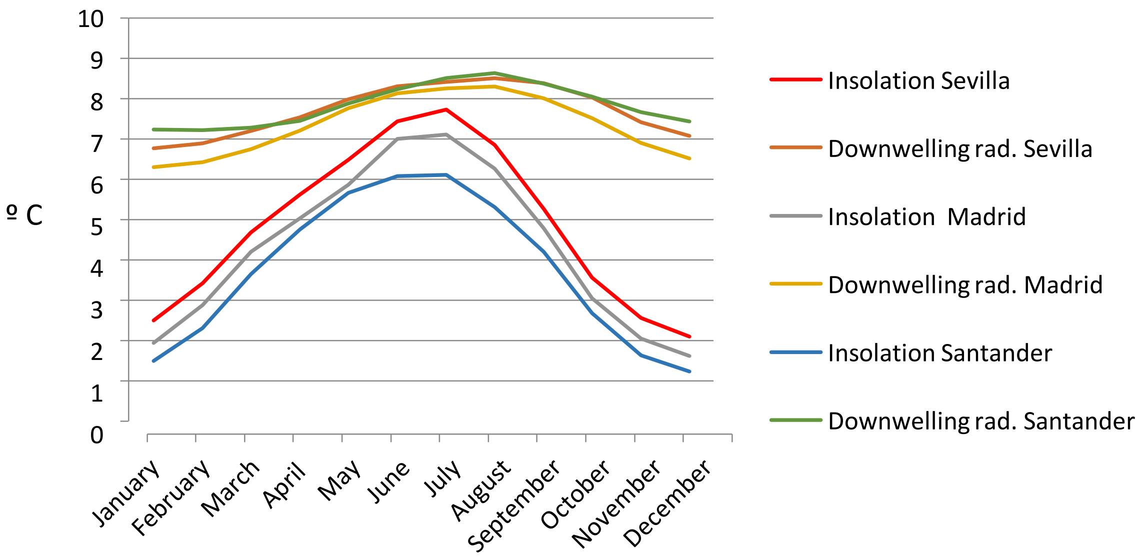

Figure 3 Monthly Averaged Insolation and Infrared Radiation Incidents on a Horizontal Surface (kWh/m2/day)

By contrast, in oceanic climates, such as the case of Santander, temperatures are more uniform throughout the year, being the daily variation range quite narrow. The temperatures do not change so strongly throughout the year as it does in Seville and Madrid and the sky is often cloudy that implies less direct solar radiation but higher values of infrared sky radiation that for the other cities.

Behaviours of the temperatures and the radiation for the three cities can be seen in Figure 2 and Figure 3 that illustrate the above.

In all cases winds are not usually strong but can range from total calm to moderate that can significantly increase heat transfer by convection between the roof and the ambiance. The studied velocities for the wind entering in the inlet of the computational domain are equal to 1, 2 and 4 m/s, which are considered sufficiently representative of the average values given in the considered climatological frameworks.

Physical modelling

In this section a generic description of the physical problem involving the heat transfer and the movement of the air mass is set out. Specifically, the heat transfer in the roofs are determined by:

- Heat gain on the outer slab due to solar irradiation.
- Heat exchange by radiation between the outer surface and the sky.
- Heat exchange by convection between the outer surface and the ambient air.
- Heat transfer by conduction through the layers of the roof.
- Heat exchange by convection and radiation between the internal surface of the roof and the interior of the building.

Other possible factors such as radiative exchange between the roof and adjacent buildings or vegetable masses, even terrain, higher than the studied building, have not been taken into account in this study for the sake of brevity.

In order to establish the physical model it must be taken into account that the equations describing the air flow, the equation for energy transport by the air flow and the heat transfer equations through the different layers of the roof must be solved in every time step. Likewise the radiative exchanges must be computed in each time step in order to adequately approximate the heat transfer through the roof.

Convective heat transfer coefficients

Convective heat transfer coefficient for external building surfaces is essential in order to calculate heat gains and losses from the roof to the ambiance air. Following the recommendations of Hagishima and Tanimoto (2003) for low-rise buildings, we have considered the coefficient value equal to

$$h_c = 8.18 + 2.28\, U_R \quad W/m^2K$$

where U_R is the velocity in m/s measured $0.6\, m$ away from the external roof surface. Since according to the authors this value is calculated specifically for convection heat transfer on the flat roof of a building with two floors, it adequately matches our case study. This correlation allows a more accurate calculation of the convective coefficient h_c because it takes into account the wind speed calculated next to the roof surface by solving the Navier-Stokes equations instead of employing the wind speeds provided by weather stations as it is usual in energy simulation programs.

Internal roof surface energy balance calculation is made by taking a comfort room temperature T_{room} constant for each season. Then we calculate the exchange of heat by convection and radiation between the internal roof surface and the room by using a mixed convective-radiative transfer coefficient given by $h_i = 8\ W/m^2K$, which is usually recommended in the technical specifications for this kind of indoor heat exchange. The values for T_{room} are usually taken like the temperature of indoor comfort.

Estimation of the downward long-wave radiation of the sky

An essential difference between the two types of radiation affecting the roofs is that solar short wave radiation takes place only during daylight hours and thermal downwelling radiation is present throughout the whole day. So, although this radiation is usually named nocturnal radiation, it takes place even during daylight hours, although at night the thermal radiative exchange is usually negative, that is, more longwave radiation is emitted that received by the roof giving rise to the so-called radiative cooling. Hence the need of a calculation as accurate as possible of this kind of radiative balance.

The presence of clouds significantly affects this type of radiation, increasing its value when the clouds have a higher density and a lower height.

A correlation quite used in such situations is the one presented by Goforth et al. (2002). Their model is a variant of the Swinbank model and is given by the following expression:

$$Q_{sky} = (1 + KC^2)\, 8.78\, 10^{-13} \quad T_{amb}^{5.852} \quad RH^{0.07195}$$

Where K is a parameter that depends on the height of the cloud layer, C is the percentage of cloudiness, being 0 for fully clear skies and 1 for completely cloudy skies and RH is the relative humidity. For this purpose we have used the values provided by different climatic organisms: the Spanish Meteorological Agency, the Meteorological Services of the National Aeronautics and Space Administration (Nasa) .

The obtained monthly average values for shortwave and longwave radiation are showed in Figure 3, for the studied geographical locations.

Numerical simulation

The numerical simulation of the flow air has been made by using a FEM discretization of the thermodynamic equations of NavierStokes. The free code FreeFem++ software, from the french "Institut National de Recherche en Informatique et en Automatique" (INRIA), has been used for the computational implementation of the considered discretizations.

The problem has been solved in a time period of one week for each month of the year, making use of the typical meteorological monthly data for every month. The time dependent problem has been solved by using the non-stationary equations of Navier-Stokes for the fluid thermodynamic dynamic and the non-stationary equations of heat conduction through the different layers of the cover. To solve the equations of fluid dynamics it has been used the $k - \varepsilon$ model for turbulence. This is necessary due to the characteristics of the problem in which the air flow over the roof of the building presents high Reynolds values that make necessary modelization of the turbulence.

At each time step the energy balance for radiation and convection in the interior and exterior surfaces of the roof are taken as boundary conditions.

Results

In order to calculate the heat flows through the roofs, constant temperatures inside the building have been considered for each calculation period. This constant temperature is the comfort temperature and it has been taken equal to 22 °C for winter months, 23 °C for spring and autumn and 24°C for summer.

Monthly heat flux

In Figures 4 and 5 monthly flows of heat in kWh/m2 are shown for the Cool Roof and for the ceramic tiles roof for different wind speeds. Positive values represent heat flux into the building and negative values outward heat flux.

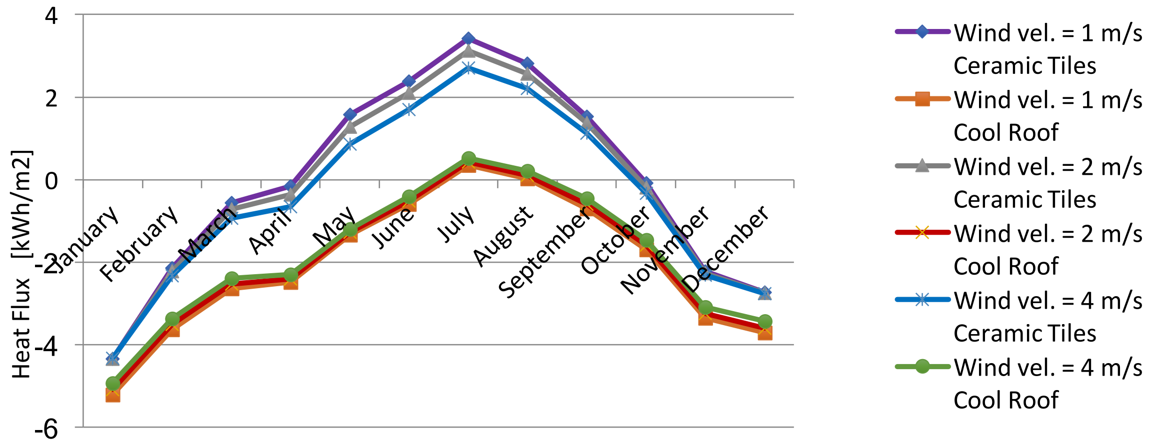

Figure 4. Monthly heat flux (kWh/m2) in Sevilla

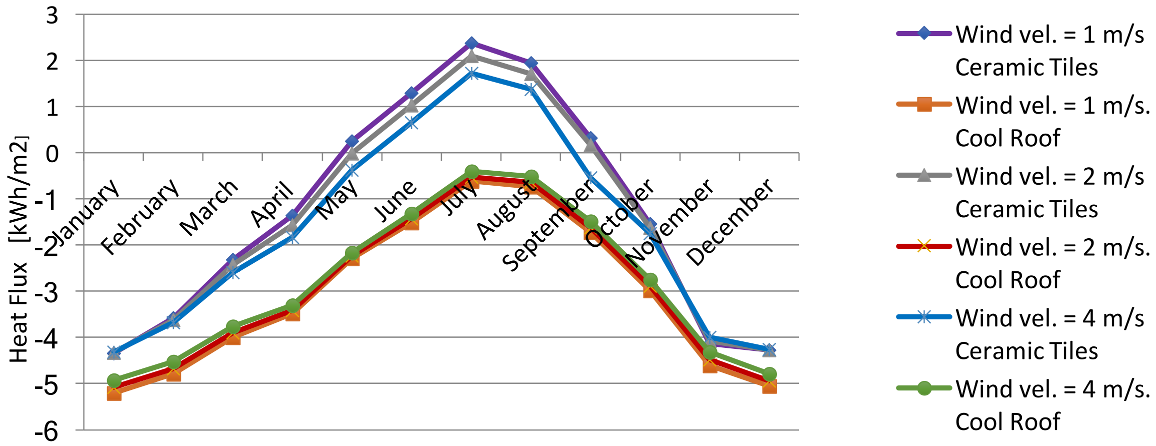

Figure 5. Monthly heat flux (kWh/m2) in Madrid

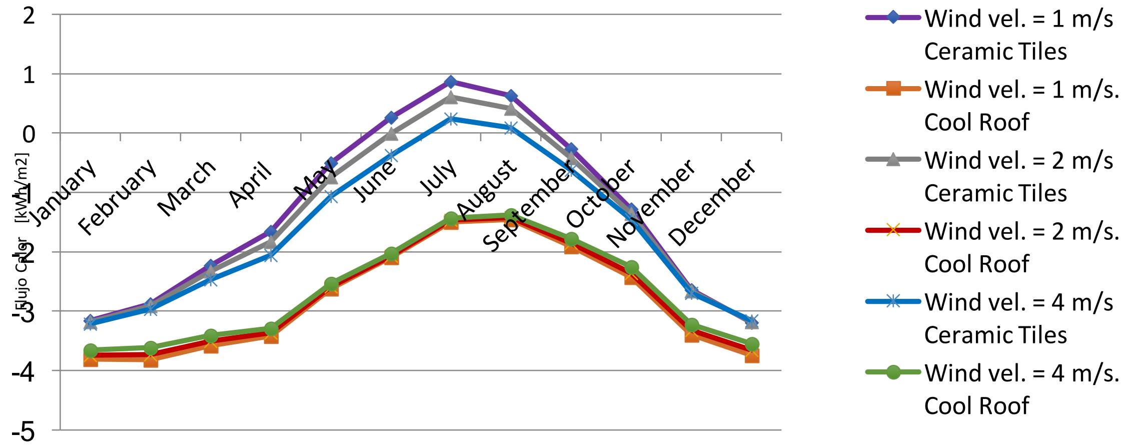

Figure 6. Monthly heat flux (kWh/m2) in Santander

It is noteworthy that the curves of heat flux for the Cool Roof are lower that the ceramic tiles ones for the whole year and for all the wind velocities. For the cool roof, only in Seville there is some positive flux in summer, whereas that for the other locations, the cool roof provides negative flux for the whole year. The effect of the wind velocity is only noticeable for the tiled roofs and in summer, when the increase of the velocity reduces the heat gain. No remarkable effect is observed for the cool roof.

Heat flux yearly balance

In Figures 4 the heat flux yearly balance for the Cool Roof and the ceramic tiles one are shown for the analysed locations for a wind velocity of 2 m/s which is close to its yearly average. For the city of Seville, the global balance doesn't take account of the heat loose in the warm months because this fact even contributes to increase the thermal comfort in such months.

The obtained results show for Madrid and Santander a higher heat flux through the Cool Roof than through the classical ceramic tiles roof. Only for Seville we find a yearly heat flux reduction because the positive balance between the cooling savings in summer and the heating penalization in winter.

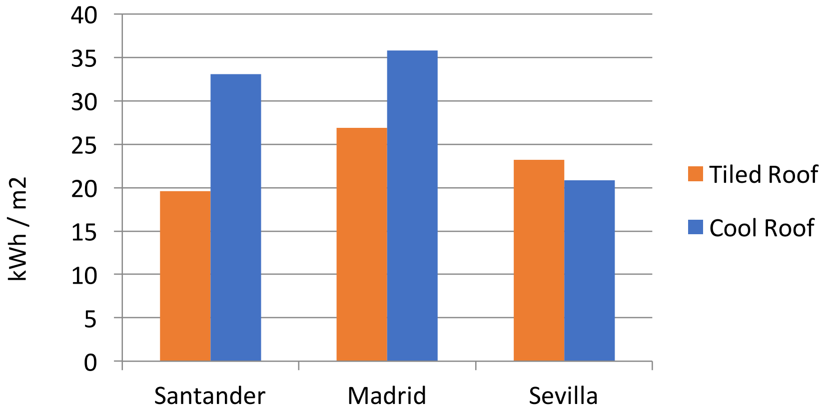

Figure 7 . Heat flux yearly balance

Conclusions

It can be established as a final conclusion that among the analysed locations, only for the city of Seville the studied Cool Roof provides energy savings. Instead for Madrid and Santander, the Cool Roof increases the energy consumption in order to get thermal confort indoor. However, other possible configurations of this kind of roof should be studied before to reject its use in cities with high levels of insolation like is the case of Madrid. However, its use in zones of colder climatology should be evaluated with caution due to the penalty in terms of the heat gain from a radiative source which is produced by this type of roof during the cold season, although in the light of climate change it should become clear, that the need for cooling most likely will increase, and that 'cool roofs' might be one part of potential measures to deal with increasing temperature levels.

deljavan.nastaran@gmail.com; soofia@metu.edu.tr

Abstract: Sustainable facades can be classified from many points of views. One may look at them according to their bioclimatic, energetic or technological properties; which in turn may change according to the geographic location or climatic zones, in which the building is to be constructed. Facades of high performance buildings may incorporate active or passive systems; and bioclimatic features having single, double or multiple skins. They may be completely or partially static or kinetic; stationary or dynamic; rotating, sliding or folding; with fixed or movable shading. The façade structure may be made of concrete, timber or metal with glazing, shutters, screens or trellises. The glazing may be clear, tinted or photo chromic; or it may be filled with a gas or a phase change material. In other words there are many different approaches to façade design for sustainability. This paper shall present the taxonomy of façade systems based on a survey of more than fifty buildings from around the world, which claim to be sustainable, low-energy, bioclimatic or green. Such a classification will be helpful in matching the objectives of façade design with appropriate design alternatives to achieve them.

Keywords: Sustainable facades, Responsive facades, Adaptive facades, Dynamic facades, Stationary facades.

Introduction

Responsive or adaptable building facades are being designed, developed and installed to lower energy consumption and increase human comfort at the same time. Ideally, the aim of façade design should be to improve the building's performance by providing thermal, visual, and acoustic comfort as well as a high level of indoor air quality for the health and well-being of the occupants. While the aim of the whole building design should be to ensure sustainability through energy efficiency, in order to reduce consumption; and energy generation, in order to become self-sufficient. A high performance façade is one which is able to attain both goals concurrently, i.e. energy autonomy and human comfort. To this end, various strategies can be adopted to achieve better human comfort and lower carbon footprint of the building. These strategies, some of which are active measures while others are passive, have been presented in Figure 1.

New techniques are being investigated to produce buildings that are more efficient and use renewable energies to reduce their carbon footprint. The most abundant and freely available resource being solar energy, which can be harvested through the building envelope and used for providing heating, cooling, electricity and hot water. Such building envelopes are generally referred to as solar façades, and can be classified into two main groups; opaque and transparent or translucent solar facades (Guillermo Quesada. Quesada *et al.,* 2012a). Both of these groups may have single or double skin façades (DSF) and may use passive or active systems to maximize the integration of solar energy; however, both are fixed or stationary facades. On the other hand, solar envelopes are undergoing a true revolution and their performance is being improved by adding movement to the façades or their components, in order to respond to the external climatic conditions. Such envelopes, that are also called kinetic façades, either track the sun to gain more energy for the buildings or use movable devices to avoid excessive solar gains.

New technologies and materials have made innovative facade designs increasingly possible for different climatic regions and different building typologies. Hence, many high performance buildings with sustainable, adaptive and responsive façades are coming up around the world, which are unique in their design. This study was aimed at classifying such buildings, located in different geographic and climatic zones, according to the design objectives and related strategies outlined in Figure 1.

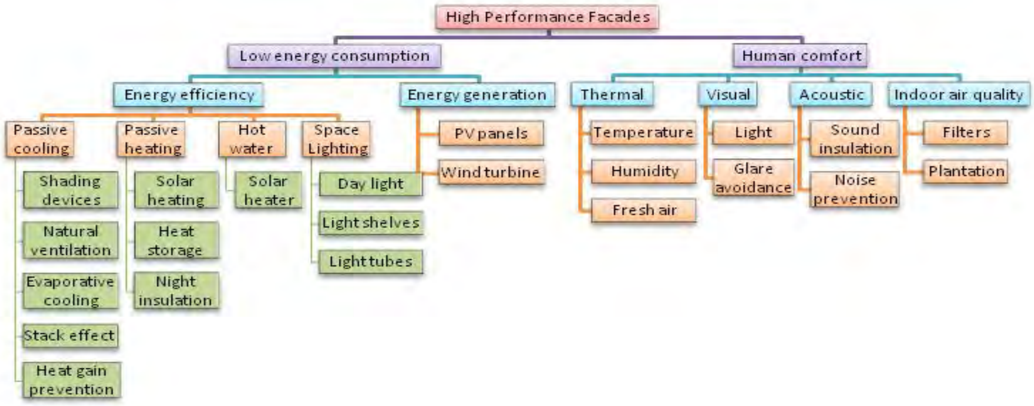

Figure 1. Design strategies for high performance façades with low energy consumption & high human comfort

Methodology

Fifty two buildings, which are acknowledged as having high performance façades that provide comfort condition and low energy consumption, were selected from literature and web-sources. These sources also included online videos and websites of the architectural firms that had designed these buildings. The 52 case-study buildings were then investigated according to the goals and related strategies presented in Figure 1 for high performance. The unique facades of these buildings were then classified according to the strategies that were considered in their design to achieve lower energy consumption without jeopardizing human comfort. These buildings were also grouped together according to 4 of the 5 main climatic zones as classified by Köppen; i.e. Tropical/megathermal climates, Dry (arid and semiarid) climates, Temperate/mesothermal climates, and Continental/microthermal climates. It was also possible to group the buildings according to dynamic or stationary façades; the former were further divided into three according to the movement of the facade elements, the whole facade or the entire building. Thereafter, all of the features mentioned in Figure 1 were identified in the fifty two building facades in order to understand which technique was used to attain higher performance. As a final step the façades were re-grouped from the point of view of these techniques and the taxonomy of sustainable façades was developed (Figure 3).

Case Studies

The fifty-two case studies belong to four of the five climatic zones defined by Köppen; there being none in the polar region. These buildings are listed in Table 1; and case study numbers assigned to them in this Table are given within curly brackets (e.g. {1,2,3..}) in the text.

Table 1. Information pertaining to the fifty-two case studies regarding their location, climatic zone, year of construction, facade typology; and web pages from where the information was retrieved.

Climatic zones are important in designing efficient buildings since they influence the selection of various façade technologies. As can be seen in Table 1, 33 of high performance case study buildings are located in the sub categories of the Temperate (mesothermal) climate zone;.9 each are in the continental and dry climate zones, while only one example belongs to the tropical zone. Also, most buildings are offices or residential buildings. Four of the case studies {6,7,17,27} were building refurbishment projects where the façade was renovated to include sustainable features. On the other hand, seven of the case studies {14,15,32,37,42,43,51} are conceptual designs that have not yet been constructed. Table 1 gives us a list of the 52 projects, their location and climatic zones, as well as the web sources from where additional or important information was retrieved. This table has also grouped them according to the facade typology (static or dynamic); strategies adopted and type of movement in the dynamic façades. Figure 2 shows facade details from {8, 16, 17,18, 28, &31}

Figure 2. Façade details from some of the case study buildings: Al Bahar Towers {31}, Hospital Manuel Gea Gonzales{17}, New Kuwait University{8}, Kiefer Technic Showroom{28}, Sony City Osaki{16} and Green Cast{18}

Approaches to sustainable strategies

An investigation into the 52 case studies helped to identify the various approaches to sustainable strategies most commonly used in the world. The most important goal in the design of facades being energy efficiency was achieved by using passive strategies for cooling, heating, hot water, and space lighting. Passive cooling design was based on solar shading devices, natural ventilation, evaporative cooling, stack effect, and avoiding excessive heat gain. The techniques to integrate these strategies in the façade designs are explained in the following sections.

Shading devices

Various solar shading devices with different materials, shapes, sizes and orientations were identified in the case study buildings; some were stationary and others dynamic; some were parallel to the large glass windows to block out the sun while others were perpendicular to provide shading. Shading was generally achieved with a second layer made of translucent materials, or perforated or punched metals. Movable panels tracked the sun's position not only for shading but also for views and natural light. Some buildings {1, 2, 12, 23, 24, 25, 26, 35, 36} had movable panels or horizontal louvers that rotated around their axes automatically, according to the sun's position; this is called axial movement {27}.

In one building {31} the facade elements close and open with sliding and retracting movements and could maintain several positions between fully open or fully closed. In one case {32} the elements were made of flexible strips and their sliding and retracting movement helped to achieve a metamorphic facade. The sliding motion has also been used for moving the entire shell (walls and roofs) in order to have closed or open spaces {33}. Folding technique is also used in the kinetic facades where perforated panels as the second layers fold up mechanically according the solar position {28, 29}. In two buildings {40, 41} shading devices in the form of panels unfolded automatically or manually to block intense sunlight or strong winds; another {30} had roller blinds to do the job.

Sun screens are designed as a second layer for shielding facades, in the form of translucent, perforated, or punched panels; or as enclosing metal mesh screen with various densities in different directions. Some screens were made of glass {3, 5, 17} while one {7} was made of textile stretched on three-dimensional support system around the building.

The new self-shading facades are composed of 3D elements which are designed according to the sun's angles and movement to shade the building facade at all times. These facade elements have many different forms with inclined surfaces or curved geometries and different depths; and are designed by using parametric design software which can model optimized elements to block out direct solar radiations. {6, 8, 9, 10, 14}

Horizontal and vertical panels or louvers as fixed or dynamic elements are designed in the cavity of DSFs as shading devices, with axial, folding or sliding movement. The materials which are used as panels in the cavity are translucent, or opaque with rectangular or curved shapes. The panels track the sun's movement automatically and computerized Building Management systems control the movement of the kinetic facade elements to provide environmental comfort. {34, 35, 36} Balconies and terraces act as an environmental buffer that protects the building from climate extremes in both summer and winter. {4, 23, 19, 16}

Natural ventilation

The most efficient way to provide fresh air is to cross ventilate a building, by installing operable windows in appropriate locations; In some buildings {2, 8, 13, 30 34, 41} automated management systems regulate the openings for occupant comfort. Night purging due to temperature differences between indoor and outdoor removes the heat accumulated during the day {23}

Extending the DSF beyond the roof and installing glass vents on the roof side instead of openings on top of the facade maintains transparency of the building facade {34}; the glass vents open automatically when the warm air needs to be exhausted. In another tall building {25} with a DSF, coloured ventilation flaps enable natural ventilation by opening automatically to maintain a constant temperature and pressure within the air cavity; this protects the occupants from intense air flow due to the inconsistent pressure differentials when the inner windows are opened. This system allows controlled natural ventilation for eight months independent of outside conditions. In order to withstand the high winds from the harbour, the second layer of a building's {20} DSF is made of fluorine-based plastic instead of glass and, the width of the cavity ranges from 1meter to 1.8 meters.

Stack effect

Vertical shafts designed as a solar chimney can enhance natural ventilation due to the stack effect; this principle has been used in two of the case studies {22, 30}; one on the north façade and the other on the south. Cooler air from openings on the opposite side of the solar chimney is exhausted by using a combination of stack effect and external pressure differences in summer to decrease indoor temperatures..

Evaporative cooling

Evaporative cooling can help reduce cooling energy loads; for example in one building {3} a pool is designed next to the building facade, which cools the air passing over it. The façade also has a sun screen in front of it that works as a vertical ventilation system and draws the cooled air into the building. A building {23} in Australia has five shower towers integrated into its north façade, that draw outside air from above the street level and cool it by evaporation of the rain water collected on the roof. The cooled air is channelled into tanks to pre-cool the water coming from the chillers panels which in turn contain steel balls filled with phrase change materials to keep them cold.

The Sony building {16} utilizes specialized ceramic louvers on the façade which circulate rainwater collected from the roof and stored in tanks; when the water evaporates it causes a drop in the surface temperature of the terracotta louvers, which are coated by titanium oxide (TiO_2) for retarding moss growth. This evaporative cooling system emulates traditional Japanese evaporative cooling screens made of thin bamboo.

Heat gain prevention

One way to decrease cooling energy loads is to prevent excessive heat gain through the façades, by using glazing material and strategies appropriate to the climatic zone where the building is located. The case study buildings have used insulated glass: insulated panels: high performance double glazing: double-glazed argon-filled glass; triple-glass with 3 mm Flake's glazing; laminated glass; various ceramic fritted glass types; and multiple-layered laminated glazing with an outer layer of ETFE (ethylene tetra fluoro-ethylene).

Some buildings have used DSF or multi-layered facades with insulated glass to prevent heat gain. Openings at the top and bottom of the cavity in a stationary DSF are used for regulating natural ventilation by stack effect thus decreasing indoor temperatures during summer. In dynamic DSFs of some buildings {21, 22, 25, 35, 36}, the windows are fitted with sensors and open or close automatically according to human comfort requirements. In one building {25}, the internal layer of the DSF is opened completely by the building automation system; thus reducing the annual energy consumption for HVAC; additionally blinds or solar shading in the DSF is also very effective. One other method to avoid heat gain in summer is to install vertical gardens on the facade; some buildings {18, 19, 22} have used such green walls as the southern façade

Passive heating

Using solar energy as a heat source can reduce heating energy consumption through passive strategies, such as a DSF that acts as a passive solar-thermal collector and heats the air in the cavity. This warm air augments space heating and also acts as an insulating buffer, that helps to conserve heat energy in winter {25, 34, 30}.

Hot water

It is possible to use solar energy for heating water for domestic hot water supply or for space heating. A pool in front of one building {3} contains water that gets heated due to solar energy and is then circulated in the heating system of the building. Another building {44} has solar tube collectors as balcony railings to provide hot water that can be used for domestic hot water needs or for space heating.

Day light

Maximizing natural light in the buildings is one of the important strategies to decrease consumption of electricity. The case study buildings have transparent or translucent materials to benefit from daylight; but its ratio to opaque materials differs, hence the amount of natural light penetration from various facades is completely different. Usually the northern facade is transparent to allow ambient light inside, whereas the southern facade is more opaque to protect the building from excessive heat gain. By incorporating a courtyard the number of facades are increased in the building, thus increasing the amount of external surfaces from which the building can take in natural light {1, 4, 33}. DSFs also allow maximum daylight penetration since both skins are composed of transparent materials {21, 22, 34, 35, 36}, which is usually glass. Although in one building {20}, ethylene tetra fluoro ethylene (ETFE), which is a kind of semi-transparent foil that allows natural light penetration, was used. Another way to maximize lighting levels is through dynamic facades that use light sensors which can monitor natural light availability and adjust interior lights accordingly, to reduce energy consumption {23, 24, 28, 35}. In one building {13} automated venetian blinds are installed leaving the top one-third of the window bare to admit natural light.

Visual Comfort

Large windows or glass facades allows for a visual connection between indoors and outdoors; however they also allow excessive sunlight and solar gains. But glare from reflecting or direct sunlight causes visual discomfort and should be avoided. Three approaches for glare avoidance were identified. The first one is using suitable material which can diffuse sunlight; such as: reflective glass, laminated glass, various ceramic fritted glass types, Flake's glazing, ethylene tetra fluoro ethylene (ETFE), or coloured glass {2, 8, 11, 12, 15, 25}. The second method is to integrate fixed or dynamic sun screens made of translucent materials; perforated panels; or metal mesh screens with various densities on the building facades {3, 5, 7, 27, 28, 29}. The third solution is to design self-shading facades with curved or inclined surfaces that can also diffuse day light {6, 8, 9, 10, 14}.

Acoustic comfort

In order to achieve acoustic comfort in the building, considering sound insulation and noise prevention are useful. In some DSFs the sealed cavity between the two layers, is used as an acoustic buffer. {20, 21, 22, 25, 34, 35, 36}

Indoor air quality

Indoor air quality has been provided through air filters or façade plantation. For example, special filtering screens having five three-dimensional modules made of titanium dioxide, been designed to provide fresh air in the building. This material possesses photo catalytic and anti-microbial properties that break down nitrogen oxides and other compounds by using high UV radiation levels and transforms them into water and calcium nitrate, which are washed off by the rain. The shape of the modules for filtering air pollution and emission is designed to receive maximum sunlight {17}. In one building a regular air pollution filter was installed {20}. Another more ecological solution is to use plants as air filters; e.g. in one building Bamboo plants are grown in the triangular cavities of its DSF; air is drawn in from the top of the DSF where the plants absorb the CO_2 and release oxygen into the air.The filtered air then flows under the building to be cooled through a thermal labyrinth and then supplied to the building {24}. Meanwhile, vertical gardens on the facades of 3 buildings {18, 19, 23} have been designed to act as an air filters.

Energy generation

Generating electricity by installing photovoltaic (PV) panels or wind turbines on the building can help achieve sustainability; excess energy that is not used can be stored in batteries for use when there is no solar or wind energy available. In some buildings, PV panels are installed on their facades to generate electricity and the angles of PV panels are arranged to maximize energy production {2, 10, 15, 42}. In some buildings {6, 16}, PV panels are installed on southern facades as shading devices with an angle which is appropriate for generating electricity as well as for blocking unwanted solar radiation. In a cylindrical building {38}, its dynamic PV integrated solar facade rotates around it to follow the sun, thus producing an energy surplus over and above the building's needs. The other source for producing energy is wind turbines, which are installed on facades or roof of some buildings {42, 52}; while on another building {23} it is installed on the shafts of the building facades.

Rotating buildings and towers

All rotating buildings have a fixed central service core while the living spaces rotate around it according the position of the sun. In winter time large insulated windows capture and store maximum solar energy during the day to heat the building at night; while during summer, the building rotates to face the right direction for natural ventilation, daylight, and shade. In dome-shaped homes, vertical windows assist to get more solar energy. By rotating the building, it is possible to control indoor temperature as well as provide a change of scenery {42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52}. Except for one building {52}, the others can rotate 360 degree on their own axis with various speeds for different buildings, automatically or manually with remote control. In most of the rotating buildings, the motor sizes are small, which can work with solar energy. In the rotating towers {42, 43}, the floors rotate independently thus changing the facades constantly. The unique envelope of the Rotating Ecohome possesses a high thermal mass; since the exterior walls are made of plastic pipes with vertical ducts passing through; and heated or cooled air is blow through these ducts according to seasonal demands, in order to heat and cool the building. The energy from the roof and facade of the building is stored in the machine room for later use.

Taxonomy of sustainable façades

From the case studies around the world, we can see that high performance facades can be divided into two categories, namely: stationary facades and dynamic facades; while each category can be further divided according to the technologies utilized (Figure 3). Dynamic façades are gaining popularity because they can respond and adapt themselves to the external climatic conditions by tracking the sun's position and thus enabling passive heating, cooling, ventilation, and daylight for saving energy. In most dynamic facades, photovoltaic panels are also integrated to produce the energy required for the mechanical movement of the façade elements. Kinetic facades elements with various motions help to optimize and regulate solar heat gains, light and air quality in the buildings and act as shading devices as well as energy engines. Additionally, shading devices are also important elements in stationary facades to block or allow solar energy inside the buildings.

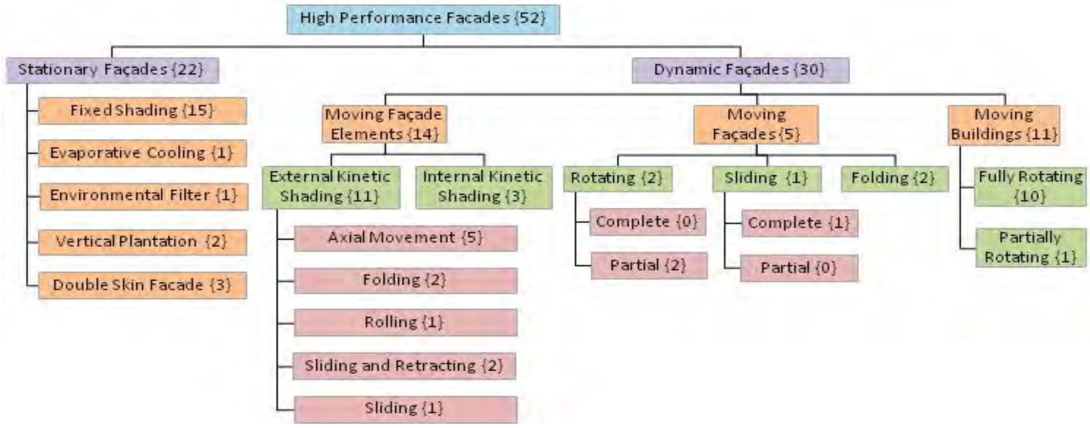

Figure 3. Taxonomy of high performance façades; numbers within brackets show the number of case studies.

Passive Low-energy Residential Buildings in China：Features and Calculation of Energy Demands*

Wu Di[1], Wang Nan[1] and Liu Conghong[1]

[1] School of Architecture, Tianjin University, Tianjin, China, conghong_Liu@163.com;

Abstract: Passive House provides beneficial lessons to Chinese energy efficient buildings. *Passive low-energy* or *passive ultra-low energy* buildings are concepts that are developed based on PH. During 10 years of development, many passive low-energy building projects have been constructed and being accepted by more and more people. However, the energy efficiency levels of Chinese passive low-energy buildings are still to a large extent using the PH standard. Besides, energy efficiency levels of current built energy efficient buildings are not clear because of most Chinese standards do not regulate energy performances. Since energy efficiency levels are the first step to achieve the nZEB goal, this study aims to calculate the energy demands of Chinese energy efficient buildings and passive low-energy buildings by a case study. Features of Chinese passive low-energy residential buildings will be summarized firstly, then the calculation will be conducted based on a high-rise residential building in Sino-Singapore Tianjin Ecocity (SSEC), in the cold zone of China. Six construction concepts will be modelled to represent the design patterns of Chinese energy efficient buildings as well as passive low-energy buildings. Energy demands of the six construction concepts will be calculated using PHPP.

Keywords: passive low-energy building, residential building, energy demands calculation

Introduction

Passive House（PH）is a solution for cold climate countries to reduce heating demand associated with buildings energy consumption. Under the support of Chinese government and Dena (Deutsche Energi-Agentur), China began to promote the concept of passive low-energy or passive ultra-low energy buildings to minimize the building energy consumption since 2007. During 10 years of development, there have been 37 demonstration projects constructed and the total construction area is 33,000 m^2 (2015 statistics).

The concept of passive low-energy or passive ultra-low energy buildings is developed based on the PH concepts and made some adaptive changes as Chinese climate is different from Germany. Previous studies have investigated the energy performance of passive low-energy buildings in different climate zone of China (Qiu Le,2014; Fan Yifei, 2013; Ma Yishuo, 2015). Xu Wei (2015) promotes energy performance criteria of Chinese passive low-energy buildings considering the construction technology, heating method, design layout of residential building and people’s living habits. Zhang Xiaoling (2012) points out that the expensive price of imported building components and equipment which reaches the

* The research is supported by International Science & Technology Cooperation Program of China (2014DFE70210);The National Key Research and Development Program of China(2016YFC0700201);The Program of National Natural Science Foundation of China (51338006); Innovation Base Introducing International Talents (Referred as 111 project) (B13011).

requirements of PH, and the defection of construction quality are also challenges of promoting PH designs in China. Peng Mengyue (2015) suggests to dividing the PH standard to four levels, they are bronze, silver, gold, and PH from low to high. However, the four levels only regulate design strategies and energy performance are not shown.

However, researches on the energy efficiency levels are relatively infrequent seen except for the mentioned studies above. One reason is the current Chinese standards systems define energy efficiency by means of percent (which will be discussed later) and lack of regulations on the energy performances. Since energy efficiency levels are the first step to achieve the nZEB goal (M. Ferreira et al, 2016). This study aims to calculate the energy demands of Chinese energy efficient buildings and passive low-energy buildings. Features of Chinese passive low-energy residential buildings will be summarized firstly, then the calculation will be conducted based on a high-rise residential building in Sino-Singapore Tianjin Ecocity (SSEC). Six construction concepts will be modelled to represent the design patterns of Chinese energy efficient buildings, including passive low-energy buildings. Energy demands of the six construction concepts will be calculated using PHPP.

Features of Chinese passive low-energy residential buildings

According to standard GB50176-93, China was divided into five zones in terms of climatic differences. They are severe cold, cold, hot summer cold winter, hot summer warm winter and mild. The following discussions are based on cold zone since heating demand account for a large proportion of total energy demands in this zone.

Architecture design

Compact high-rise buildings are predominantly built in China with the background rapid increase of urban population and the consequent shortage of urban land. In Beijing, the ratio of high-rise buildings has already increased to 50%-53% during 2000-2003, among which 16-20 storey buildings are the most common type (Jin Haiyan et al, 2012). Therefore, many passive low-energy demonstration projects are equally high-rise buildings, such as Zaishuiyifang C15# in Hebei(Figure1). The standard floor plan(Figure2) contains 3 apartments with a traffic core. Living room and main bedrooms usually locate in the south while kitchen, study room and secondary bedrooms in the north. All subordinate rooms are accessible from the central living room. No bay windows can be seen in this plan since bay windows are not encouraged for energy-efficient reasons since 2006.

Figure 1. Appearance of Zaishuiyifang C15#（18 storey）

Figure 2. Standard floor plan（the fifth storey）

Energy consumption

The interior environment, ventilation, heating and cooling method of Chinese passive low-energy buildings have some localized features due to Chinese people’s living habits or building standards (Table1). Compared with PH, the interior environment comfort level of

Chinese passive low-energy residential building is lower and natural ventilation is the primary way to solve the overheating problems in summer. People will open windows irregularly even during heating period according to a questionnaire survey (Chen Qingzhou, 2015). District heating is used with Split air conditioner is the most common cooling method. The cooling energy consumption of Chinese residential buildings varies radically due to different user behaviour and operating modes of HVAC systems. It ranges significantly from 164-2519 kWh/apartment·a (THUBERC , 2013).

Table 1. Design parameters comparison of PH and Chinese passive low-energy residential building

Design parameters	PH standard	Chinese passive low-energy residential building	
		Design or system choice	Reference
Interior environment	20℃ / 25℃ (winter/ summer)	▪18℃/ 26℃(winter/summer for bedroom and living room)	▪China energy efficient standards JGJ26-2010 and DB29-1-2013
		▪20℃ / 26℃(winter/summer)	▪China passive low-energy standards DB13(J)/T177-2015 and DB37/T 5074-2016
Ventilation	mechanical ventilation	▪natural ventilation primarily, even during heating period ▪fresh air mainly by opening windows and exhaust fans installed in toilet or kitchen	▪Chinese living habits and questionnaire survey
Heating	compact unit	▪district heating all time and all rooms in an apartment during heating period ▪or compact unit	
Cooling	compact unit	▪split air conditioner separately in each room ▪or compact unit	

Design parameters

The design of Chinese residential buildings shows obvious correlation with energy efficiency goals. The national energy efficiency goal of China is 65%, which means the design building should consume 65% less heating energy than the reference building (a typical residential building in the cold zone of China built in 1980-1981). Some local standard, such as Tianjin, has increased the goal to 75%. Passive low-energy standard such as Hebei standard is developed based on German basis PH criteria. The requirements of airtightness, envelope and energy performance are in line with PH criteria. The requirements of building thermal performances and airtightness are obviously higher than current national and local standard (Table 2).

Table 2. Energy efficiency design parameters

Design parameters		National standard (cold zone)	Local standard (Tianjin)	Passive low-energy standard (Hebei)
Height（m）		—	h≤3.0	—

Methodology

Based on the above analysis, six construction concepts can be extracted to conduct the following calculation (Table 3). These construction concepts are marked with specific energy efficiency goals, envelope performance, air tightness and ventilation mode. The analysis in Table1 and Table2 provide beneficial reference to these settings.

Case1 and Case2 are set to achieve a 65% energy efficiency goal. Case3 is set to achieve a 75% energy efficiency goal. Case4 is set based on project Zaishuiyifang C5#, first labelled passive low-energy building in China. This kind of setting is to represent a higher level of energy efficient buildings, with envelope very closed to PH but is natural ventilated and the common construction quality. Case5 and Case6 are set to achieve PH standard. The only difference lies in the ventilation mode. In Case5, hygienic air is provided by natural ventilation, while in Case6, the hygienic air is provided by a mechanical ventilation system with heat recovery. The envelope parameters of Case2 are the same with Case1, but the design layouts are optimized.

Since airtightness is hard to determine and lack measurement data, the n_{50} value of Case1, Case2 and Case3 is calculated based on GB/T 7106 level7, which represent a common level of airtightness of residential buildings, and convert to n_{50} according to the research of Feng Xiaohang (2014). The airtightness of Case4 is set as $2h^{-1}$, which is the medium level of double glaze windows according to EN12831. The airtightness of Case5 and Case6 is set as $0.6h^{-1}$.

Table 3. Six construction concepts of Chinese energy efficient buildings

Case	1	2	3	4	5	6
Model	Original	Optimized	Optimized	Optimized	Optimized	Optimized
Energy efficiency level	65%		75%	Zaishuiyifang C15#	natural ventilated PH	PH
Interior environment(C°)	18/26(winter/summer)					20/25(winter/ summer)
External wall ($W/m^2 \cdot K$)	30mm EPS-insulation U=0.69		75mm EPS-insulation U=0.45	150mm EPS-insulation U=0.3	250mm EPS-insulation U=0.150	250mm EPS-insulation U=0.150
Window	double glazing, 12mm Ar		double glazing, 12mm Ar	tripe glazing low-e, 9mm Ar	tripe glazing low-e, 12mm Ar	tripe glazing low-e, 12mm Ar
$U_g/U_f/U_w$ ($W/m^2 \cdot K$)	2.44 / 2.6 / 2.5		1.5 / 2.1 / 1.8	0.88 / 1.5/ 1.0	0.735 / 1.0 / 0.8	0.735 /1.0 / 0.8
SHGC	0.76		0.57	0.48	0.46	0.46
$n_{50}(h^{-1})$	4		4	2	0.6	0.6
Vent	only window ventilation		only window ventilation	only window ventilation	only window ventilation	balanced PH ventilation with HR

Numerical models will be built by Sketchup with DesignPH plugin. Calculation is conducted by Passive House Planning Package (PHPP), a comprehensive Excel workbook that was specially developed for planning Passive Houses.

Calculation of Energy Demands

Numerical model

Calculations are performed based on a high-rise residential building in Sino-Singapore Tianjin Ecocity (SSEC). The building can represent the common design of high-rise residential buildings in the cold zone of China. The 16-storey building contains four apartments per story, each with living area of 60-90m^2. An optimized model is formed by decreasing room height and heat loss form factor (ceiling and floor not included). The position of windows basically remains the same as the original model (Table4).

Table 4. Description of numerical models.

Model	Plan	Simplified appearance
Original Height:3.1m Areas:311m^2	Heat loss form factor (ceiling and floor not included):1.01	
Optimized Height:3.0m Areas:299m^2	Heat loss form factor (ceiling and floor not included):0.9	

Weather data other simulate assumption

Calculations are based on the PHPP climate data of Tianjin. This study considers the standard floor plan of an intermediate story. Details of a possible basement, the ground floor and the top floor are ignored in this analysis. Heat loss from the ceiling and floor is not considered so the U value of the ceiling and floor of the intermediate story is set as 0.25 for case1-case6. Geometric thermal bridges are ignored since they are not the main factors considered in this paper. Install thermal bridges are set 0.04 for all cases. The shading of surrounding buildings and window shading are not considered in this study.

Results and discussion

This study mainly investigates the heating and cooling energy consumption. Lighting, DHW, and auxiliary electricity energy consumption are not considered.

Figure3 depicts the heating and cooling demands of case1 to case6. We can see that heating is the main energy consumption for the cold zone of China compared to cooling and the total energy demands decrease significantly from case1 to case6 due to the decrease of heating demand. Only the energy demands of case6 almost achieve the PH standard. However, energy demands of the other five cases also make sense since they help clarify the energy efficiency levels.

The energy demands of 65% energy efficient buildings of China (case1) are 72 kWh/m^2·a for heating and 23 kWh/m^2·a for cooling. After optimizing the geometric factors (case2), the heating demand decreases 4% to 69 kWh/m^2·a but the cooling demand increases 8.7% to 25 kWh/m^2.a. The decrease of heating demand is predictable because the combined effect of optimizations in room height and heat loss form factor. However, total energy consumption does not show an obvious decrease in an optimizing model. Therefore, we can conclude that for conventional 65% energy efficient residential building designed according to JGJ26-2010, only optimize geometric factors such as heat loss form factor, room height or WWR are not enough to decrease total energy demands, further optimizations of envelope must be performed to achieve a higher energy efficient design.

The energy demands of 75% energy efficient buildings of China (case3) shows evident decline compared to Case1 and Case2. Energy demands are 54 kWh/m^2·a for heating and 21 kWh/m^2·a for cooling. Transmission heat losses through envelope decrease 27% compared to case1, which is the main reason of the decreasing of heating demand.

The energy demands of Zaishuiyifang C15# (case4) is 36 kWh/m^2·a for heating and 17 kWh/m^2·a for cooling. Heating demand decreases 50% compared to case1. Therefore, increasing the thermal performance of envelope as well as enhance airtightness are effective strategies to half the energy demands of current 65% energy efficient buildings. However, we can see that although the energy demands show an obvious decrease but still deviate from 15 kWh/m^2·a regulated by PH standard. The reason may be in the natural ventilation mode and the air tightness exceeding the recommended level(0.6h^{-1}). However, whether it is necessary to achieve this standard is another problem worth discussing.

For passive low-energy building which the envelope and airtightness achieve the PH standard but is natural ventilated (case5), energy demand is 21 kWh/m^2·a for heating and 16 kWh/m^2·a for cooling. The heating demand further decreased to 11 kWh/m^2·a after equipping a mechanical ventilation system with heat recovery (case6). However, cooling demands of case5 and case6 are basically the same, both 16 kWh/m^2·a. With the same air change rate, ventilation heat losses through mechanical ventilation system with heat recovery is near 50% less than natural ventilation through windows. Therefore, ventilation heat loss is the most important factor that affects heating demand for an apartment with high performance envelopes.

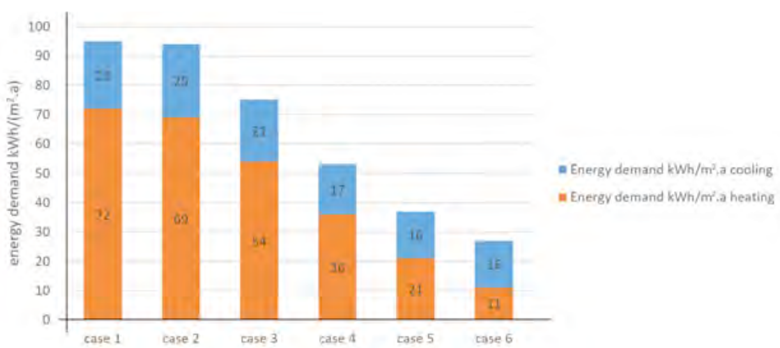

Figure 3. Energy demands of Case1 to Case6.

The comfort level presents a different trend from energy demands(Figure5). The discomfort level of over-humidity showed a basically increasing trend from case1 to case6. However, the discomfort level of over-heating has an inflection point. The natural ventilated passive low-energy building (case4) shows the lowest over-heating rate. PH, no matter natural ventilated (Case5) or with mechanical ventilation system (Case6), have the highest discomfort level though their energy demands are very low.

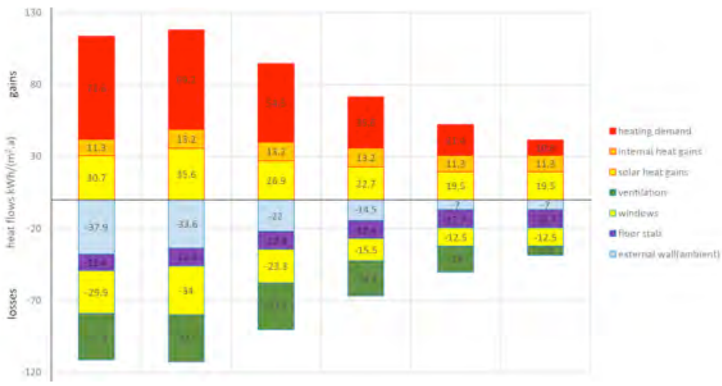

Figure 4. Energy flows of Case1 to Case6 in heating period.

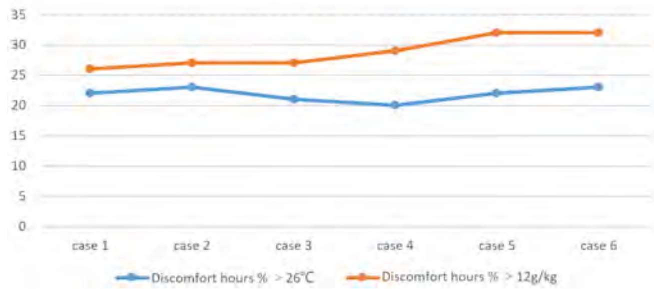

Figure 5. Discomfort hours of Case1 to Case6.

Conclusion

Six construction concepts were set according to the features of Chinese passive low-energy buildings. The energy demands are calculated.

For current 65% and 75% energy efficient Chinese residential buildings, the energy demands are 54-72 kWh/m^2·a for heating and 21-23 kWh/m^2·a for cooling. And the results show that further optimizations of the envelope must be performed to reach a higher energy efficiency level, instead of optimizing heat loss form factor and room height.

For passive low-energy residential buildings designed and constructed according to PH principles. The energy demands are calculated considering the impact of natural ventilation. Results show that for natural ventilated PH, the heating demand is 21-36 kWh/m^2·a, the cooling demand is 16 kWh/m^2·a. The heating demand decreases to 11 kWh/m^2·a when the natural ventilation is off and replaced by mechanical systems with HR. However, the over-heating rate of a natural ventilated PH is lower than a PH equipped with heating recovery mechanical ventilation system.

Design to Thrive

Research on winter physical environment and comfort of atrium space in public buildings in China's cold region

Yiming Du[1], Qiong Huang[1], Han Zhang[1], Nanjue Wang[1], Yu Mu[1] and Qi Zhang[1]

[1] School of Architecture, Tianjin University, Tianjin, China

Abstract: Atrium space energy consumption is an important part of public building energy consumption in china's cold region. Therefore, it also possesses huge energy saving potential. Because of the complexity functions of public building, atrium space usually have a higher demand in physical environment and comfort which are more important than the pursuit of energy saving. In this paper, the investigation focused on the winter physical environment and comfort of atrium space in hotel buildings, libraries and shopping centers. Arranged through the measured data and subjective questionnaire data, it revealed the shortage of atrium space physical environment and comfort in cold region. The main conclusions of this paper include: 1. According to the research, the average air temperature of atrium space in the public buildings is 22° in winter. This temperature stays in a relatively comfortable range. 2. The average humidity of the public buildings atrium space is less than 15%, which cannot display in the measuring instrument. 3. The average illumination of the public buildings atrium space is 1279 lux. Although 1279 lux stays in a comfortable lighting condition, its distribution is not uniform.

Keywords: Winter Physical Environment, Atrium Space, Public Buildings, Cold Areas in China

Introduction

The energy consumption in public buildings is much higher than that in the residential buildings. According to the data of China Building Energy Consumption Report 2014, public buildings' energy consumption is about three times that of the residential buildings. Compared with residential buildings, the atrium space is a unique part of the public building space types, which meanwhile means that the huge energy consumption of public buildings may be related to it.

As to the indoor comfort level of public buildings, China has the relevant standard gb//, in which indoor environment comfort indicators of public buildings with different sizes, scales and categories are limited. However, the design of public buildings is mostly in accordance with the "function-form" mode, with less consideration of the physical environment. Usually, high comfort level is achieved through air conditioning and heating systems and the artificial lighting system. The architectural design without the physical environment taken into account and the high requirements for comfort level are bound to produce higher energy consumption.

Public buildings have many categories, and this paper selects the atriums of library, shopping center and hotel as large space research objects. The choice of the atrium of library, shopping center and hotel is firstly because these buildings are the most frequently contacted and used buildings, whose energy consumption shall be the largest; secondly, these types of buildings are more, so the larger number of samples can provide more objective research results.

Object

The goal of this paper is to find the balance between the physical environment and comfort level of atrium space of the public buildings. The physical environment data for public buildings were obtained through field measurements of nine hotels, four libraries and six shopping centers in the cold climate area. By comparing the yearly physical environmental data of the public buildings with the environmental requirements put forward in the standard, the design refinement suggestions to improve the energy consumption of the public buildings in cold areas are proposed.

Methodology

This paper is based on the field measurement to achieve the physical data about the atrium space of public buildings. Through the comparison between measured data and standard data, find where the public space in cold areas can be improved.

For the field measurement, the physical environment measurement is mainly divided into thermal environment measurement and light environment measurement: the thermal environment takes air temperature and relative humidity as evaluation indexes, with HOBO U100-003 temperature data logger to measure, while the light environment takes illumination as the evaluation index, with XYI-III full digital illuminometer to measure.

The measure points' layout of the thermal environment is divided into the basic measurement points and the additional measuring points. The basic measurement points are the four directions of each floor in the measurement area and the corresponding position of the center, avoiding the position with large fluctuation of the environmental parameters such as the air outlet, the building entrance and exit; and as the supplement to the basic measurement points, additional points can provide the closer thermal environment data when the atrium area is too large.

As to the measurement points' layout of light environment, select the first floor of the atrium as the measurement area, with the 2-meter grid to lay out measure points.

Figure 3-1 Layout Diagram of HOBO Basic Measurement Points

Measurements

National Standard

The thermal environment takes air temperature and relative humidity as evaluation indexes. As to the standard, Code for Design of Hotel Building (JGJ 62-2014), Code for Design of Store Building (JGJ48-2014) and Code for Design of Library Building (JGJ 38-99) are the main reference, with relevant provisions of Design Standard for Energy Efficiency of Public Buildings (GB50189-2015) and Design Code for Heating Ventilation and Air Conditioning of Civil Buildings (GB50736-2012) as the comprehensive reference. And thus the thermal environmental assessment criteria are set as follows:

Hotel: air temperature at 20~22℃, and relative humidity ≥30%.

Shopping Center: air temperature at 18~24℃, and relative humidity ≥30%.

Library: Summer: air temperature at 18~20℃, and relative humidity of 40%～60%.

The light environment takes the illumination value as the evaluation index. Taking Standard for Daylighting Design of Buildings (GB50033-2013) and Standard for Lighting Design of Buildings (GB50034-2013) as reference standard, the light environment evaluation criteria are set as follows:

Hotel: Natural lighting: side lighting illumination of not less than 300lx, the top lighting illumination of not less than 150lx; Artificial lighting: no less than 200lx.

Shopping Center: General store business hall for 300lx, high-end business hall for 500lx, high-end hall for 200lx, corridor and mobile areas for 100lx.

Library: Natural lighting: reading room, side lighting of open-shelves stacks is not less than 450lux; the top lighting is not less than 300lux; side lighting of catalogue room is not less than 300lux; top lighting is not less than 150lux; side lighting of stacks and traffic is not less than 150lux ; and the top lighting is not less than 75lux;

Cases Selection

The standard for the choice of the atrium cases is determined as top surface lighting, with 75% of the enclosed surface as non-external wall surface. According to the above criterion, we have selected nine hotels, four libraries and six shopping centers in the cold climate area as the research objects.

As the physical environment involves the sensitive information of the hotels and other public buildings, the article takes H1-H9 as hotel cases number; L1-L4 as library cases number; and S1-S6 as shopping center cases number.

Table 1 Diagram and Information of Hotel Sample

L4			Skylight and Sidelight	No	
L5			Skylight and Sidelight	Yes	
Table 3 Diagram and Information of Shopping Center Sample

Sample NO.	Spatial Diagram		Spatial Interface		Picture
	Plane	Profile	Lighting Form	Sunshade	
S1			No Natural Lighting	Yes	
S2			Skylight	Yes	S3			Skylight	Yes	
S4			Skylight	No	S5			Skylight	Yes	
S6			Skylight and Sidelight	Yes	
Measured Data

In case of field research, collect the data specifically for twice daily at 10 a.m. and 2:00 p.m. respectively in winter.

Hotel:

Serial NO.	Thermal Environment			Winter Average Illumination
	Air Temperature		Humidity (medial humidity)	
	Maximum Temperature	Minimum Temperature		
H1	22.5	20.2	18	1564
H2	26.5	23.2	＜15	1240

H3	23.5	20.0	＜15	839
H4	23.8	22.8	＜15	46
H5	25.6	16.2	22	200
H6	26.3	21.9	＜15	274
H7	23.2	20.0	26	1564
H8	26.5	21.4	＜15	1240
H9	23.9	20.8	＜15	839

In winter, most of the low temperatures are in the comfortable range, and the high temperatures are generally higher; the humidity is seriously inadequate, with most below the instrument measured value, while in summer the humidity is in a more comfortable range Only one atrium cannot meet the standard requirements of illumination, and other atriums can meet the standard in winter.

Library

Serial NO.	Thermal Environment			Winter Average Illumination
	Air Temperature		Humidity (medial humidity)	
	Maximum Temperature	Minimum Temperature		
L1	22.6	19.36	<15	1400
L2	22.01	15.05	<15	1500
L3	27.5	21.4	<15	1500
L4	29.01	17.33	<15	580
L5	27.76	19.3	<15	280

The air temperature distribution is uneven: there are overheating phenomena for part of the survey samples, and also there is the situation that the temperature is below the standard requirement, which has the greater impact on comfort level. All the air humidity in winter is below the minimum measured value.

In terms of illumination, only one sample has the too low illumination, while the data of others are in the range of comfort level with slight fluctuation.

Shopping Center:

Serial NO.	Thermal Environment			Winter Average Illumination
	Air Temperature		Humidity (medial humidity)	
	Maximum Temperature	Minimum Temperature		
S1	24.53	18.23	＜15	437
S2	22.84	15.85	22.7	1018
S3	25.11	18.72	18.8	328
S4	24.25	14.98	＜15	485
S5	19.04	24.10	＜15	648
S6	18.26	25.94	＜15	649

In winter, the air temperature distribution interval is larger, and the lowest temperature is below the minimum of standard interval, and the high temperature is higher than the maximum of standard range.Only two centers' air humidity in winter can be read.

Calculation and Acknowledgement

Air Temperature

The average air temperature of atrium space of the public buildings in cold areas is 22°C, which is in a more comfortable and reasonable interval. Among them, the average air temperature of the atrium space in the shopping centers is the lowest at 20.6°C; the average air temperature of the atrium space in libraries is the highest at 22.7°C.

In terms of the hotels, the situation that the temperature is higher than the standard maximum occurs in winter. The too high temperature in winter will increase the heating energy consumption of the buildings, so it's suggested to do appropriate adjustment.

As to the libraries, the air temperature in winter fluctuates greatly, which needs to be adjusted appropriately.

With regard to the shopping centers, the air temperature fluctuates greatly in winter.

Air Humidity

In cold areas, the medial humidity of the atrium space in public buildings is very low, and most of the humidity of the studied atriums is less than 15% of the minimum measured value. Among the 41 studied atriums, only the exact value of 8 atriums can be read and the average humidity is only 22.9%.

Illumination

In cold areas, the average illumination of the atrium space in public buildings is 1279lux in winter. Although 1279lux is a more comfortable illumination environment, its distribution is not even. Among the 41 studied atrium spaces, the illumination of four spaces is less than 300lux, that of five spaces is more than 2000lux, and the illumination of these atrium spaces is beyond the comfortable range.

Abstract: With little regulation over energy consumption and a climate of cold winters and warm summers, the lack of benchmarks and built exemplars is a serious barrier to the development of an environmentally responsible architecture in Ankara, Turkey. The paper focuses on office buildings and draws upon the findings of recently completed research based on computational studies, using Radiance for daylighting and Energy Plus for thermal simulations, to explore the potential of passive design strategies taking account of orientation, external obstructions, solar protection and operational schedules including ventilation strategies.

Keywords: Thermal Performance, Daylight Performance, Ventilation Strategy, Office Building, Ankara

Introduction

According to national statistics some 470 office buildings were given building permits in the Turkish capital of Ankara in 2015 (TurkStat, 2016). Considering that the building sector is one of the largest energy consumers, it is crucial to follow-up current and future trends in occupancy and appliance use and how these affect internal heat gains and energy demand. There has been little research in Turkey on this topic especially in response to climate change. Johnston et. al (2011) described two likely future scenarios; one, where developments in technology would reduce the loads represented by appliances and artificial lighting (energy conscious scenario), and another where more and larger appliances (multiple monitors, media walls, etc.) would cause a massive increase in energy use (techno explosion scenario). The present paper summarises recent research (Durmaz, 2016) that looked at both of these scenarios as well as drawing comparisons with historical weather data and current operation of office buildings in Ankara.

Climate

Ankara is located in the central Anatolia region at latitude of $39^{o}56'$N and longitude $32^{o}52'$ E. Owing to its inland location winter months are cold and snowy, summers are hot and dry. Peak daily maximum temperatures can rise to 33^{o}C in summer with minima as low as -20^{o}C in winter (Fig. 1). Predictions for the year 2050 suggest an average increase of some 2^{o}C compared to recent historical data. Thus, future overheating problems should be considered while coping with the low winter temperatures. The high diurnal temperature fluctuations provide good potential for night-time cooling during summer. The adaptive thermal comfort band was calculated according to EN 15251 for Building Category II under present and future scenarios.

Analytic Work

Daylight Analysis – Part 1: Solar Protection Strategies

Daylight simulations were performed with Radiance using the Ladybug and Honeybee user interfaces. A room of depth 6.0m and floor-to-ceiling height 3.2m was used throughout (Fig. 2). The periods selected for study include the most problematic times for each window orientation. The different solar protection devices considered by the study were tested under both overcast and sunny sky conditions. The simulation parameters are listed in Table 1. Figure 3 shows details of the solar protection devices that were assessed. For south-facing openings an overhang of 1.5m was assumed in conjunction with translucent or opaque horizontal blades. For east-facing openings, horizontal foldable panel and vertical shading devices were modelled. For west and north orientations, variants of vertical devices were assessed. The figure summarises the results highlighting the best shading strategy for each orientation. The simulation results showed that all orientations except for north require solar protection on openings to control illumination levels (Fig. 3). Translucent shading devices perform better than opaque elements and can eliminate the need for artificial lighting during daytime even when the shading devices are in place. As can be seen in Figure 3, translucent vertical shading and horizontal foldable elements performed similarly on east-facing openings. The horizontal foldable panel has the advantage that it does not impair the view. The north facade required internal roller due to over illumination next to the window.

Daylight Analysis – Part 2: Determining Depth

For these studies the plan depth was varied in the range of 8.0-10.0m with one of its side looking into a three-sided atrium (Figs. 4 and 5). On the street side, the obstruction angle was assumed to be of 30 degrees from window sill. Vertical shading devices (VT: 0.25) were assumed for atrium roof and vertical glazing in the west facing atrium. Orientation of the atrium was varied between north and west in further studies. For this, shading devices were only applied to atrium roof and north facade left unprotected. On the atrium side of the new shoe-box, glazing was assumed to have a visible light transmittance of 0.85. Daylight factors (DF), the useful daylight illuminance (UDI), the daylight autonomy (DA) and glare risk were calculated to assess daylighting performance.

As expected, Fig. 6 shows that obstruction from buildings across the street results in lower DF values in all cases. With daylighting incoming from two sides, the CIBSE (1999) minimum requirement of 2% daylight factor was achieved for south, east and west oriented offices even when the plan depth was extended to 10m depth. A wide circulation zone was positioned near the center of the room with the workstations placed closer to the facades. For rooms with north-facing openings the 8.0m depth gave better results.

UDI predictions are summarized in Figure 6. Low UDI values near windows are an indication of over-illumination that may cause glare. For this study workstations were assumed to be positioned at a distance of 0.5m from the window for the south-facing cases, Fig. 6. This was increased to 1.0m for east and west facing offices. The UDI pattern on the west-facing case was not homogenous within 1.0m setback due to the nature of the vertical shading devices. On north-facing cases workstations were positioned at a distance of 1.4m from the facade.

The Daylight Glare Probability (DGP) was found to be below 0.35, corresponding to imperceptible glare. A higher prediction of 0.43 was obtained for west-facing openings fitted with vertical shading devices under overcast sky. This problem can be eliminated by tilting the vertical shading devices.

Thermal Analysis

Thermal simulations were undertaken with Energy Plus using the Open Studio plugin for Google SketchUp. The building model used was that for the "Daylight Simulations - Part 2". Key input data for the simulations are listed in Table 2 and Figure 7. Case A is based on the minimum standards of the TS825 Regulation (2008) for Region III. Case B represents typical construction in Ankara. Case C stands for best practice. A number of variants and operational conditions were studied and the results are summarized in Figure 8. Space heating and cooling loads were calculated for set points of 20°C and 26°C respectively. The simulations showed that differences in external obstruction did not have a significant impact on cooling loads owing to high summer sun angles. However, on East-West facing variants, the urban canyon had a significant effect in reducing cooling loads. Space heating loads increased, but by no more than 5 kWh/m² in all cases. Application of solar protection reduced cooling loads significantly, especially for Case C. Application of night shutters from November to mid-April improved performance in all cases. The efficacy of the night shutters was found to be directly related with the airtightness of the facade. The effect of higher air exchange rates, applied from May to October, varied.

Table2. General inputs and 3 envelopes defined for thermal simulations

GENERAL INPUTS	
AREA	225 m² (22.5 x 10m)
VOLUME	720 m³
OCCUPIED HOURS	09:00- 18:00 weekdays only
OCCUPANCY DENSITY	7.2 m²/person
LIGHTING POWER DENSITY	7 W/m²
EQUIPMENT POWER DENSITY	12 W/m²

	CASE A	CASE B	CASE C
INFILTRATION	0.75 ACH	0.5 ACH	0.3 ACH

EXT. WALL U VALUE	0.5 W/m²K	0.5 W/m²K	0.17 W/m²K
GLAZING U VALUE	2.5 W/m²K	1.55 W/m²K	1.55 W/m²K

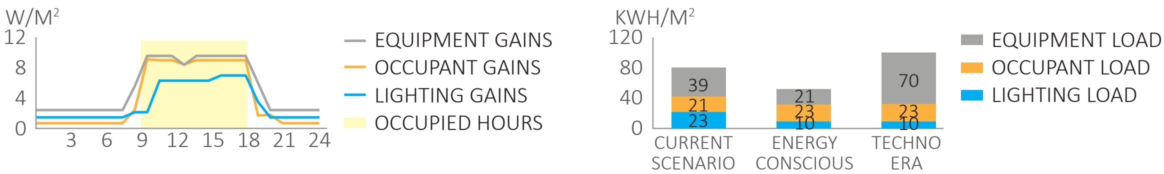

Fig7. Internal heat gain profiles for typical weekdays at present (left) and internal loads under current and future scenarios (right)

Space heating and cooling setpoints were re-adjusted for naturally ventilated cases in compliance with the EN 15251 (2007) adaptive thermal comfort band. For Case 4.3C, the cooling loads were reduced by up to 92% on the south-facing variants, Fig. 7. The south-facing offices were found to be free-running for 72% of the occupied time, Fig. 9. For other orientations, the free-running periods for Case C were 65%, 57% and 63% for east, west and north, respectively.

Cross ventilation and night-time cooling (Case 4.3) resulted in the best performance for all orientations. This variant was taken as a base case for the mitigation of climate change effects and for future trends in office design. Two future scenarios, Energy Conscious (5.1: EC) and Techno Era (5.2: TE) were tested (Fig. 10). South-facing Case C was found to perform best with 684 hours out of comfort under the EC scenario and 454 hours under TE, over a total of 2610 occupied hours, Fig. 10. Figure 11 shows simulation results for future variants of a south-facing office on typical summer and winter days. As can be seen in the figure, higher future outdoor air temperatures will make night-time ventilation necessary for summer cooling. Windows were assumed to be kept mostly closed during daytime. In winter, the rise in outdoor temperature may not be sufficient to compensate for the lower internal heat gains of the energy conscious scenario (Fig. 11 - Case 5.1). Hence, this will continue to require additional heating input for occupant thermal comfort. On the other hand, the techno explosion scenario (Fig. 11 - Case 5.2C) was shown to lead to overheating problems potentially throughout the year. The naturally ventilated period might need to be extended over the whole year or the building design specification should be reassessed.

Conclusions

The research summarized in this paper has shown the importance of window orientation in determining room depth and solar protection of workspaces in the climatic conditions of Ankara. Implementation of passive design measures can go a long way toward providing occupant thermal comfort for new office buildings. Conflicts between winter and summer performance tend to appear, but trade-offs can be found. The simulation studies showed that the atrium typology can provide better results for natural ventilation by exhausting warm air through the stack effect, and by creating a pleasant working environment for occupants. Occupant thermal comfort can be achieved for 72% of the time by the application of stack ventilation and night-time cooling on top of other passive strategies. Apart from the qualitative benefits, cooling loads can be reduced by up to 92% with a small penalty on heating loads.

Shading Historical Commercial Streets in Hot Arid Areas: Questioning the Common Wisdom

Mohamed H. Elnabawi[1], Dr Neveen Hamza[2], and Dr Steven Dudek[2]

[1] Faculty of Engineering, MSA University, Cairo, Egypt, melnabawi@aucegypt.edu;
[2] School of Architecture, Planning and Landscape, Newcastle University, UK

Abstract: Vernacular shading systems dealt with solar radiation as the dominant components driving the heat balance equation for the hot, arid climate. Its positive climatic effectiveness as a traditional solution are herewith questioned. In order to improve the microclimate conditions at pedestrian level three different shading scenarios addressing the form and the opening of shading devices were simulated using CFD Fluent, based on two dependant variables including air temperature distribution and wind velocity. The findings show that typology and the opening locations are the paramount factors in providing a temperature reduction in the urban scale.

Keywords: CFD, historical settings, microclimates, shading

Introduction

According to Ibn-Khaldun (14th-century Arab historiographer and historian), one of the primary tasks of architecture is to create favourable microclimates where humans can live and work (Rotledge and Paul, 1987). Successive processes of trial and error over long periods of time have given satisfactory answers of architectural concepts and techniques concerning human comfort and the surrounding environment. In Islamic Cairo, a number of strategies attributed to the Arab vernacular architecture and urban design were developed over a long period of time, such as fabric compactness, the thermal mass of the street surroundings' buildings, shading, night ventilation and evaporative cooling. Accordingly, shade is still the main variable to be taken into consideration when aiming for the rehabilitation of traditional retail streets, and its implementation in locations characterized by outdoor hot discomfort conditions for pedestrians (Marques de Almeida, 2006)

In Fatimid Cairo, The topology and form of the shading structures were designed to protect the pedestrians beneath from the hot arid climate (figure 1). The structure was shaped and oriented to provide shade by screening solar radiation and the shading materials was chosen to absorb and transmit a minimum amount of solar heat into the space, and work in conjunction with thermal mass distributed within the enclosure to stabilise temperatures. The shading structure was also designed with a number of different openings so that the stratified air escapes at night and to allow the daylight to penetrate the space in order to reduce the need for artificial lighting.

The research attempts to investigate three different shading scenarios, in the Fatimid city of Cairo, addressing the form and the opening of shading devices by employing

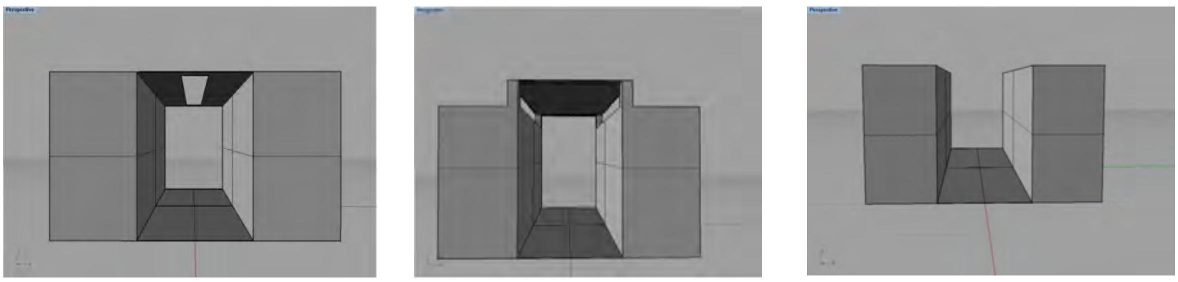
Computational Fluid Dynamics (CFD) to analyse two dependant variables including air temperature distribution and wind velocity.

Figure 1 the base case, as used by ancient town planners in the main commercial Street of the Fatimid city in order to provide both shading and daylight

Comparative study

The current research parametrically compares two shading configurations against a non shaded street in order to obtain the air temperature distribution and natural ventilation performance under each scenario. Each tested scenario, of the first two cases, consists of one specific geometrical change in the roof structure shapes and opening locations, while there was no roof for case number three as shown in Figure 1. The appropriate boundary conditions were set according to the same date used in the validation on 1st July 2012 as a representative for an extreme hot day (Elnabawi et al. 2013). All results were recorded at 1.4m above the ground level representing the average thermal affected pedestrians' height (Ali-Toudert and Mayer, 2007).

As shown in Figure 2, the aspect ratio (H/W) was the same for all the cases in being equal to 1.5, while the roof structure varied between the different cases. For instance, Case 1 was fully covered with one opening in the middle which is the existing configuration for the Fatimid city of Cairo, Case 2 had a roof 1m higher than the previous cases, with one opening on both sides and there was no roof for Case 3.



Case 1 (base case) Case 2 Case 3

Figure 2the alternative configurations for each case study with specific changes in the roof shape and opening locations

CFD simulation model

All the simulations were adjusted according to the best practice guidelines (BPG) scenario for developing existing urban configurations (Blocken, 2012), where the domain size, computational grid, boundary conditions, discretisation schemes, algorithms for pressure interpolation and pressure-velocity coupling are all well prescribed by BPG as stated in table 1.

Table 1Table 1Requirements for a consistent CFD simulation (AboHela et al., 2012).

Solution method	Second order schemes or above should be used for solving the algebraic equations
Residuals	in the range of 10^{-4} to 10^{-6}
Mesh	Multi-block structured mesh Carrying out sensitivity analysis with three levels of refinements where the ratio of cells for two consecutive grids should be at least 3.4
Turbulence model	Realizable k-ε turbulence model
Accuracy of studied buildings	Details of dimension equal to or more than 1m to be included
Domain dimensions	If H is the building height; lateral dimension = 2H+building width Flow direction dimension = 20H+building dimension in flow direction Vertical direction = 6H While maintaining a blockage ratio below 3%
Boundary conditions	Inflow: Horizontally homogenous log law ABL velocity profile _velocity inlet Bottom: No-slip wall with standard wall functions Top and side: symmetry Outflow: pressure outlet

Computational domain dimension and ABL profile

One of the main parameters affecting the reliability of the CFD simulation results is the horizontal homogeneity of the Atmospheric Boundary Layer (ABL) profile, which means the absence of streamwise gradients in the vertical profiles of the mean wind speed and turbulence quantities. This flow type occurs when the vertical mean wind speed and turbulence profiles are in equilibrium with the roughness characteristics of the ground surface. Fulfilling this requirement, first the model was placed in a computational domain with dimensions 147m x 85m x 45m as X, Y and Z (length, width and height), respectively. Then the user defined function (UDF) was used to specify the inlet boundary conditions satisfying equations (1), (2) and (3) for the velocity (u), turbulent kinetic energy (k) and turbulent dissipation rate (ε) respectively as mentioned by Richards and Hoxey (1993).

$$U = \frac{u^*}{k} ln \left(\frac{z+z_0}{z_0}\right) \quad \text{(Eq. 1)}$$

$$K = \frac{{u^*}^2}{\sqrt{C_u}} \quad \text{(Eq. 2)}$$

$$\varepsilon = \frac{{u^*}^3}{k(z+z_0)} \quad \text{(Eq. 3)}$$

Where (u^*)is the friction velocity(m/s), (k) is the von Kármán constant (= 0.40 or 0.42), (C_u) is the turbulence model constant, (z) is the height (m) and (z_0)is the aerodynamic roughness length (m), which is 0.5m or 1.0m depending on the wind direction. It is determined based on the updated Davenport roughness classification (Wieringa, 1992).

The bottom boundary condition was assigned as a rough wall and standard wall functions were used; the roughness height (ks) and roughness constant (Cs) were determined according to the relationship between ks, Cs as derived by Blocken et al. (2007b) satisfying equation (4) while the roughness length differs according to the nature of the terrain which is according to the case study equal 2.0 as described according to Davenport et al. (2000) for rough country as City centres with mixture of low-rise and high-rise buildings.

$$k_s = \frac{9.793\, z_0}{C_s} \qquad \text{(Eq. 4)}$$

The applied boundary conditions comprised of an inlet velocity of 3.5 m/s approaching from the north direction and inlet air temperature of 35^{o}C. The boundary conditions were assigned as symmetry conditions for all the sides and top boundary conditions, while the pressure outlet was imposed for the outlet boundary. The CFD simulations were then performed using the commercial CFD code Fluent 13.0 and the 3D steady RANS equations. Closure is provided by the realizable k-ε turbulence model (Shah et al., 1997). The choice for this turbulence model is based on the recommendations by Franke et al. (2004) and on earlier successful validation studies for pedestrian-level wind conditions (Blocken et al., 2007a, 2008b). Pressure velocity-coupling is taken care of by the SIMPLE algorithm. Pressure interpolation is second-order, and second-order discretisation schemes were used for both the convection terms and viscous terms of the governing equations (Blocken et al., 2012). The iterations were terminated when the scaled residuals did not show any further reduction with an increasing number of iterations. Horizontal homogeneity for the velocity (u), turbulent kinetic energy (k) and turbulent dissipation rate (ε) profiles were achieved throughout the computational domain. The profile was written from the outlet to be used as the inlet profile for all the simulations in the research.

The CFD model validation

According to the best practice guideline (BPG), the study was developed in an existing urban configuration with the availability of on-site field measurement. Therefore, the simulated CFD output was validated against the experimental measurement for the existing case. The results of the validation are presented within the graph as shown in Figure 3, and the simulated air temperature is compared with the in-situ air temperature measurements taken at three-hour intervals starting from 3:00 until 24:00 on 1st July 2012. It can be observed that the simulation results show a consistent trend with the observed ones and that the temperature differences are within 0.8°C to 1.2°C.

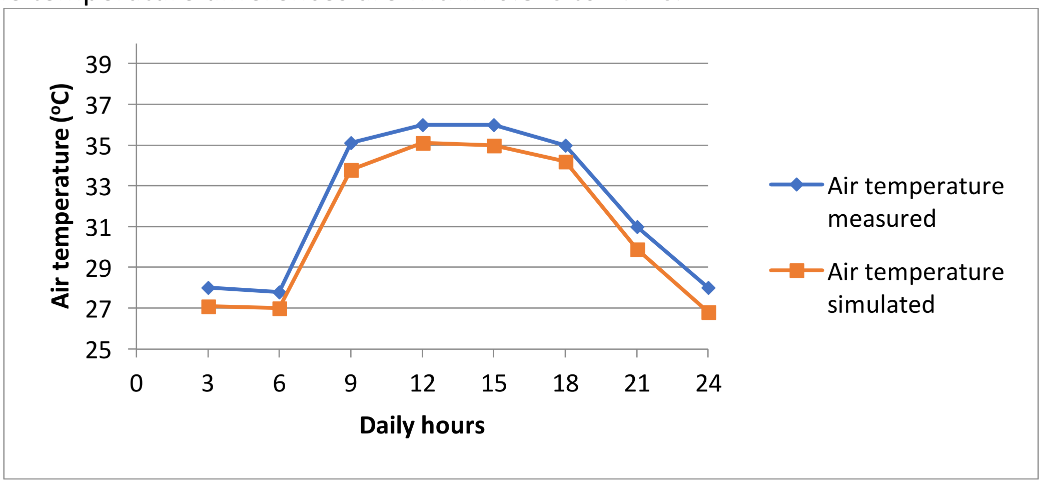


Figure 3 Comparison between the air temperature measured and the CFD output for the existing case on 1st July at pedestrian height of 1.4m

CFD simulations: comparative results

Comparison of the vertical profiles of the mean wind velocity

In order to examine the effect of wind speed at the pedestrian level, the vertical profiles of the mean wind velocity were measured at a point on the centre line of the street across the prevailing wind direction with a reference wind speed equal to 3m/s at U10 (at10m height) based on field measurements. Figure 4 shows the vertical profiles of all the cases from 0m at the ground level to 7m at the roof level. All cases may have had a similar profile until they started getting closer to the roof and the openings when the vertical profiles started to vary.

All three cases showed a consistent increase in air velocity with height but varied at roof level. Case 3 (without a roof) kept on the increasing trend of its vertical profile. In case 1, the centre roof opening assisted the wind to rise smoothly without much slowing down of its speed (almost 0.05m/sec velocity reduction). On contrary to case 2, where there was no opening in the roof centre, the wind velocity had to slow down and was released through the two side openings instead where the wind velocity reached its maximum, at 2.1m/sec, before it declined by reaching roof level recording 0.70m/second. This indicates that roof structure and different openings significantly affect the wind profiles beneath. The result is consistent with a previous study by Ng et al.(2011), which stated that the wind environment at the pedestrian level is not affected by building height but is significantly influenced by urban geometry in the pedestrian level.

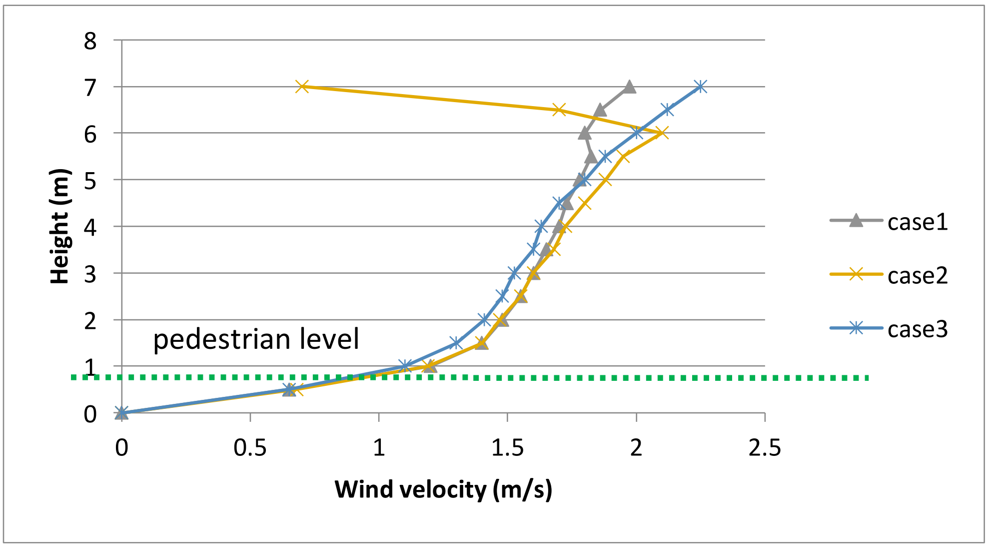

Figure 4 the vertical profiles of the mean wind velocities from the CFD simulation located at the centre line of the street (from 0m on the ground level to 7m on the roof level)

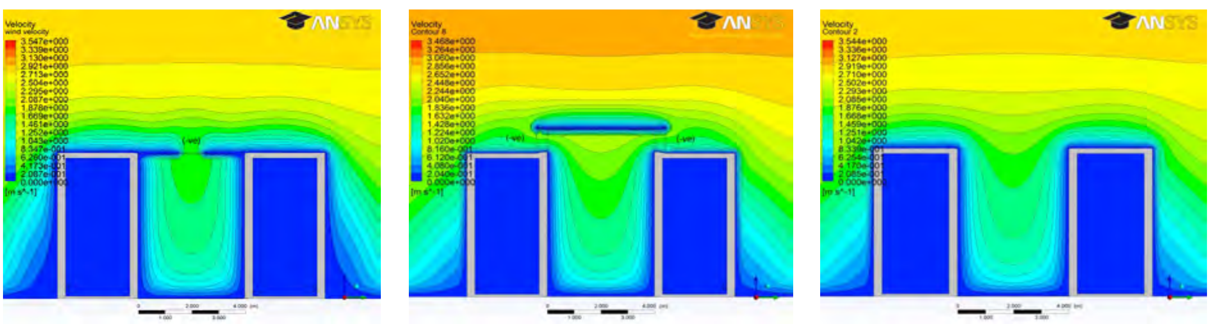

Case 1 (base case) Case 2 Case 3

Figure 5 the vertical wind speed contours at the centre line of the model

Comparison of air temperature distribution

The vertical profiles of the mean air temperature were measured at a point on the centre line of the street across the prevailing wind direction with a reference air temperature at the inlet equal to 35°C, as conducted from the field measurement. As illustrated in Figure 6, the air temperature vertical profiles were plotted for all the cases from 0m to 7m above the ground level.

All cases started between 32.4°C to 33.4°C at level zero as the surface temperature, which is lower than the inlet temperature due to the shading effect. Once the vertical profiles reached the pedestrian level (1.4m) above the ground level, case 3 recorded the highest air temperature followed by 1 and 2, all with minimal difference less than (0.2°C). The same four cases had the same trend of the vertical profile till reaching the roof level when case 2 faced a slight increase in air temperature directly under the roof before decreasing again at the side opening level. Therefore, it can be concluded that case 2 represented the best performance for having the lowest air temperature at the pedestrian levels between (1m to 2m above the ground level), as it kept 0.4°C difference with case 3 and 0.2°C difference with the base case 1. The air temperature distribution was directly proportional to level height: the higher the level, the higher the air temperature till the vertical profile meets the side openings when the air temperature suddenly increased due to the direct contact with the external air temperature at 35°C. This migration of warm air to the top of the enclosure offers potentially more comfortable conditions resulting from cooler air collecting at ground level in the inhabited zone. Moreover, the results indicated a negative correlation between the air temperature distribution underneath the different roof shapes and the ambient wind speed, as the wind speed increased about 1.4m and there was a rapid drop in temperature. This effect of wind velocity has been reported by numerous studies (Ng et al., 2008; Yuan and Ng, 2012), including Cheng et al. (2011), who reported that a 1.0m/s to 0.3m/s decrease in the wind speed is equal to a 1.9°C temperature increase, and Memon et al. (2010), who stated that air temperatures rose as high as 1.3K when ambient wind speed decreased from 4 m/s to 0.5 m/s.

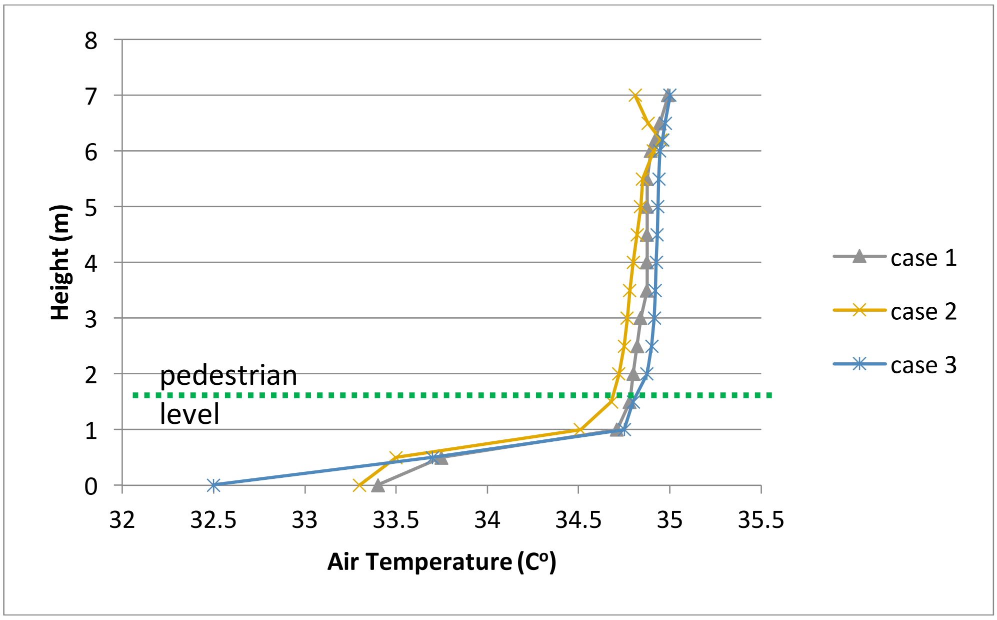

Figure 6 the simulated vertical profiles of the air temperature located at the centre line of the street (from 0m on the ground level to 7m on the top roof level)

Conclusion

As stated by numerous researchers, (Ali-Toudert and Mayer, 2006; Pearlmutter et al., 2007; Middel et al., 2014), the shading is the dominant factor driving the heat balance equation in the hot, arid regions. shading can provide a favourable reduction of the air temperature underneath up to 2.5^{o}C (Elnabawi, 2016) and it can improve the ambient air temperature by up to 15% based on a study conducted by Arizona State University in Phoenix, which is classified as a hot, arid climate (Love, 2009). However, during the night time the effect of the high shading patterns was largely reversed, which impeded the long wave radiant heat loss to sky due to the constricted SVF. According to Oke (1981) and Barring et al. (1985), the low sky view factor delays the cooling surface during clear calm nights where the heat released from the canyon materials is trapped in the canyon air volume (Svensson, 2004). In Japan, Kakon and Nobuo (2009) reported that increasing SVF by 10% would decrease UHI by 0.3% at night time.

The findings show that the structures' typology is one of the paramount factors in providing a temperature reduction on the urban scale while the opening locations is responsible for facilitating the heat release to escape at the night-time, where the minimal modification between the two scenarios leads to a reduction of air temperature with almost 0.5^{o}C due to the change in the opening locations and numbers as it causes a higher air exchange rate underneath, which has a positive effect in decreasing the air temperature. Hence, a high level of shading is required in outdoor environments to increase thermal comfort and extend the continuity of the acceptable thermal conditions during the day (Ali-Toudert and Mayer, 2006; Makaremi et al., 2012; Middel et al., 2014). However, a quantitative based study was still required for more different shading patterns.

[2.] sdeschiller@gmail.com

Abstract: This paper presents studies developed for the new energy labelling of housing in the proposed Argentine IRAM Standard 11.900 showing the potential for reducing energy demand in the residential sector. The process identifies the role and importance of passive bioclimatic design as a vital component of the estimated energy demand. In this framework, the proposed energy standard for energy labelling of housing includes a classification for passive design strategies that contribute to reduced energy demand in the widely varying climatic regions of Argentina, from latitude 22° in the tropics to 55° S with a sub-Antarctic climate, and from the coast to the high Andes. The paper then explains the climatic analysis procedure compared with comfort conditions to detect bioclimatic indicators that identify general strategies and specific design resources. Based on the concepts of the Mahoney Tables, Givoni's bioclimatic chart and the Evans Comfort Triangles, the study includes additional design resources and criteria to evaluate projects at the design stage, providing a list of passive design resources while defining the thermal properties contributing to reduce energy demand in existing and new housing. An alternative method evaluates their effectiveness of design resources when the design process is complete using detailed energy simulation.

Keywords: Bioclimatic Design, Energy labelling, Climate analysis, Thermal comfort.

Introduction

This paper first analyses the energy intensity of different sectors of the economy over the last decade to show the poor performance of housing when compared with other sectors of final energy use. This factor has promoted the introduction of energy labelling for housing to measure and promote energy efficiency, including the thermal performance of the building and the efficiency of the installations, following the strategy adopted in Europe (BRE, 2014, EU, 2010).

The energy certification of housing in the proposed Argentine IRAM Standard 11.900 (2010) identifies the importance of passive bioclimatic design as a vital component of the estimated energy demand. This study presents a method for identifying passive design strategies that will achieve reduced energy demand in the widely varying climatic regions of Argentina, from latitude 22° in the tropics to 55° S, and from the coast to the high Andes, over 3000 m above sea level. The paper presents the sequence of climatic analysis and comparison with comfort conditions, to detect indicators of dryness, humidity and coldness. This leads to the identification of general strategies and specific design resources. The paper indicates complementary actions to verify the results.

Comparative Energy Intensity

The Argentine National Energy Statistics show the energy demand according to primary and secondary energy sources for each economic sector for the period 1965-2015 (MINEM, 2017). The analysis presented in this paper shows that the residential sector has the highest average annual increase in both relative and absolute terms over the last 50 years. It also has the worst tendency in energy efficiency in the last decade.

To estimate changes and tendencies of efficiency in different sectors, variation in energy intensity in each of them were estimated for the last decade (2006-2015). Figure 1 shows an index of the estimated energy intensity per sector compared with indirect indicators of the level of energy service, according to the following evaluation:

- **Gross Domestic Product**: The GDP per capita, at constant dollar value, is compared with energy use. After a decade, the GDP per capita has increased 127 %, with little change in the energy demand for all final uses. The generation of 1 dollar GDP in 2015 requires 47 % less energy than in 2016.
- **Automobiles and other light vehicles:** The number of registered units is compared with the final petrol and gas use in transport (gas is widely used in light vehicles). In 2015, each vehicle used on average 16 % less energy than in 2006.
- **Heavy vehicles, buses and lorries**: The number of vehicles is compared with the diesel fuel used. At the end of the decade, each vehicle uses on average 33 % less energy.
- **Non-residential buildings:** The number of employees in the service sector, excluding occupations that do not use buildings is compared with energy use in non-residential buildings. On average, the energy used by employee in this sector has not changed significantly over the decade.
- **Residential sector:** The number of houses is compared with energy demand. Each house has increased its energy demand by 25 % during the decade, though the number of occupants has declined, average house size is lower and the efficiency of equipment and installations, heaters, air-conditioners, lighting, fridges and freezers, etc., has increased significantly.

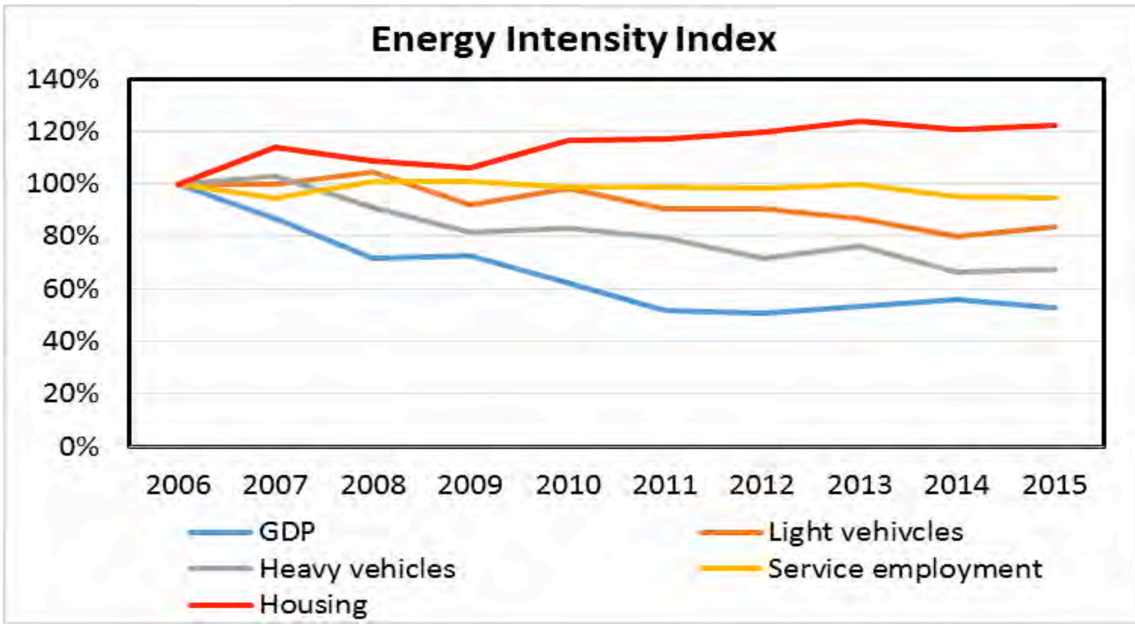

Figure 1. Index of energy intensity in different sectors according to final energy use, 2006-2015 (Authors estimates using data from MINEM (2017), INDEC (2017) and other sources.

The clear difference between increasing energy use in housing and stable or reduced energy use in other sectors is due to a number of factors: improved environmental quality with better thermal and lighting conditions, increased numbers and sizes of electrical goods, such as televisions, computers, wifi, cell phones, refrigerators, etc. However, most of the energy demand in the residential sector is for heating (de Schiller and Evans, 2015), and it is concluded that the declining thermal quality of buildings is a major factor.

Standards of energy labelling and performance

Energy standards for buildings were introduced in Argentina in 1970 to ensure minimum thermal performance of low cost housing (IRAM, 2009). These have been modified and adjusted over the years, although today's low cost housing standards continue to have similar thermal performance to the requirements of 40 years ago. Apart from local legislation in the Province of Buenos Aires (2007), the City of Buenos Aires (2017) and the Municipality of Rosario (2015), there is no obligatory thermal performance standard for building of the private sector. One of the difficulties of implementing improved thermal standards is the existing legal framework, as municipalities with limited technical capacity are responsible for developing and applying building codes, considering over 2000 different municipalities in Argentina, with 124 in the Province of Buenos Aires. Another difficulty is the wide range of conditions, from warm humid sub-tropical climates at latitude 22°, hot dry continental climates, cold and dry windy climate in Patagonia, with sub-Antarctic climates at latitude 55°, and cold climates in the high Andes at over 3000 metres.

Energy labelling is an effective measure to evaluate and improve energy efficiency, and Argentina has achieved considerable improvements in fridges, freezers and lamps, as a result of compulsory labelling and eventual prohibition of equipment with low efficiency. A standard for labelling of efficient windows, based on IRAM (2010), will be approved shortly. In 2007, a new standard for energy labelling of housing was approved (IRAM, 2007) but was not compulsory, so it had no practical effect on energy efficiency in buildings. Due to difficulties with increasing energy tariffs, high costs for exploration and extraction of hydrocarbons and growing energy imports, the present government is proposing a revised energy labelling standard. In addition to the estimated annual energy demand, the proposed new standard includes indicators of the components that contribute to energy efficiency: efficiency of heating, cooling, artificial lighting, and hot water systems, incorporation of renewable energy and bioclimatic design.

This paper describes the proposed procedure to evaluate the contribution of passive bioclimatic design indicators to energy efficiency. This is considered especially important in new buildings, as designers can use these indicators to identify bioclimatic design resources for each climatic region, before detailed energy performance calculations can be made. They also show possible but limited bioclimatic improvements in existing housing.

Figure 2 shows the structure of the proposed standard, the relation between different components of the standard and the importance of bioclimatic design strategies. Appropriate passive or bioclimatic design solutions will have a cumulative effect, reducing the energy demand for heating, cooling and artificial lighting, acting in combination with improved efficiency of the installations. They also increase the percentage contribution of renewable energies.

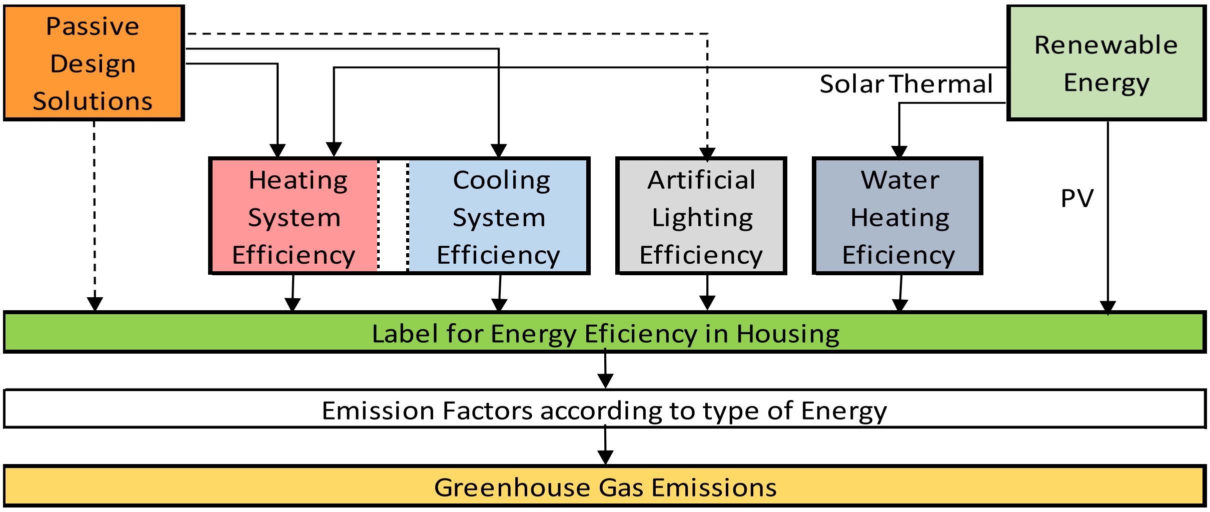

Figure 2. Structure and components of the proposed standard for energy efficiency in housing, IRAM 11900.

Procedure

The procedure aims to evaluate the contribution of bioclimatic design to energy efficiency in housing projects using a scale from 0 to 6. This complements a similar evaluation of the energy efficiency of heating, cooling, lighting and water heating installations as well as the possible contribution of renewable energy installations. The procedure consists of four stages starting from the design and construction components that can contribute to energy efficiency and finishing in the degree to which the design responds to the bioclimatic strategies required in a specific climate:

- **Ranking design and construction solutions:** 18 potential bioclimatic design and construction resources incorporated in the house design are evaluated according to performance alternative standards on a scale from 0 to 6, for example different levels of thermal transmittance, roof reflectivity or compactness of building form.
- **Integrating response to bioclimatic strategies:** Groups of these design resources are evaluated according to their response to each of the 6 bioclimatic strategies considered, with a weighting system to obtain a composite score using the same 0 to 6 point scale. These resources include energy conservation, solar protection, and response to cross ventilation.
- **Identifying the importance of each bioclimatic strategy:** Climate files of daily data for specific locations are analysed to detect the proportion of time that each design strategy is required.
- **Relating bioclimatic responses to the required strategies:** The final score is obtained according to the importance of the response to each bioclimatic design strategy that contributes to energy efficiency according to balance of bioclimatic requirements and the bioclimatic characteristics of each location.

Each of these steps is explained in the following sections. The relation between the design and construction solutions and the bioclimatic strategies is shown in Table 1. Initially 43 design and construction solutions were identified, but this number makes the application of these criteria difficult. So those solutions that had limited effect on overall energy efficiency were eliminated, for example the thermal performance of window frames. The number of bioclimatic design strategies was also reduced to 6 from the initial 16 defined for housing in the Climate Consultant (UCLA, 2017), or the 11 strategies proposed by Givoni (1980). For example, the humidification strategy recommended for very dry conditions was eliminated as the frequency of these conditions is very low in most locations in Argentina and the impact on energy efficiency is limited, although this strategy does contribute to comfort. As another example, wind protection in outdoor spaces was also eliminated as it has limited impact on energy demand in indoor spaces

Table 1. Relation between bioclimatic design strategies and design and construction resources.

		Bioclimatic design strategies						
N°	Bioclimatic resources, design and construction	Thermal insulation	Thermal inertia	Solar protection	Cross ventilation	Passive solar	Selective ventilation	Total
1	Thermal insulation roof	1	1	1		1		4
2	Thermal insulation walls	1	1			1		3
3	Thermal insulation glazing	1	1			1		3
4	Thermal insulation floors	1	1			1		3
5	Thermal inertia roofs		1			1	1	3
6	Thermal inertia walls		1			1	1	3
7	Thermal insulation floors		1			1	1	3
8	External colour roof			1				1
9	Window orientation, sun			1		1		2
10	Solar protection, glazing			1		1		2
11	Passive solar systems					1		1
12	Floor to cieling hieght	1					1	2
13	Contact, party walls & other dwellings	1						1
14	External solar shading			1		1		2
15	Glazing in roof	1		1		1		3
16	Compact form	1	1		1	1		4
17	Glazing as % of wall	1		1	1			3
18	Conditions for cross ventilation				1			1

Ranking architectural and construction solutions

In order to evaluate existing housing or projects at the design stage, possible alternatives of each of the bioclimatic design or construction solutions were identified, based on quality levels defined wherever possible in existing standards and qualified in a 6 point scale ranging from ‘deficient’ to ‘optimum’. The simplified definition of alternatives is designed to facilitate evaluation of both new and existing housing.

Table 2 shows an example for the thermal insulation solutions. The standard identifies these alternatives and the rating for each of the 18 design resources or solutions.

Table 2. Example of the rating for thermal insulation alternatives.

Rating	Criteria	Standard	Example: walls in Buenos Aires
0	Deficient	Not compliant IRAM 11605	K > 1,85
1.5	Minimum	IRAM 11605, Level C	1,85 < K < 1,0
3	Average	IRAM 11605, Level B	1,0 < K < 0,38
4.4	Excellent	IRAM 11.605, Level A	0,15 < K < 0,38
6	Optimum	Passive House standard	K < 0,15

Notes:

- K = Air to air thermal transmitance W/m^{2}K (U Value)
- IRAM Standard 11605 (1998) defines three levels of thermal transmittance values for walls and roofs according to the winter minimum design temperature and the maximum summer design temperature with average external reflectivity. (Roof colour is covered by different design solution (N° 8 in Table 1).
- Passive House Standard (PHS, 2017) indicates an optimum level although not an Argentine standard.

Integrating response to bioclimatic strategies:

There is a complex relation between bioclimatic strategies, and design and construction solutions, with many solutions contributing to more than one strategy, and all strategies are modified by two or more design and construction solutions. As Table 1 shows, 9 design and construction solutions contribute to energy conservation and to thermal inertia, while 13 are related to the effectiveness of passive solar systems. Solar protection and ventilation strategies also relate to various solutions. The aim of this section is to evaluate the partial contribution of each solution to bioclimatic strategies.

The standard proposes a weighting system to evaluate the impact of each solution in the response to each bioclimatic strategy. The weighting can depend on aspects of house design. For example the overall thermal inertia of the house depends on the thermal inertia of the building elements in contact with indoor air, and surface areas of each as well as compact form and the contributory effect of thermal insulation. Table 3 presents an example of the application of the weightings for thermal inertia. This includes weighting factors for the proportion of floor to wall surfaces for two story housing compared with one story housing. A spread-sheet has been prepared to facilitate the application of the weighting system using the selection of alternatives from pull-down lists.

Table 3. Example of the application of the weighting system to evaluate response to thermal inertia strategy.

Design solutions	Weight	Points	N° of Floors = 2	Weighted Points
Thermal inertia roof	Average	2,5	0,19	0,5
Inertia external walls	Average	2,5	0,19	0,5
Inertia internal walls	Heavy	5	0,19	1,0
Inertia ground floor	Very heavy	6	0,12	0,7
Inertia ceiling	Average	2,5	0,19	0,5
Thermal Inertia upper floor	Average	3	0,12	0,4
Points without weighting				3,5

Housing form	Compact 2 floors	0,4
Thermal insulation	Minimum, Level C	0
Total points with weighting	Average	**4**

Reference tables identify construction alternatives that correspond to thermal inertia levels, based on surface density in the construction layers in the 10 cm closes to the indoor surface of the component.

Identifying the importance of each bioclimatic strategy

For consistency, EPW data files are used for the analysis of climatic data, as these are also used in the detailed energy performance calculation. The 'climate evaluator' (UCLA, 2017) based in the bioclimatic chart (Givoni, 1980) was used initially to analyse the relative requirements of each strategy. It requires adjustments for the climate variations, comfort expectations and building technologies of Argentina. A revised chart was prepared using a spreadsheet to process the EPW files and obtain indicators of the bioclimatic requirements based on the number of hours with specified conditions, with the following adjusted criteria.

- The lower limit of the winter comfort zone is fixed at 18° as proposed by Givoni, rather than 20° C, considering an average indoor temperature.
- Passive solar systems are only indicated for daylight hours with solar radiation. Solar radiation is also favourable for energy savings when the temperatures are below 10° C.
- Thermal inertia is indicated when heavy construction can improve thermal comfort on days with high thermal swing, or when heat storage improves energy efficiency. The comfort triangles (Evans, 2003) are used to establish requirements for thermal inertia.

The climate data analysis shows the proportion of time that each strategy is required. In addition to the analysis based on the Climate Evaluator, two further analyses are included:

- Passive solar heating strategies only correspond to hours when the sun altitude is over 10°. Solar protection is also limited to the hours when the sun is above the horizon.
- The requirement for thermal inertia is based on the daily temperature swing, and the spreadsheet analysis of the EPW climate files also presents a graph of the Comfort Triangles (Evans, 2003) showing daily temperature swing on the vertical axis and average daily temperature on the horizontal axis.

Relating bioclimatic responses to the required strategies

The final stage is the adaption of the response to each strategy according to the importance of each strategy and the relative importance of each for energy conservation. The procedure is complex, reflecting the difficulty in evaluating the bioclimatic and passive thermal performance of housing in the wide range of climatic conditions found in Argentina. The final result is a score on the 0 to 6 point scale.

In parallel to the passive bioclimatic evaluation outlined in this paper, various studies are being developed to cover the different aspects of energy efficiency:

- The calculation method for evaluating energy efficiency is being developed for the standard, based on ISO Energy simulation standard.
- A pilot project for applying the draft standard is underway in the Province of Santa Fe to test the calculation method.
- A demonstration project for reducing energy demand in social housing will measure performance in 8 locations in new houses with different thermal envelopes, bioclimatic design resources, construction alternatives and renewable energy installations (de Schiller and Evans, 2016).

Conclusions

The paper presents the proposed procedure for evaluating the contribution of passive and bioclimatic design solutions to energy efficiency in housing. As well as integrating this key factor in an energy efficiency label, the procedure indicates favourable design solutions for the designer at an early project stage. As the objective is to evaluate projects, the procedure reverses the conventional bioclimatic design process which starts with climate analysis in relation to comfort requirements. Design and construction solutions are classified and compared with bioclimatic strategies and then scored according to their contribution to energy efficiency in a specific location. Although the procedure is complex to describe, the spreadsheet simplifies application with the selection of alternatives from pull-down lists. The procedure will be tested by comparison with measurements in housing and a new calculation method. It is anticipated that this will confirm the important contribution of passive bioclimatic design to energy efficiency in housing.

Thermal Performance of a Thermal Performance of a Roof-Pond System Under Subtropical Conditions

Leandro Fernandes[1], Eduardo Krüger[1]

[1] Programa de Pós-Graduação em Tecnologia, Universidade Tecnológica Federal do Paraná, Curitiba, Brazil, fernandes.ufpr@gmail.com , ekruger@utfpr.edu.br

Abstract: Under subtropical conditions with mild winters, a roof pond-based passive system should ideally be designed to promote cooling and heating, according to different operation modes. This study aims to evaluate the thermal performance of roof pond configurations by means of experiments in test cells in Curitiba, Brazil (25.5°S, 49°W, 910 a.m.s.l.). Different modes of operation were tested in the warm and in the cold seasons of the year in respect of indoor temperatures. Configurations of the system encompassed: a) roof pond with indirect evaporative cooling function, shaded; b) roof pond with sealed water reservoir, naturally ventilated and shaded (for testing the effect of thermal mass with no evaporative function); c) roof pond, unshaded; d) selective solar exposure of the pond in winter, with venetian blinds during daytime and fully closed at night. Results show that, in summer, on a clear day, indoor temperature can be lowered by approximately 7°C relative to outdoors; in winter, the best configuration (selective solar exposure) yielded a rise of almost 12°C. Time lag and decrement factor were found to be significant only in summer with virtually no time-lag effects in winter, also with increased indoor swings when shading was not present.

Keywords: roof pond, evaporative cooling, thermal, passive heating.

Introduction

There are several possible configurations of passive evaporative cooling systems (Chan et al. 2010, Sharifi & Yamagata 2015), many of which have been reported in the literature during the last half-century such as roof ponds with or without moveable insulation, roof ponds with shading elements, natural draft cooling towers, among other systems. One of the most reported cooling systems consists of using roof ponds directly over the area to be cooled. The pond's water temperature will be close to the average wet-bulb temperature (WBT) and the ceiling, cooled by the pond, acts as a heat sink to the space below it. Such system can be permanently shaded, selectively shaded (during daytime only) or remain unshaded (open roof ponds) (Yannas et al. 2006).

Apart from providing indirect evaporative cooling, another way of thermally using a roof pond consists of sealed water containers with no need for replenishing. The evaporative cooling function is cancelled and the system runs based on the increased thermal mass of the water container. The Skytherm system (Hay and Yellott 1969) combines the use of closed water containers with moveable insulation for controlling heat gains or losses, depending on the season of the year. The effect is a pronounced stabilization of indoor air temperature. Givoni (1994) reports on the cooling performance of the "Atascadero House", in Atascadero, California which uses the Skytherm system and shows that ambient temperature fluctuation can be sharply reduced due to the combined use of stored water-filled plastic bags and insulating panels.

Winter applications of roof ponds are not as frequently reported in the area literature as in the case of roof pond-based cooling systems for summer conditions. The Skytherm system uses a reverse operation of the insulating panels in winter, covering the roof during the night to prevent heat losses and opening it during the day to absorb solar heat (Sharifi & Yamagata 2015). More complex systems can be used in combination with supporting storage heating systems, collection of solar-heated water from tiles and draining the pond at night. The most simple variant, yet not quite effective is to expose the roof pond continuously, in this case however with evaporative and radiant heat losses (Sharifi & Yamagata 2015). Using a glass cover on top of the pond could restrict such losses, turning it to a water-tight chamber.

The operation modes of a roof pond depend on a great extent on the user when automation is not an option. Thus, simplicity in operation is desirable. In this paper we analyse diverse modes of operation of a roof-pond passive system in respect of seasonal changes in ambient temperature patterns under the climatic conditions of a subtropical location. Tests have been carried with a same test cell and using the same instruments, so that inter-comparisons were made possible.

Materials and methods

Location

Curitiba (25.5°S, 49°W, 910 a.m.s.l.) is located in a tropical climate zone in a relatively high-altitude region of Brazil (Cfb/Koeppen). It often experiences unstable meteorological conditions with large daily and annual air temperature fluctuations. Average air temperature in summer is approximately 20°C, though average air temperature in winter is quite low for tropical standards, averaging 13°C in June/July. The evaporative cooling potential estimated for an existing system based on such strategy and applied to an experimental dwelling was considered to be significant (Gonzalez & Krüger 2015), responding with nearly 90% of the annual cooling demand in that location.

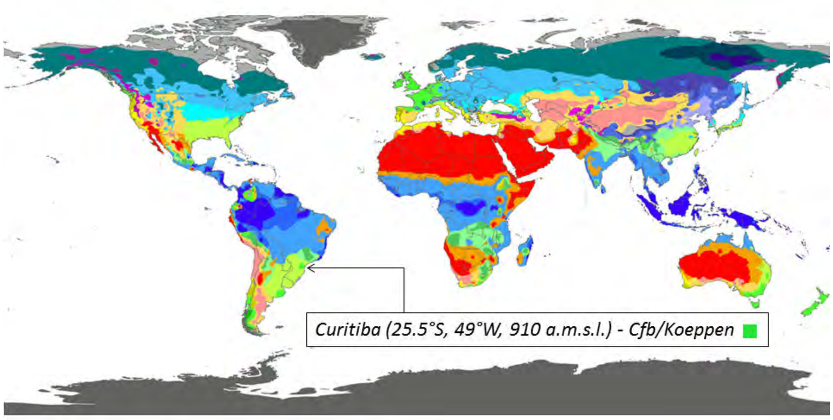

Figure 1: Location on Koeppen’s World Map with climate classifications

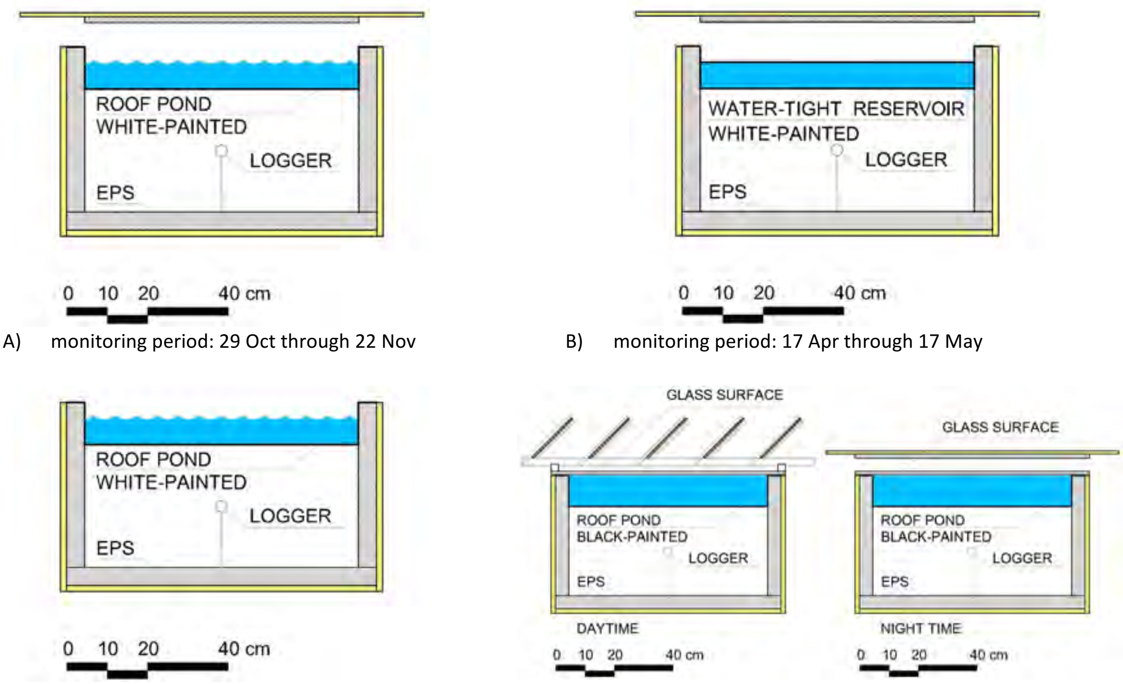
Experimental Setup

A small test cell (80×80×45cm) was used for testing different configurations of the roof pond. The test cell is made of lightweight, low-density wood panels, whitewashed and with an internal 4.5 cm thick layer of expanded polystyrene, which ensured a low U-value of 0.70 W⁄(m².K). The roof consists of a metallic water reservoir, white-painted with approximately 6cm of water. When shaded, an insulating wooden roof cover is used. Underneath it there is a 1.5 cm thick layer of EPS. Configurations of the system tested are the following:

a) roof pond with indirect evaporative cooling function, shaded and with a ventilated crawl space between the roof pond and the cover to enhance evaporative processes; the cover provides a small overhang and has measures 1.0×1.0m;
b) as in (a), but with water-tight reservoir, covered by the same metallic material as the reservoir's (for testing the effect of thermal mass though with no evaporative function);
c) roof pond, exposed and unshaded;
d) selective solar exposure of the pond in winter, with venetian blinds (with a tilt angle of 45°) used during daytime and fully closed at night; the pond is permanently covered by a glass surface to prevent convective heat losses and the reservoir is painted black and filled to the top (with water depth 10cm).

Figure 2 shows schematically the diverse configurations tested in this paper with corresponding periods of the year during which indoor temperature monitoring took place. Temperature data loggers were used both for monitoring indoor air temperatures and for recording ambient temperature, in 15-minute intervals.



A) monitoring period: 29 Oct through 22 Nov

B) monitoring period: 17 Apr through 17 May

C) monitoring period: 19 Jan through 21 Jan

D) monitoring period: 11 Sept through 13 Sept

Figure 2: Configurations tested and periods analysed

Results

Within each of the four monitoring periods, a day with clear-sky conditions was sought for analysis. Table 1 shows overall conditions for each configuration.

Table 1: Monitored data in the four configurations, on a clear day, in °C

Variable	Configuration a *29 Oct*		Configuration b *2 May*		Configuration c *20 Jan*		Configuration d *11 Sept*	
	T_{out}	TC	T_{out}	TC	T_{out}	TC	T_{out}	TC
T_{max}	32,0	22,3	25,2	22,4	29,4	31,6	27,4	40,1
T_{min}	14,6	15,4	13,2	15,7	17,1	14,4	14,5	24,1
T_{swing}	17,4	6,9	12,0	6,7	12,3	17,2	12,9	16,0
T_{avg}	22,2	18,8	18,8	19,0	22,1	20,9	19,3	30,9

Ambient temperatures (T_{out}) behaved quite differently in the four monitoring rounds, with seasonal effects. Daily temperature swings varied among the four days with the highest fluctuation occurring in the shoulder season. In general, daily swings were high (>10K), which reflects local climate. Measured indoor temperatures in the test cell (TC) showed varied behaviour. The first two configurations, which tested the evaporative and function of the roof pond and the thermal mass of the water body without evaporation, but under a shading cover, had quite similar fluctuations. The two other configurations, in a shaded mode, showed higher swings. Relative differences between indoor and outdoor temperatures ($\Delta T=TC-T_{out}$) as well as the decrement factor f ($T_{swing}(TC)/ T_{swing}(out)$) and time lag (φ in hours) are presented in Table 2. The decrement factor and time lag are important characteristics to determine the heat storage capability of a given operation mode of the test cell (Asan 2006). Negative differences suggest a heating behaviour of the test cell, negative values indicate a cooling potential.

Table 2: Relative differences between internal and external temperatures ($TC-T_{out}$), time lag and decrement factors (f) for the four configurations

Variable	Configuration a	Configuration b	Configuration c	Configuration d
ΔT_{max} (°C)	1,6	3,6	2,3	16,0
ΔT_{min} (°C)	-11,8	-4,8	-4,3	6,9
ΔT_{avg} (°C)	-3,4	0,2	-1,2	11,5
f	0,4	0,6	1,4	1,2
φ (h)	3	3	0	0

The first two modes of operation (shaded) differ from the unshaded modes with respect to f and φ, raising the first and cancelling the latter. The test cell does not reduce ambient temperature fluctuations and the time-lag effect is null. As regards the effectiveness in cooling, the first configuration is significantly more effective than configuration b, meaning that the evaporative cooling function is greatly responsible for the cooling effect than the simple use of thermal mass. Indeed, in configuration b, the water-tight reservoir will add heat to the internal space. The heating capability of the test cell is noticed in configuration d, with a substantial rise in indoor temperatures relative to outdoors. The full exposure of the roof pond (configuration c) is effective for cooling purposes to a certain extent but, unless the pond is covered at night, the absorbed heat is wasted during the night. Figure 3 further demonstrates such behaviour.

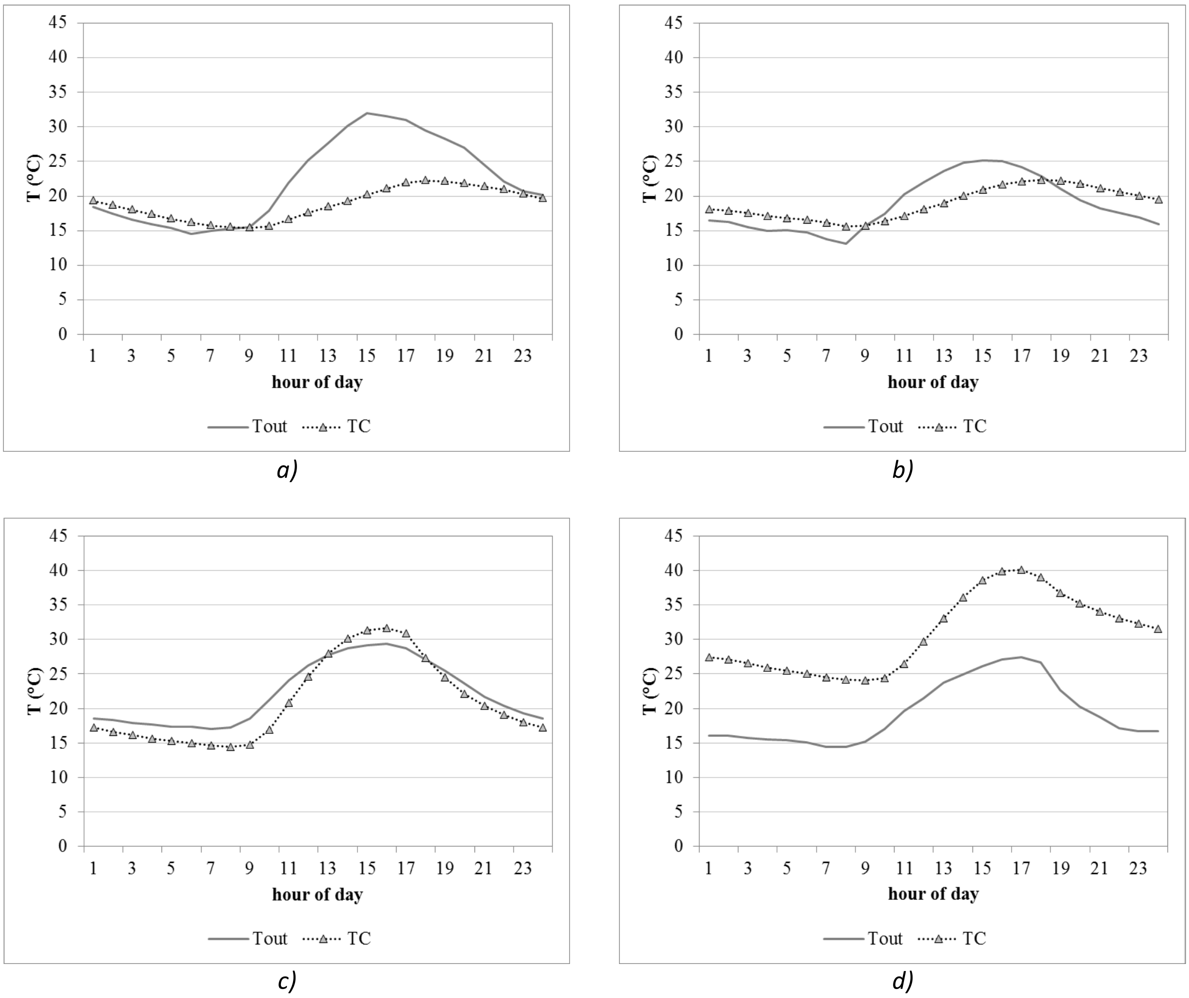


Figure 3: Indoor temperatures for the four configurations (a-d) over the background of outdoor temperatures

Indoor temperature graphs show very different relationships to outdoor temperatures. The evaporative function of the pond (a) is an important design parameter for summer operation of the system, whereas selectively covering the roof at night preserves absorbed heat during the day (d). Enclosing the water within a metallic container, permanently ventilated and under shade, with radiant cooling at night is not as efficient as allowing evaporation to take place even though a small cooling effect is noticed. The unshaded open pond, white-washed, will have not heating effect and daytime cooling due to evaporation is hindered by the direct solar warming of the water. The comparative performance of the four modes can be expressed as relative differences to ambient temperatures (Figure 4).

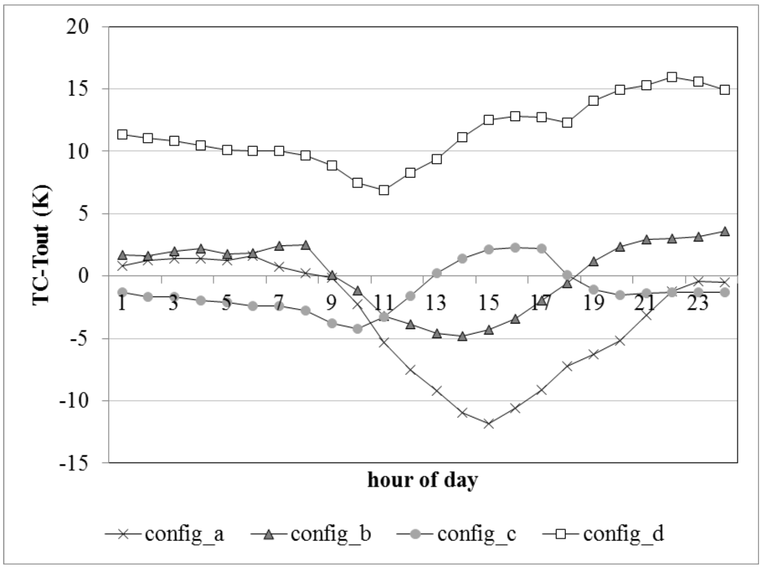

Figure 4: Relative temperature differences between indoor and outdoor air temperatures for the four configurations on clear days

Configuration d shows a perhaps unnecessary heating of the test cell which results from the solar exposure of the test cell, and due to the fact that the reservoir is painted black. Solar absorptance is increased from an estimated 0.2 (white paint) to 0.9 (black paint), which will directly influence indoor temperatures during the day due to the high conductivity of the metallic panel (assumed 60 W/(m.K)). Moreover, the increased water depth also stores absorbed heat more effectively.

Discussion and conclusions

In the case of the first configuration tested, an important parameter discussed in several studies refers to the depth of water in the roof pond. In a simulation study of a ventilated roof pond under hot-arid conditions, Raeissi & Taheri (1996) found that the increase in water depth may affect the evaporation rate per unit volume of water and therefore decrease overall daily heating requirements. Shallow water depths would thus extract more heat from the ceiling, which should be avoided in the heating season. For uncovered roof ponds, values of water depth recommended should be higher than in the case of covered roof ponds. For non-shaded roof ponds, Yannas et al. (2016) recommend that, with permanent exposure of the water pond and no spraying system, water depth should be at least 30 cm. Thus, for the uncovered roof pond to be more effective, an increase in water depth would create more stability and store more heat in the pond. According to literature, configurations a and c should optimally operate with different water depths: low water depths for covered ponds and high water depths for uncovered roof ponds.

However, a higher performance of configuration c, which showed a very high fluctuation of indoor temperature even higher than the outdoor temperature swing, according to literature, should be reached not only with increased water depth but also with an additional insulation layer (Sharifi & Yamagata 2015, Runsheng et al. 2003).

Water depth is thus an important consideration and should even affect the thermal performance of Configuration d, along with the adequate dimensioning of the opening area.

Advantages of ventilated roof ponds are many (Kharrufa & Adil 2008): low initial costs, null maintenance and running costs, low water consumption, the fact that the roof pond can be more easily embodied to the building form, among others. The drawback is the additional weight that has to be supported by the building's structure, ranging 200-400kg/m².

The experimental study provided insightful information on the operation of roof ponds, suggesting that the water tank itself with no evaporative function is not as efficient in lowering indoor temperature in summer conditions as with it. For winter conditions, night time coverage of the pond is essential for maintaining absorbed heat during daytime, yet fine tuning, i.e. local climate-related adjustments should be made as regards water depth and solar absorptance of the water reservoir. Parametric analyses are recommended to test such factors in future studies.

Ventilation and Sound Reduction Through the Form

Ader Garcia Cardona, José Luis Arredondo R, Diego Delgadillo A, Luis Gabriel Muñoz and Jeiser Rendon G.

Abstract : Medellín (Colombia) is a tropical city located at 6, 25^{o} of the North latitude, 1495 metres above sea level, average temperatures between 17 and $28^{o}C$ and relative humidity between 40% and 80%. These conditions requires natural ventilation which in turn passes the outside noise and creates problems of intelligibility in naturally ventilated spaces. This research identified the theoretical performance of wind and sound attenuation for classroom in Medellin by evaluating scale models 1:25 of the façades of classrooms with windows, evaluated in a reverberant Chamber to scale, according to Norm UNE - EN ISO 354: 2004, ventilation measurements made in a wind tunnel CFD software simulations. Found that horizontal windows reduce 0.5 decibels the noise transmission to the frequency of 500 Hz in relation to vertical windows of the same size. For ventilation windows, horizontal and vertical, whose proportions were 1/3 and 2/3 the area of the facade, presented a ventilated area of the classroom around the 86.1% and the flow increased by 16% with on ½. Means that the windows of the classrooms of Medellín must be horizontal and in proportions of 1/3 to 2/3 the area of the facade

Keywords: vent, attenuation, noise background, windows, classrooms

Introduction

Medellin has 476 between private and public, distributed educational buildings (Anon n.d.)along the Valley of Aburrá, these buildings do not have air conditioning systems and cross-ventilation is the general technical choice. These classrooms are in areas of the city with noises of 80dBA traffic and the level of background noise in classrooms are higher than 60dBA. It is necessary to find the dimensions of the windows of the classrooms that achieve attenuation without prejudice of the ventilation. Colombian legislation NTC 4595 (Anon n.d.) requires a level of noise in the background between 40 and 45 dBA, well below the European standard that is between 30 and 33 dBA,. (Award et al. 2000) (Evans, n.d.) (Department for Education 2015) , i.e. front are a problem facing two key variables for the comfort inside the classroom that are ventilation and noise.

Procedure

For the study, evaluations were made with scale models 1:25 of the facades of the classrooms with windows located in the center and in proportions of: 1 / 3,1 / 2 and 2/3 of the size of the facade, with vertical and horizontal shapes and taking into account the requirements of the Colombian technical standard (NTC 4595) for ventilation of school classrooms, which is 1/6 of the classroom area. (INCONTEC 2006). The size of the classrooms in the floor plan was 7.20m * 4.80m, with the entrance of air into the short facade. These models are placed in an anechoic chamber on a scale where the transmission loss was measured for a 500Hz signal with a Cesva brand sound level meter.

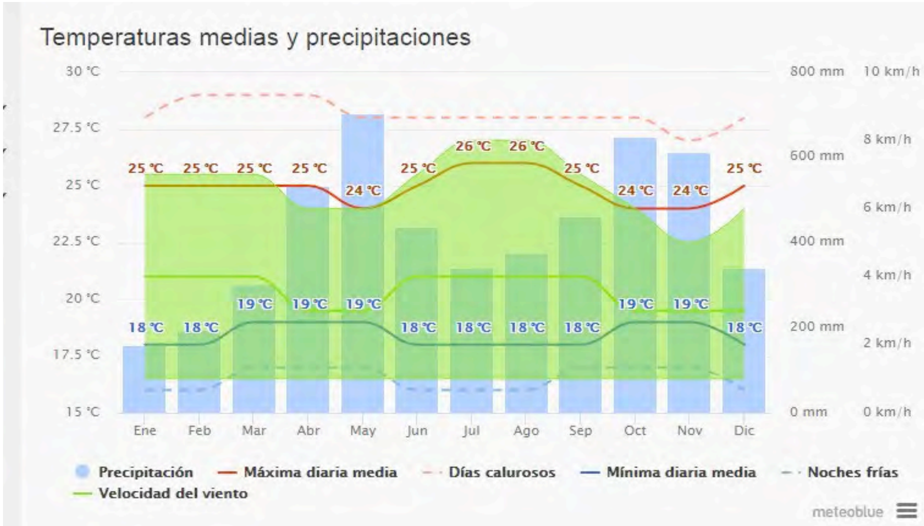

Fig 1. Average temperatures and the wind speed in the city of medellin. Retrieved from https://www.meteoblue.com/en/weather/archive/histogram/medell%C3%ADn_colombia

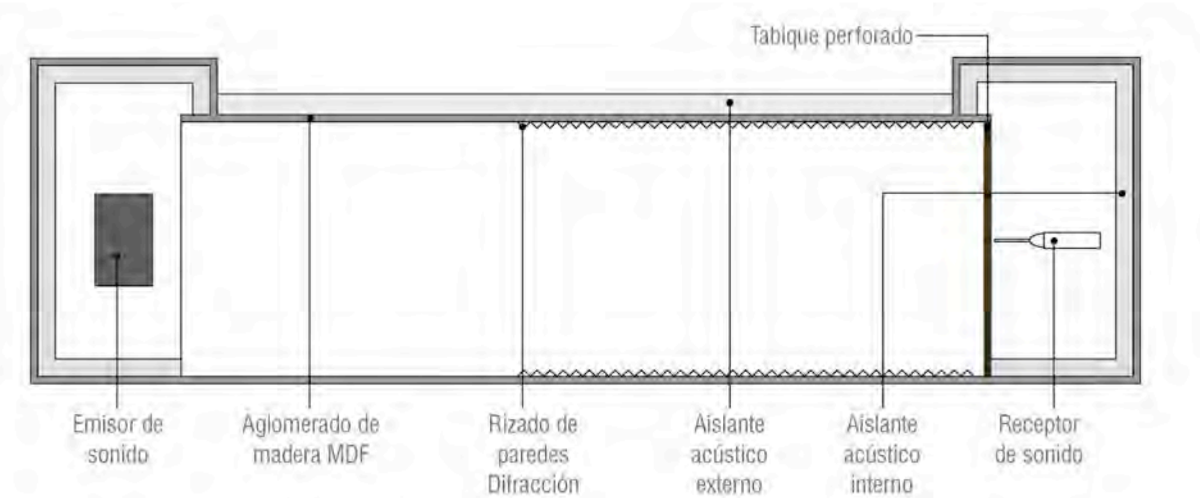

Fig 1 anechoic chamber section

The device or anechoic chamber is composed of two devices at the ends in which in one of them is located the sound source and in the other is the receiver or sound level meter. The chamber is constructed with 19mm agglomerated wood lined inside with expanded polystyrene of medium density of 50mm thickness, and outside lined with a 2 "layer of rock mineral wool. Figure 1 shows section of the chamber and the location of the perforated panel with the window gap in the proportions mentioned.

According to UNE-EN ISO 354: 2004 standards, the minimum frequency at which measurements can be made is one whose wavelength is equal to the length of the shortest edge of the chamber, in the case of the chamber used, that frequency corresponds at 500Hz.

Measurements and observations of indoor ventilation behavior were done in wind tunnel and in CFD software. In order to carry out the evaluation of airflow in the wind tunnel, a scale model in acrylic was used and it was recorded by means of photographic shots. These same conditions were simulated with a CFD software to know the internal wind speeds and the propagation of the flow through the space.

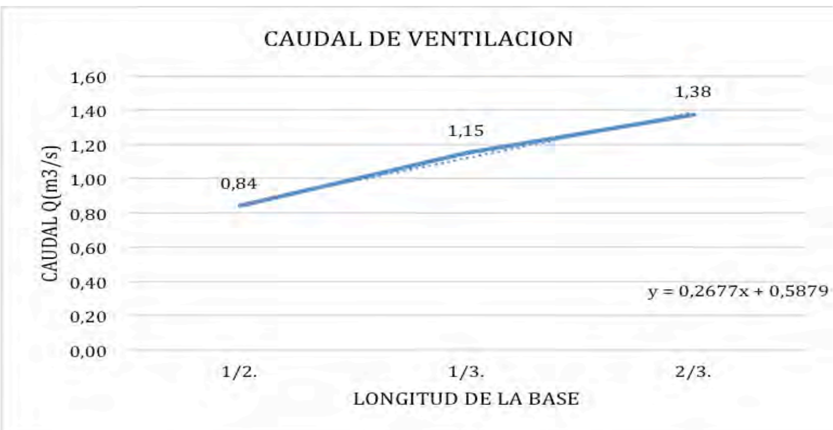

Fig. 7 flow of ventilation. Execution

Noise attenuation in regards to the ratios 1/2, 1/3, 2/3 is presented in Table 1 and in Figures 7-9.

Table 1 results of measurement in anacoica execution Chamber

Position of the vain	LeqA	500Hz	1000Hz	2000Hz	4000Hz
BACKGROUND NOISE	77.89	34.60	32.93	37.67	40.80
1/3 - Horizontal	100.68	70.43	73.37	80.13	80.53
1/3 - Vertical	100.53	70.93	72.50	79.20	82.63
1/2 - Horizontal	101.57	74.33	74.83	79.20	81.50
1/2- Vertical	101.83	74.73	75.17	80.93	81.10
2/3 - Horizontal	101.23	71.97	73.40	78.97	80.20
2/3 - Vertical	101.23	72.83	73.60	79.77	81.53

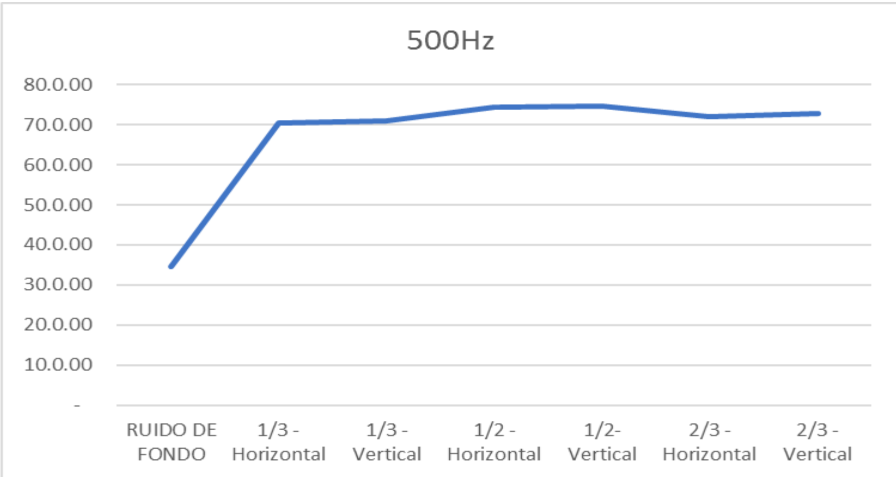

Fig 7 behavior of attenuation in the range from 500 hz execution

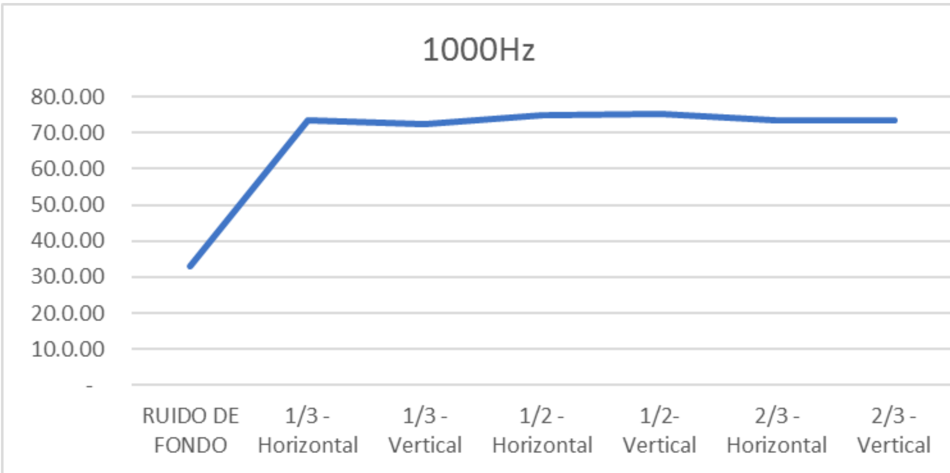

Fig 8 behavior of the attenuation at 100 hz execution band

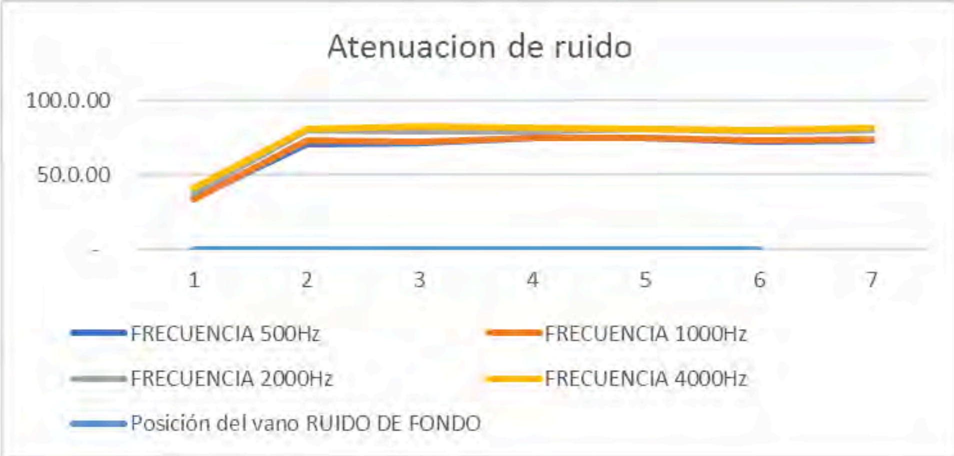

Fig 9 behavior of attenuation in 500,1000,2000,4000 HZ band execution

Discussion and Findings

Analyzing the results of the attenuation of the noise according to the shape of the window, it was identified that the horizontal proportions in the 500 hz band are that presented greater attenuation, between 0.5 and 0, 86dBA, with ratios of 1/3 and 2/3 that presents higher attenuations. For high frequencies in the band from 4000 Hz higher attenuations are for windows with ratios of 1/2 y2/3, falling between 2 and 4dBA.

Models CFD noted that the areas and the speeds of the air inside of the classrooms did not exceed 1, 2 m/s and that the flow increased by 39% when the window passes proportions 1/2 to 2/3, covering an effective area of the enclosure of 86.1%. For windows with ratios of 1/3 the percentage of effective ventilated area within the classroom is a 75.36% and for a window with a proportion of ½ percentage of ventilated area is of 59.71%, the upsell benefit ventilated ara of ½ to 1/3 ratio is around from a 15.65% and the increase from 1/3 to 2/3 is from the 10.73%.

In summary the horizontal proportions of windows reduce between 0.5 and 0, 86dBA noise for the frequency of 500 Hz transmission. In ventilation change in proportions of 1/3 to 2/3 both for horizontal windows as vertical increases the ventilated area of the classroom around 16% and the flow rate by 16%. To say that the windows of the classrooms of Medellín must be horizontal and in proportions of 1/3 to 2/3 the area of the facade.

Conclusions

It is that for classrooms of Medellin's elongated proportions with air intake for its façade and shorter the best proportions of windows are 1/3 and 2/3 the area of the facade. Likewise these proportions are presenting greater attenuation noise for 500 Hz band. 4000 Hz frequency windows with proportions of 2/3 and 1/3 attenuated between 1 and 2dBA. In summary the best proportions for ventilation and attenuation of noise at 500 hz band are 2/3 and 1/3

Design to Thrive

Low cost, energy and impact ceramic cladding cooling system by means of evapotranspiration or ‘botijo-effect’

Javier García-López

Instituto Universitario de Arquitectura y Ciencias de la Construcción, Escuela Técnica Superior de Arquitectura, Universidad de Sevilla. Email javigalo@us.es

Abstract: A new ceramic cladding system was first applied in the house prototype named "SOLARKIT”, representing the University of Seville in the international competition Solar Decathlon Europe 2010, where its effectiveness was registered by thermographs y and the monitoring of the building. Therefore, as a result of this R+D+I experience derived from the search of a low energy and innovative cooling bioclimatic strategy, a new cladding system has been invented and patented. Consequently, the patented invention relates to an external cladding system using tiles made from a porous-ceramic material or similar, named as a façade with “botijo-effect”. Thus, the system can be applied directly as a final cladding or used in external sheets of ventilated façades. Compared to traditional claddings, this system provides de possibility of cooling its surface by means of evapotranspiration generated by supplying water through a network of canaliculi inside the tiles. An estimated superficial cooling power of over 80 W/m² can be considered, plus an 8 to 10ºC cooling effect on the air temperature Its application is particularly interesting at locations with hot-dry climates where there is a high cooling energy demand or where is intended to mitigate the "heat island" effect in urban environments.

Keywords: evapotranspiration, botijo effect, ceramics, patent, biomimetic technology

Introduction

The use of techniques of using water cooling or "evaporative cooling" in buildings has been present in architectural culture Andalusian, North Africa and the Middle East for centuries (J.Neila). Examples have survived until the present day in the form of archetypes such as the Andalusian patio, or monuments of the Nasrid Alhambra and Generalife of Granada architecture. Ventilation chimneys, originating in the Middle East, also use the cooling by humidification and dehumidification to downdraught cooling the interior of the buildings (B.Ford, S.Álvarez et.al).

Contemporary examples of the use of surface evaporation in ceramic materials as passive conditioning technique can be found in the forest of ceramic pillars of the Pavilion of Spain at Expo-Zaragoza 98 designed by Francisco Mangado, or in the ‘bioskin’ ceramic tube brise-soleil façade of the Sony Osaky Building in Tokyo (V.Lerum), designed by Nikken Sekkei.

Figure 1 SolarKIT prototype at Solar Decathlon 2010 with ceramic ventilation towers ©R. Santoja

Fundamentals

The ambient water surface evaporation is an endothermic process, which absorbs energy. This energy or heat of evaporation is provided by direct conduction through the materials from the environment such as water or a solid saturated of humidity as the ceramic element or other porous materials. This phenomenon is based on traditional techniques of cooling as the botijo (Fig 2), a type of Spanish handmade ceramic jug, which keeps it cool the water content for your drink thanks to its surface evaporation.

The operation of the botijo has come to be described through a very complex formulation, according to published authors J.I. Zubizarreta & G. Pinto (J.I Zubizarreta et al, 1995).

Figure 2 Botijos from La Rambla ©M. Ruiz Díaz

There is something which, however, is not so difficult to quantify, as it is cooling due to the water evaporation capacity. The energy used in the evaporation of water at room temperature is called heat or enthalpy of evaporation, and can be obtained from the electricity tables. At room temperature, we can consider it as 580 kcal/kgH20 (2426 kJ/kgH2O), i.e. 580 kilocalories are absorbed for a kg of water evaporates.

The so-called "mass transfer coefficient" or k' (kgH2O/hm²), estimated at 80 kg water/hm² according to (J.I Zubizarreta et al, 1995), describes the amount of water that "sweat" or passes the jug to its surface per unit area and time. This factor is the key to the ability of a surface cooling with cooling by evapotranspiration, as in the case of crops, where they join the phenomena of evaporation of water from the ground and plants.

The amount of energy extracted per unit area "botijo" and time will be

$Q=k'*H$,Being H = enthalpy or heat of vaporization (580 kcal/kgH20 = 2426 kJ/kgH2O) k'=80 (kgH2O/hm²) [1]

Then for each surface unit is would extract 53.9 joules per second, equivalent to a cooling of 53.9 Watts power per unit area (m²).

B. Morillo recent experiment has measured up to 0.224 kg/hm² of surface evaporation, equivalent to a 140 W cooling power per m².

This cooling capacity described as energy removed per unit time is getting cool the water of the pitchers, and in practice can be used in other applications as thermal building conditioning, as we will see below.

Considering these fundamentals, the geographic areas with greatest potential for exploitation of surface evaporation for the new or the refurbishment of the buildings will be those with a climate of warm, dry summers as regions with Mediterranean climate.

Problem to be solved

This section discusses the technical problem which is given solution by the new invented system. This problem could be formulated using the following questions:
Is it possible to incorporate the surface cooling to the wall of a building by means of a simple and passive technology?

Would it be possible to take advantage of this effect of surface cooling to provide air cooled flows without the contribution of additional moisture?

Origin

The origin of the invention arises during the design of a low-energy system for ventilating a housing prototype, SOLARKIT for the Solar Decathlon 2010. To this end an initial design of a ventilation chimney was developed resulting in an innovative ventilation tower (Fig 3) from the combination of solar chimney and breezes capture tower, through which the air intake and expulsion is resolved.

That new bioclimatic component combined the downstream or downdrought cooling effect to cause outside air intake, pre-cooling it by means of the evaporative cooling effect of the ceramic cladding of the north face duct before being fan-forced distributed into the building through an edge-sealed raised-floor plenum. Subsequently, the effect of solar chimney of the south face of the tower provides the extraction of indoor air without mechanical support by stack effect, since the thermal inertia of a water reservoir placed in the core of the tower keeps the thermal draft effect even when no solar radiation is available.

[1] According to experiment described in article of *J.I Zubizarreta y G.Pinto*

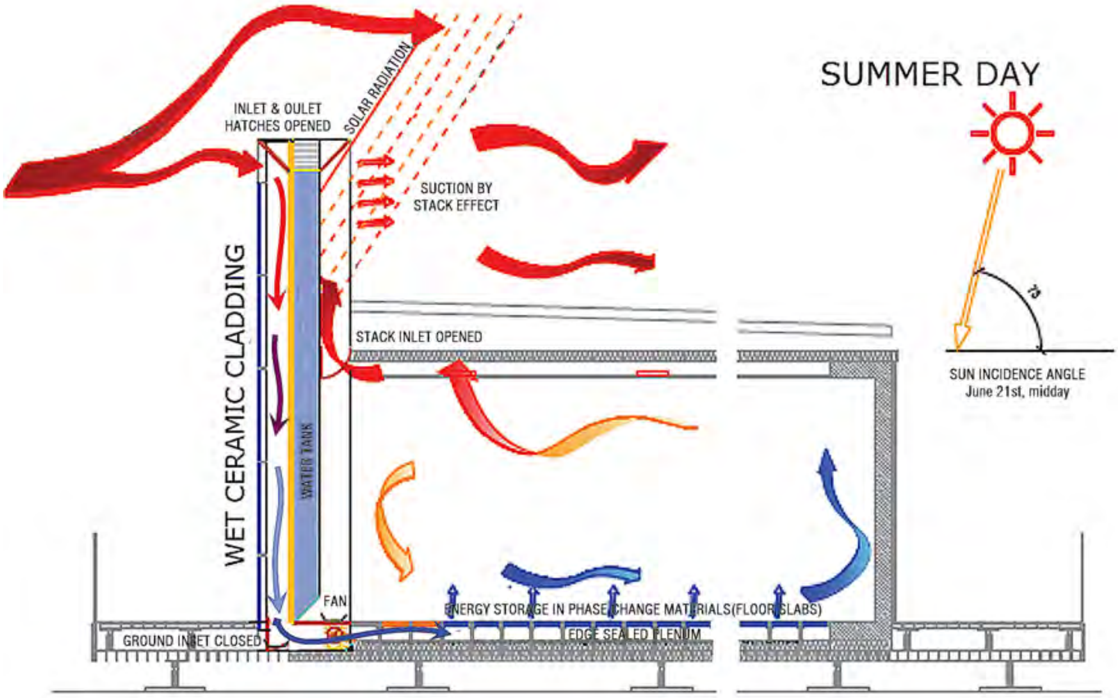

Figure 3 SOLARKIT's Ventilation tower scheme. Summer-day period.

Tests and prototypes

We found the first example of realization of this ceramic cladding tile in SOLARKIT, (Figs. 1 and 4) as it has been described in the previous point.

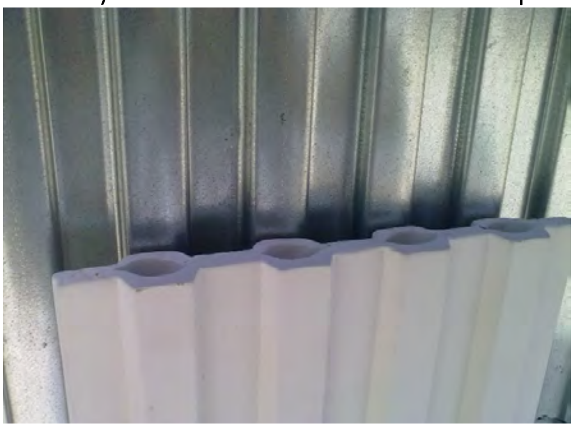

Figure 5 Porous ceramic cladding tile designed for SOLARKIT's ventilation towers

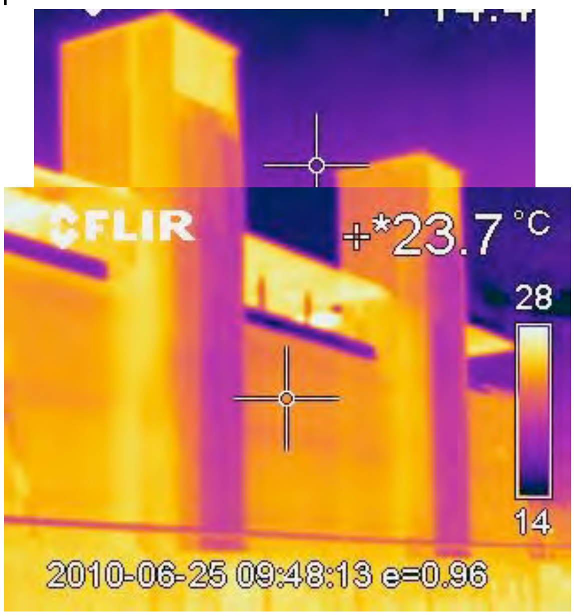

Figure 4 Thermograph image of ventilation towers with activated ceramic cladding cooling system of SOLARKIT

As a proof of system operation by thermographic images (Fig 5) it can be observed the difference in surface temperature of the wetted ceramic facings (front side) against those who are not (left and right sides)

Regarding air temperature, there has also been recorded and monitored up to 7 degrees differences between the outside (29°C) and the output of the tower at its base into the housing (22° C) without the addition of extra moisture.

The second experience where the system has been applied was in the prototype “Patio 2.12” participant in Solar Decathlon 2012 (Terrados-Cepeda F.J, 2014). However, in this case its application did not follow all the patent requirements, such as the use of a ceramic material with a high degree of porosity. The baking treatment and the surface glazing of the commercial terracotta tiles used prevented an effective evaporative desired for the passive conditioning effect (Fig 6) of the prototype as originally planned.

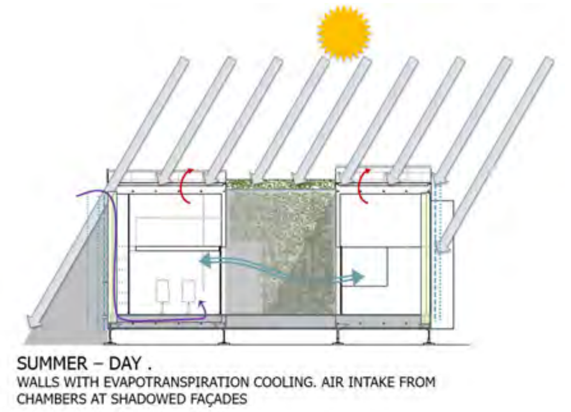

Figure 6 “Patio 2.12” bioclimatic strategy combining green-house and botijo-effect

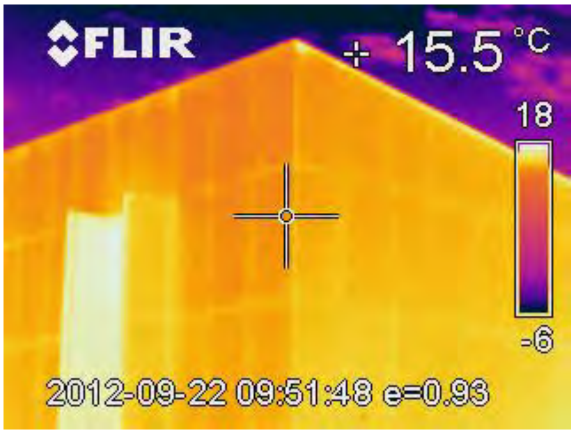

Figure 7 Patio 2.12 corner with (left) and without watering (right) at the same surface temperature

Thermographic images (Fig7) show little difference between the ceramic facades with activated watering effect and the conventional ones without water supply.

Nevertheless, this experience helped to document the influence or effect of water evaporation and the degree of porosity to allow its outcrop in the appearance of the surface cooling phenomenon. Its actual low performance in the prototype did not avoid, however, that the concept were widely celebrated by the jury and the public of the competition, which resulted in an excellent 2nd place in the competition.

Patent

Finally, in 2012, after the first satisfactory experience with SOLARKIT it was decided to promote the patent process since a high degree of innovation and novelty was detected.
Patent with prior review process has finally been completed (Patent nº ES2455415_A1) with granting a protection for 20 years.

IBI international search and reports on the State of the art in the PCT process remarks the high degree of novelty of the invention by granting a "class A-not relevant" international reference patents[2], to the main claims

In particular, it highlights the fact that provided moisture happens in the entire piece and that the contribution of water occurs by gravity, from the interior alveoli to its surface in a natural way.

Description of the system

The invention consists of a novel solution of cladding for buildings or constructions using a covering ceramic tiles or other porous material similar with a controlled water supply through a system of internal canaliculi where water flows by gravity. The evaporatation of the water

[2] (see final patent references)

absorbed by the pieces on its outer surface produces a surface cooling wich helps to reduce the surface temperature of the enclosure, and therefore, the Interior of the building.

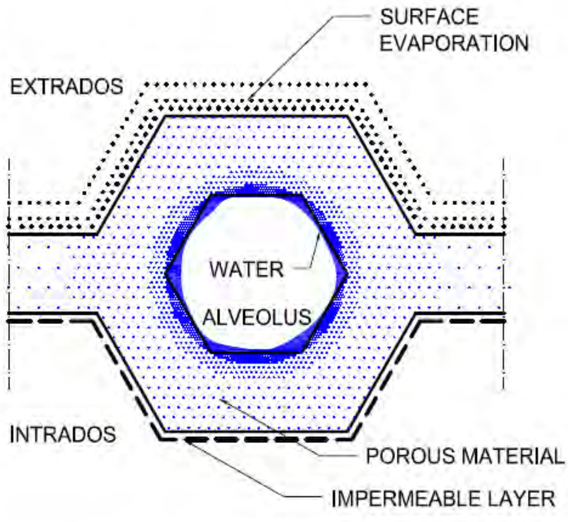

Figure 8 Horizontal section by alveolus type.
Evapotranspiration functioning.

The solution consists of elements and traditional building materials. For the operation or activation of the cooling it only needs a small supply of water to evaporation (about 0,22 dm^3/h or 1,45 dm^3/day per m^2 of façade), which can come from retrieval systems of water rain or recycling within the same building, thus reducing the demand for drinking water for their operation.

The system can be applied to walls of buildings and constructions as direct liner, using fixing techniques applicable to other stone or ceramic claddings. Equally, the system can be arranged in an indirect mounting as outer foil in ventilated facade constructive solutions.

The cooling of the surface can be used to reduce the external temperature of the enclosure, and therefore, the gain of heat transmission.

In addition, applied as the outer sheet in "ventilated facade" solutions, it can be applied for cooling the air at the chamber, which, in turn, can be used as cooled passive, natural and free of charge flow for the ventilation of the interior spaces of the building,

Functioning

Surface of this facade system cooling capacity is especially suitable for buildings or constructions at hot and dry summers climates, and wich facades prevail massif front windows. The watering system should be activated during periods of maximum insolation and higher outer temperature to optimize or cold seasons it should remain disabled.

The effect of surface evaporation benefits on the one hand inside the building by lowering their surface temperature, but also affects the near environment of buildings, since the contribution of additional moisture contributes to lowering the temperature around the building, and thus reduce the "heat island" effect.

Application

This described finishing system can be applied to the closure of the buildings in two ways:

The first or "direct fixing" consists of a solution of fixing the elements directly to the facade, whether by anchors mechanical or even with epoxy-type adhesive, to the outer layer of wall, as in a conventional solution of cladding with pieces of stone, ceramic tiles, etc. In this case the surface cooling by evaporation, when environmental conditions demanded it, would lower the temperature of the outer face. Cooling is directly transmitted this way by "transmission" to the Interior of the wall layers, which would reduce heat gain through the facade in summer conditions.

The second mounting option would be "indirect fixing", consisting of the use of a substructure or auxiliary support to hang it from. It should provide a continuous air chamber of approximately between 3 and 10 cm thickness between the outer ceramic tiles and the interior of the wall sheet.

At the bottom and the top of the façade there should be some adjustable openings in order to regulate the entry of an airflow to the air chamber. Finally, air intakes will be installed at the air chamber connecting to the inner spaces or to the mechanical ventilation of the building.

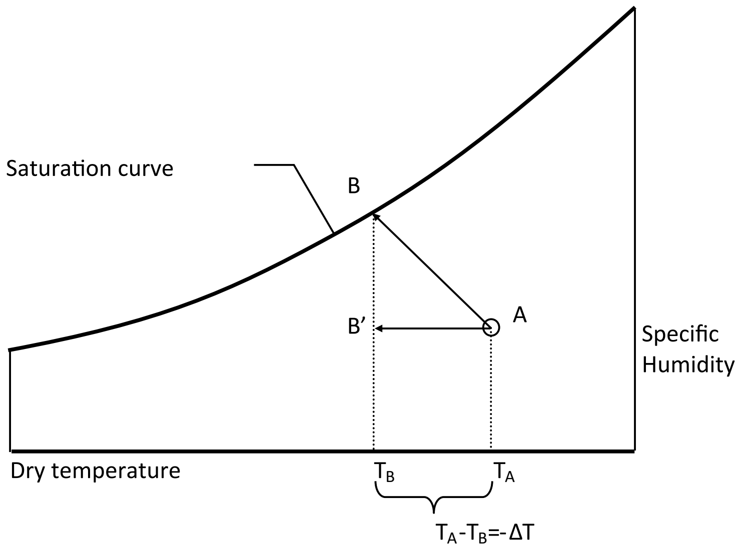

Figure 9 Sensible cooling process AB' Vs evaporative cooling AB

When reaching the thermal equilibrium, thanks to the evaporative cooling process in the outer layer surface, the air contained in the chamber will cool from the dry temperature point “A” of the outside environment until the wet bulb temperature at which the outer layer will be, but without having increased its moisture content, thus running a "sensible cooling" psychrometric process (AB' in Fig. 9).

Air cooled this way can then be introduced into the building through the admission intakes placed at the air chamber and used as a naturally and free of charge pre-cooled (-ΔT in the figure) ventilation air-flow.

This technique can reduce or even eliminate the ventilation loads in summer as the air brought in from outside, and previously cooled through the chamber reaches the interior with a temperature close to summer comfort conditions. This is particularly interesting in commercial buildings with large ventilation requirements.

It has been registered (F.J.Neila) that natural convection phenomena generally manifest at air chambers over 10 cm thick. During the surface cooling operation of the facade, air cooled in the thicker than 10 cm chamber will flow to the bottom by a natural downdraught effect. This is of particular interest in implementing this as a cladding system of bioclimatic elements such as ventilation towers used for low energy and passive air conditioning of buildings. The described ceramic coating would help to enhance the downdraught cooling effect at breezes-capture and ventilation towers as tested in Solarkit.

Conclusions

There has been presented a new and original system for passive cooling buildings, which originality has been certified by the patent authorities.

Not only is able for cooling buildings and constructions façades, but also to produce fresh air for buildings spaces' conditioning and ventilation.

Its functioning requires no energy supply but a continuous small amount of water in order to generate the cooling effect named "botijo-effect".

A set of simple devices for temperature and humidity monitoring with a control system acting over the watering system is required to optimize and manage its performance.

The surface cooling effect highest potential is located at regions with hot a dry summer periods, with a high range for evaporative cooling capacity.

The system performance will be increase when applied in façades without direct sunlight.

Arising from the state of the art and the built experiences described an estimated superficial cooling power over 80 W/m² can be considered, plus an 8 to 10°C cooling effect on the air temperature, with a total 1,45 l/m² of water per day. Both characteristics has been confirmed by means of direct measuring and thermography images.

A high potential for future developments can be foreseen considering its low cost, energy and impact for easily cooling buildings surfaces with tradition rooted techniques.

Redeveloping Informal Settlements in Kolkata: A vernacular approach to 21st century design

Oindrila Ghosh[1] and Paula Cadima[2]

[1] Design for Climate and Comfort Lab, Singapore University of Technology and Design, Singapore. Correspondence email: oindrila_ghosh@sutd.edu.sg
[2] The Architectural Association School of Architecture, London, UK

Abstract: Slums are ubiquitous in cities in all tropical regions and India is no exception. Half of the urban population of India lives in slums and in response to this ever-growing problem, large-scale resettlement colonies get built by the government on the city edge as “solutions”. However, these slum interventions end up failing as they do not address the issue of providing a “good environment” to the urban poor that make these megacities run. This research paper tries to address this loophole and its objective is to provide a modular, replicable, adaptive and sustainable residential unit made with locally available materials and suggest passive design guidelines for a holistic and successful slum redevelopment in Kolkata. Fieldwork is carried out to supplement this objective by understanding the aspirations and present living condition of slum residents. Also, performance of the local vernacular materials and passive design strategies were tested to translate them into the 21st century design of the modules.

Keywords: slum settlements, vernacular architecture, tropical design, traditional materials

Introduction

Slums are gateway to the cities for the rural people of India. They migrate with the hopes of a better lifestyle and find shelter in these informal settlements. The mega cities of India don’t have enough infrastructures to house such influx of people. This paper discusses a research focusing in Kolkata which houses the second largest slum population in India after Mumbai, (Ghosh 2016).

Slums typically begin at the outskirts of a city, located on least desirable public lands or lands with no clear land title. Over time, the city may expand past the original slums, enclosing the slums inside the urban perimeter, Figure 1. This makes the original slums valuable property, densely populated with many conveniences attractive to the urban poor. It is also a place where a lot of wealth as well as crime are generated. Slum dwellers afford a lot of modern day equipment for their daily life but only at the expense of their low-cost living conditions in the slums (Bakshi, 2013). Thus, holistic passive redevelopment can drastically improve the social and environmental quality of the resident’s lives.

The climate of Kolkata is hot and humid with high solar radiation both direct and diffuse. Mid-March to mid-June are the most problematic months, as air temperature ranges between 25 to 30°C with relative humidity levels reaching well up to 100%. As seen in Fig. 5(b) Kolkata receives a lot of horizontal as well as diffuse radiation. The comfort band ranges from an average of 25.6 to 31.6 °C, the project uses Nicol’s equation ($T_c = 0.534\ T_o + 12.9$) for adaptive comfort (Nicol, 2004). Environmental strategies call for the building envelope to work as high thermal mass during the day and low thermal mass at night for optimal comfort in this climate.

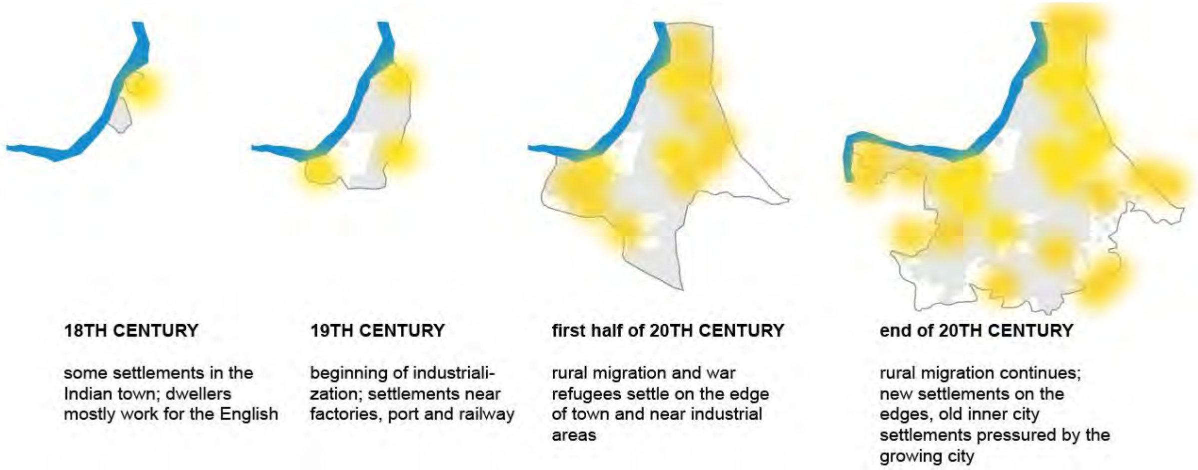

Fig. 1. Timeline of the growth of the city and the simultaneous burgeoning of slums. Source: After Herz, 2008.

Methodology

Spot measurements and slum surveys were carried out in two slum settlements in Kolkata to identify the occupant behavior, existing living conditions and aspiration of the slum residents. The data recorded also enabled the calibration of a base case scenario for thermal simulation studies.

Further fieldwork was carried out in Silchar, Assam which has a climate like Kolkata. The objective was to study four similar huts which were primarily made of 4 locally available materials like bamboo, wattle and daub, mud and traditionally available brick and mortar. Data loggers were installed in the bedrooms of these 4 huts over a period of 1 week. Resident's survey supplemented the study with useful information about the environmental and economic performance of these materials and supported the analytic work.

The information collected from fieldwork helped establish a base case model for simulation using EDSL Tas software. Subsequently, design modifications and alternative scenarios were proposed through step by step interventions to achieve a free-running residential unit.

Fieldwork

Two slum sites were visited: South city (illegal squatter) and Shahid Sriti (legal settlement), Fig. 2. The slums are 35 and 100-150 years old, respectively. Its residents work as maids, drivers in the service industry for gated communities, hospitals etc. around that area. Both the slums are located near a water body, in a low lying marshy area. This indicated that such illegal development generally occurs in unwanted spaces with a water connection.

Fig. 2. Existing slum conditions; Shahid sriti (left) and South city slum (right).

Existing slum conditions:

All basic resources are present but scarce and therefore everything is shared. Environmentally, they are in great discomfort during summer season because of the following reasons:

1. Poor dilapidated hut envelope leading to high heat gains from the leaky roof.
2. High internal heat gains from kitchen trapped inside as they have no or only one window.
3. Dense urban scenario also trapping the anthropogenic heat due to high population density.
4. High humidity levels combined with high air temperatures.
5. Flooding issues during the end of summer and monsoon period.

Winters in Kolkata are usually mild; therefore, this study focused on mitigating the summer problems.

Material survey:

The fieldwork undertaken to identify the material performance of the vernacular materials revealed that the use of the generic brick construction helped for a better thermal performance. Figures 3a and 3b present the summarized comparison of all the materials that were measured over a period of two weeks. The average temperature difference between the external and the indoor temperature was lowest (-0.1K) in brick constructions, followed by units made from mud (-0.6K). Mud performed similarly to brick due to its high thermal inertia even in units with a leaky construction, without false ceilings and mechanical fans. Therefore, mud and brick can be used in places with higher solar exposure. The unit built in wattle and daub with the thatch roof performs third best (-0.9K), followed by that built in bamboo (-1K). Materials with low thermal mass should be used in places with lesser solar exposure and require judicious study at preliminary design stages.

The study here deals with mitigating all the issues that were encountered during the fieldwork and supported the development of a free running comfortable prototype unit that can be potentially replicated throughout other locations.

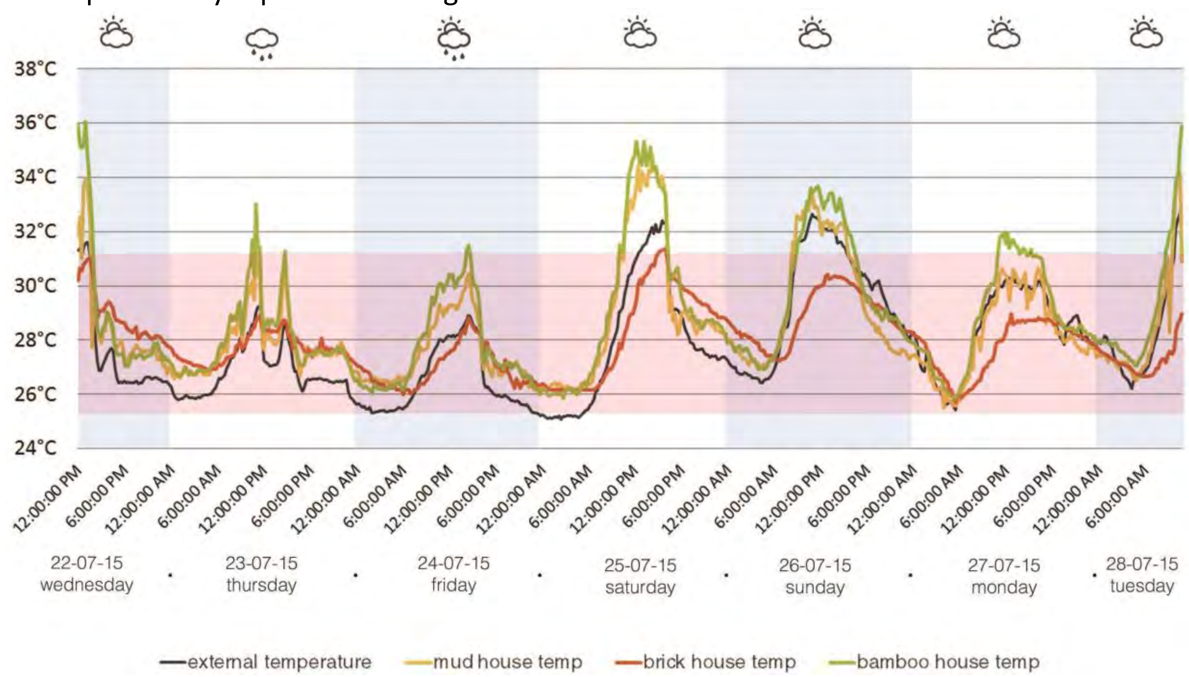

Fig. 3a. Indoor temperature measured during one week in units built in mud, brick and bamboo.

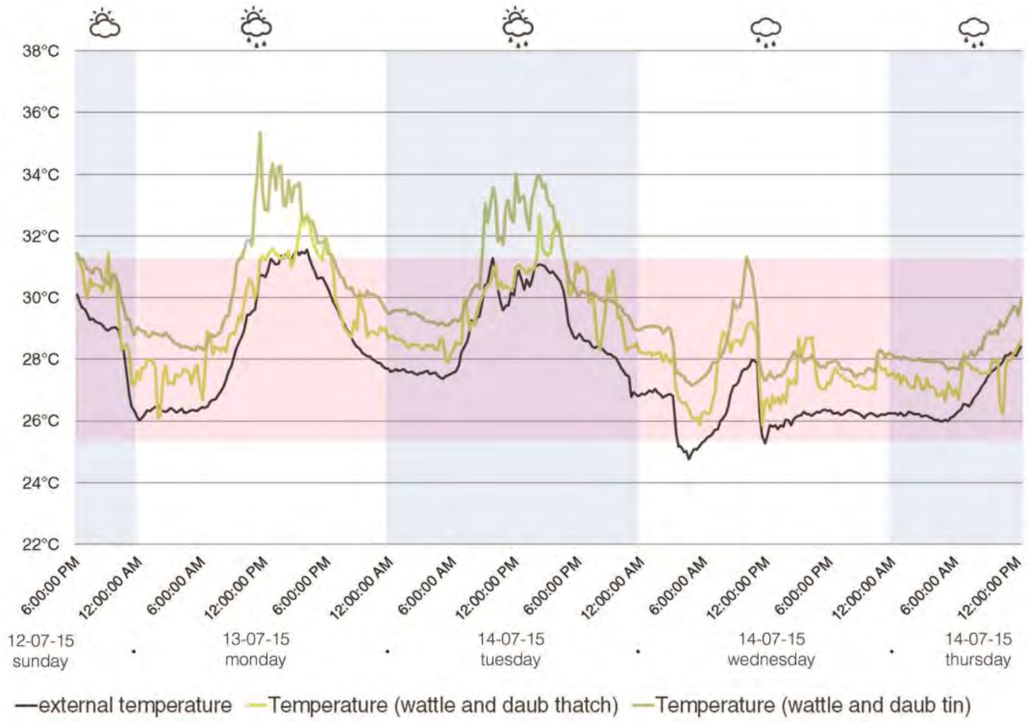

Fig. 3b: Indoor temperatures during one week in units built in wattle and daub thatch and wattle and daub tin.

Design of the dwelling unit:

A dwelling unit was used as a prototype for the study with construction specifications described below and design characteristics shown in Fig. 4. An area of 25m^2 was allotted for each unit based on minimal anthropological requirements and regulations from the National Building Code of India (NBC, 2005). The dwelling unit is designed to have 2 bedrooms and a kitchen. The design is kept simple for ease of construction by participating families. Toilet will be a shared facility amongst the residents.

Thermal analysis of base case:

The prototype incorporates all the existing problems identified in the slum settlement during fieldwork. The following input data was used for thermal simulations.

Floor Area: *25m²* Occupancy: *4 occupants*
Wall U-value: *2.6 W/m^2 K;* Floor U-value: *1. 7 W/m^2 K*
Roof U-value: *4.7 W/m^2 K;* Bamboo mat board U-value: *4.1 W/m^2 K* (ceiling)
Infiltration rate: *1 ac/h;* Ventilation rate: *1.7 ac/h*
Lighting Gains: *3.69 W/m^2 (bedroom) + 2.7 W/m^2 (kitchen)*
Occupancy Sensible Gain: *17.29 W/m^2 (bedroom)*
Equipment Sensible Gain: *126.3 W/m^2 (kitchen) + 6.34W/m^2(bedroom)*

The results show an average difference of 6K between the bedroom and the outdoor resultant temperature. The peak indoor temperature which reaches almost 38°C while outdoor relative humidity is 80% during the occupancy hours for lunch, demonstrates the high level of discomfort a slum resident experiences. Throughout the year the base case is out of comfort for 43.3% of the time, while the external temperature is out of comfort range only for 16.1%.

Therefore, the analytic work focused on improving the existing unit aimed at decreasing the resultant indoor temperature. Improving the roof specifications, varying the fenestration and changing the materiality have the highest impact (Fig. 8). Only these three cases (i.e Case 1, 4and 5) have been discussed below. Other cases (2,3,6-10) are depicted in the images for a better comparative analysis and understanding.

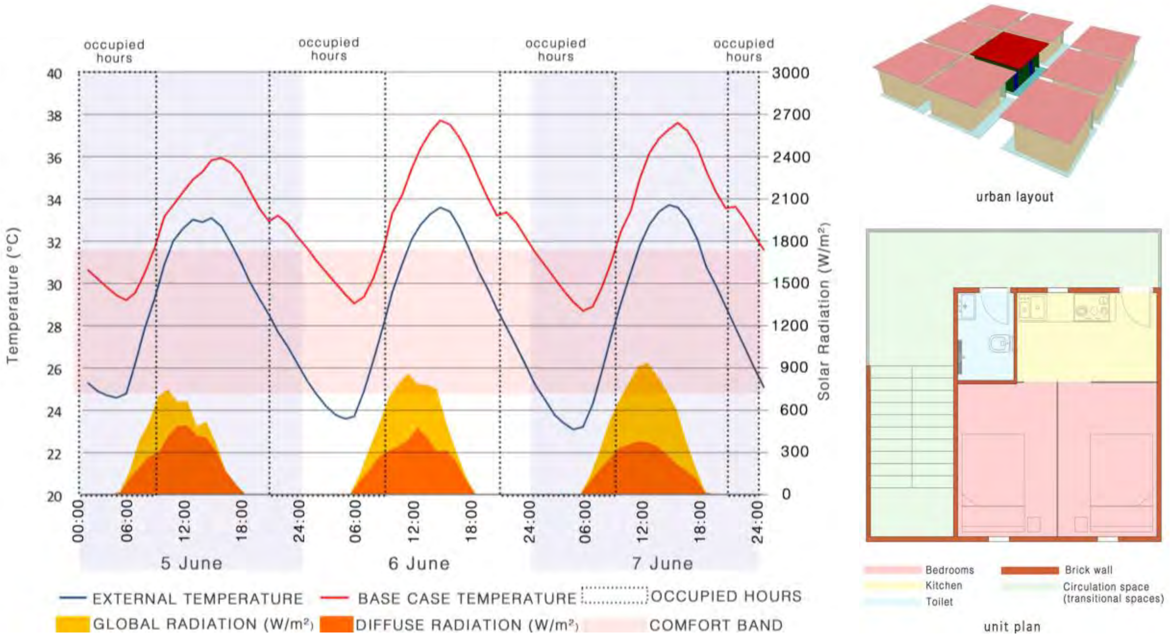

Fig. 4. Resultant temperature of base case for 3 typical summer days. TAS model layout for base case (right).

Strategic improvements of the base case:

Case 1- Improved roof: Figure 5 indicates that the roof surface receives the maximum solar irradiation. Hence the first intervention was to replace the initial clay tile by concrete slab with a layer of damp-proofing and additional solar panel installation (weighted U-value = $0.2W/m^2K$)

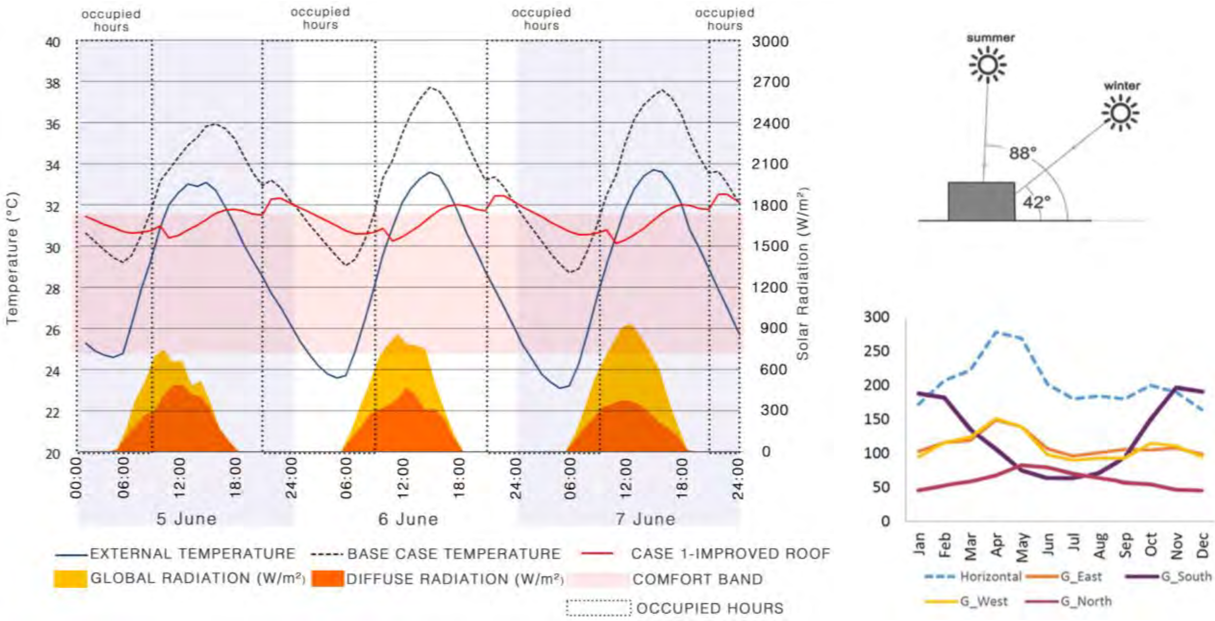

Fig. 5: (a) Resultant temperature for improved roof scenario. (b) Annual solar radiation Kolkata (right).

The TAS simulation for the typical summer days shows a significant drop in the resultant temperature in the bedroom and is more consistent throughout the day. Case 1 registered 5K lower resultant temperature than the base case during the peak hours of the day and 2K higher temperature during the minimum temperatures at night.

Case 4 - C3+fenestration change: The fenestration sizes were increased to improve ventilation. The fenestration to floor ratio was increased from the initial 9.9% to 43.4% showing a huge drop in air temperature. The bedroom is within comfort range throughout the day figure 6.

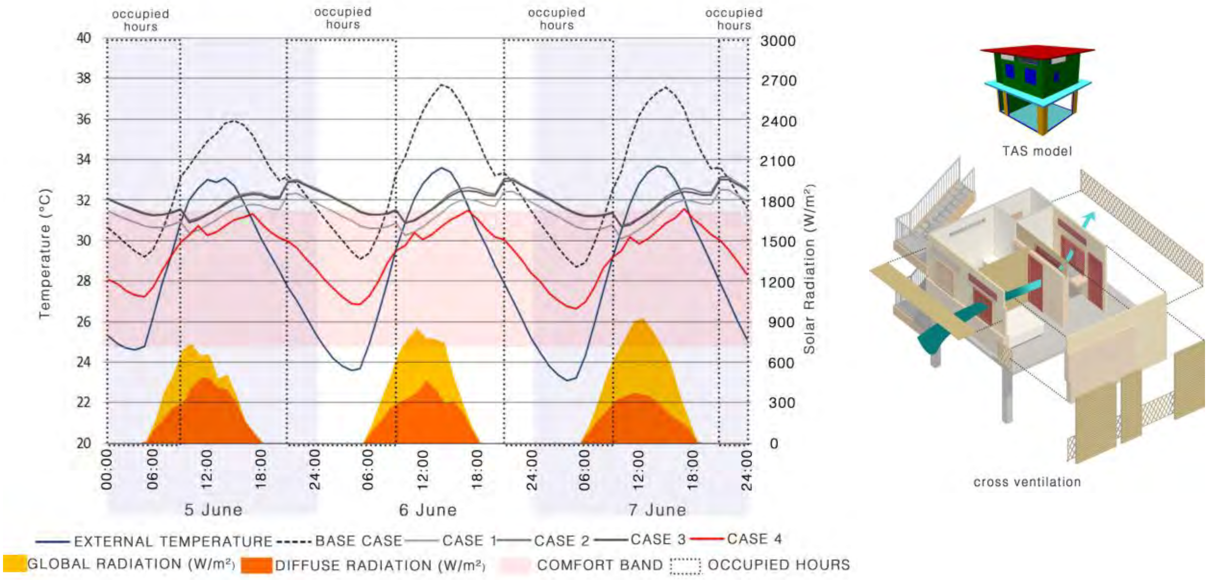

Fig. 6. Resultant temperature for improved fenestration.

The resultant temperature has dropped by 1K during daytime peak hours and by 4K at night-time. Thus, closing the window during peak hours helps benefitting from the effects of high thermal mass of the unit. At night, opening all the windows facilitates night time cooling, thereby converting it into a low thermal mass unit. This step was one of the most important interventions. The windows are louvered to block the abundant diffuse solar radiation and allow only ventilation during the day.

Case 5 - C4+all material change: The effect of replacing the generic brick construction with all the vernacular materials identified during fieldwork was studied. A series of tests were undertaken to deduce the size and height of each material panel that will be implemented on the unit, Figure 7. The final configuration of the materials to be used as the envelope had a similar performance as the existing brick one. Nevertheless, it is still worthwhile to take up this intervention because of the following reasons:

1. Energy consumption in a cubic meter of CSEB (compressed mud blocks) can be 5 to 20 times less than a generic brick and mortar construction (Auroville, 2015), (BMTPC, 2015).
2. The pollution emission for CSEB blocks will also be 2.4 to 7.8 times less than fire bricks (Auroville, 2015).
3. The unit envelope is constructed with locally available materials and semi-skilled labour (in this case the residents themselves, the majority of which are familiar to these materials), almost without transport.
4. Cost estimates for the wall envelope made of wattle and daub, bamboo and CSEB blocks can be 46% cheaper than traditional brick construction.

5. Since these local materials mentioned above are familiar to slum residents, there is the opportunity for the project finances to be used on people rather than the industry (which would have been the case had they been using brick and concrete).

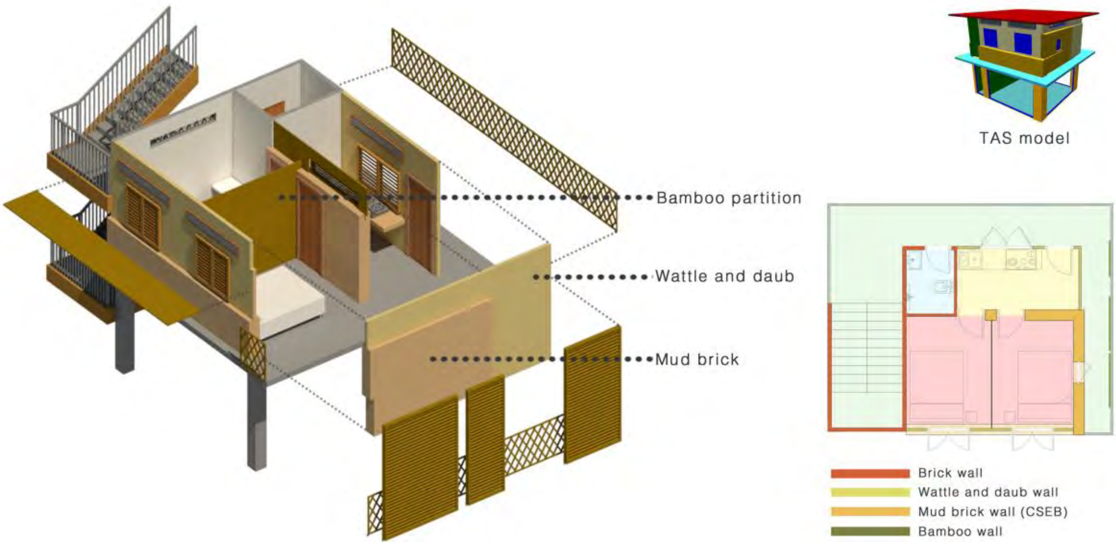

Fig. 7. Replacing traditional brick and mortar with local material panels for ease of construction.

Annual percentage of discomfort hours:

While testing the different cases, the percentage of hours when the indoor resultant temperature was beyond 31.6ºC (upper limit of comfort band using Nicol's equation for adaptive comfort) was also checked for the entire year. Fig. 8 shows how the percentage of discomfort hours have been reduced from 43.3% (base case) to 10.6% (final case), well below 16.1% (external temperature). Furthermore, if the percentage of discomfort hours is considered only during occupancy hours, it decreases to 3.25% (11 days approx.). This can be easily mitigated with the use of mechanical fans at a speed of 0.5m/s.

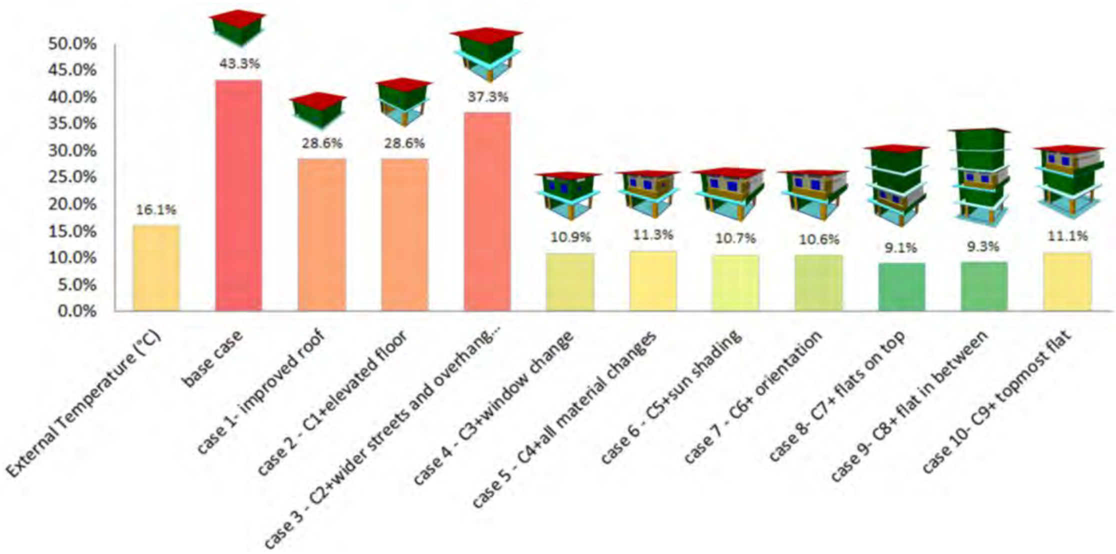

Fig. 8. Comparison of the percentage discomfort hours of all the interventions for the entire year.

Conclusions:

Extensive research, including fieldwork and analytic studies were part of the design process aiming at housing urban slums residents in habitable, sustainable and economically viable communities (Fig. 9) in the hot and humid climate of Kolkata. The study showed that free-running units providing comfortable indoor resultant temperatures throughout the year can be achieved combining new technologies with traditional strategies including low-cost local materials, such as mud bricks, bamboo and wattle and daub. The proposed unit was designed to benefit from high thermal mass materials during the day to mitigate the high incident solar radiation and from low thermal mass materials during the night to allow a better effect from the cool breeze flowing indoors through the large fenestrations, thus facilitating the dissipation of the internal heat gains. Analytic studies showed that the proposed unit would thermally perform very similarly if the use of brick was replaced by the low-cost local materials, but worthwhile due to massive economic and environmental benefits, including the possibility to being built by the owners.

Fig. 9. Future replication of the prototype unit in building and urban scale.

Defining the Right Balance between Passive and Active Systems in an Appropriate Housing Design

Achilles Sophia Madhi Gnanaprakasam[1] and Guillermo Guzman Dumont[1]

[1] Faculty of Engineering, University of Nottingham, Nottingham, United Kingdom

Abstract: Increasing concerns over global warming, energy shortage and poor occupants comfort have led to the implementation of energy efficiency standards worldwide. Passivhaus standard is an active approach, widely implemented in Europe, is now being expanded across the world, including hot and humid climates. Considering its complexity and high implementation cost, a more affordable system which integrates both passive and active design strategies are in demand for hot developing countries, but hasn't developed or implemented enough. In India, especially in Chennai, the usage of air conditioning in a housing sector is enormous, leading to high energy consumption in the present day context with respect to poor ventilation and inadequate construction techniques. Due to economic and cultural reasons, the European approach might not be a suitable solution for India, raising the question of good living quality with low energy houses that responds to future needs. By considering these aspects, this research identifies a suitable passive design strategy and a building construction technique, based on the comparisons of thermal and energy simulations of a passivhaus (Nottingham H.O.U.S.E, a case study building designed for both hot-humid and then cold climate), a present day house and a traditional house under Chennai climate.

Keywords: Energy Efficiency, Thermal comfort, Natural ventilation, Passivhaus, Dynamic simulation

Introduction

The awareness and the execution of energy efficiency standards have become a necessity in today's building context, due to the uncompromising environment. Despite, a recent baseline study for commercial and residential building found that energy consumption due to space cooling and lighting in residential buildings accounts for one third of total energy consumption in India (Bhatt, et al., 2005)

Regarding this uncertainty, the Energy conservation act introduced by Indian government commenced the Energy Conservation Building code (ECBC) in 2007 for energy efficient buildings (BEE, 2011). However, this code largely applies to the air-conditioned buildings with 1000 m² floor areas, particularly for commercial and office buildings. Besides, the other voluntary green building rating systems such as Indian green building council (IGBC) green homes, AaDarsh's SVAGRIHA which encourages the energy efficiency in residential sector have not been reached properly to the middle class families who seemed to be majority Indian population (Rawal, et al., 2014). Meanwhile, regardless to the introduction of passivhaus (also known as passive house) concept in a cold climate assured maximum thermal comfort and indoor air quality with significant decrease in primary energy demand (Feist, et al., 2005). However, the application of passivhaus, which has not been fully explored with respect to hot and humid climates, might or might not perform better under Chennai, a hot and humid climate. Or else, can eventually contribute some ideas in terms of comfort and energy efficiency in near future.

Relying on this observation, the thermal and the energy performance of Nottingham H.O.U.S.E, the typical present day and traditional house of Chennai has been studied and the results of these three houses (figure 1) has been distinguished in a way, a suitable passive design strategy and a construction method can be incorporated in future for a healthy and efficient housing in Chennai.

Figure 1. The three different houses dealt in the research

Concept of Passivhaus

Passivhaus is a voluntary standard derived from building physics, which ensures comfort, cost effectiveness and energy efficiency (Passipedia, 2015). In order to achieve the passive house standard, the required heating/cooling demand should be 15 -10 kWh/(m²yr), primary energy usage should be 60 - 120 kWh/(m²a) and the airtightness including air changes should be n50 = 0.6/h (Feist, et al., 2005). However, these three requirements can be attained through various key principles such as high performing windows, Airtightness, Thermal Insulation, Avoidance of thermal bridge and Ventilation with heat recovery (Passipedia, 2015).

Moreover, the passivhaus concept that was developed in central and northern European climates has been adapted recently to various climatic conditions including very hot climates that totally differ from Germany and Austria (Schnieders, et al., 2015). similarly , a recent research, "Passive houses for different climatic zones" carried out by Schnieders, et al., (2015) under six climatic zones including hot and humid climate, implies that primary energy demand and peak daily average load assumed for ideal heating or cooling system seemed to hold indoor temperatures in an inner comfort range most of the time.

Passivhaus: The Nottingham H.O.U.S.E

The Nottingham H.O.U.S.E, a family oriented two storied housing (figure 1) that was built with passivhaus standards was initially a diploma and master's studio design project, designed within a master plan that involved a Zero Carbon community, to meet the specifications provided by the Solar Decathlon Europe competition. In addition, the Nottingham H.O.U.S.E which is located near creative energy homes at Green Close in University Park campus, Nottingham was designed for both Madrid (hot) and Nottingham (cold) climate respectively. However, a difference in the usage of double height spaced dining area that has a roof light for ventilation, varied according to that particular climatic zone, to provide cooling in Madrid climate through Passive down draught evaporative cooling system and to naturally ventilate through stack effect in Nottingham (Guzman, 2012).

Figure 2. The Nottingham H.O.U.S.E

Climate analysis (Madrid and Nottingham with Chennai Climate)

The comparison table 1 shows that, the south facade of the Nottingham H.O.U.S.E is the most exposed facade throughout the year under Madrid, Nottingham and Chennai climate respectively. However, south façade receives high solar radiation with respect to Chennai; also the north façade seems to be exposed most of the year (summer and equinox). Besides, the average temperatures shows the clearly defined temperature range during seasonal variations for Madrid and Nottingham, whereas Chennai has steady temperatures through the entire year with a daily temperature swing between day and night of 8.3°C.

Table 1: Comparison of Nottingham H.O.U.S.E with respect to climatic zones

Location	Summer Solstice : 12.00	Equinox : 12.00	Winter Solstice : 12.00
Madrid, Spain: Latitude: 40.5° N. Average Temperatures : summer Solstice - 20.6°C, Equinox- 20.0°C, winter Solstice - 5.8°C			
Nottingham, UK: Latitude: 52.95°N. Average Temperatures : summer Solstice – 14.2°C, Equinox- 12.9°C, winter Solstice – 5.6°C			
Chennai, India: Latitude: 13.08° N. Average Temperatures: summer Solstice - 29.9°C, Equinox- 26.4°C, winter Solstice - 25.4°C. Daily temperature swing: 8.3°C			

Housing in Chennai

Many transformations are seen from early century to this era, with respect to housing in Chennai due to various reasons including westernization, population explosion, inadequate space and technological developments.

The Present day Housing

The resulted present day houses of middle class families are mostly compact in size that has single side ventilation and sometimes cross ventilation is achieved if the doors were also kept opened. In addition, a typical present day single storied house consist of a living area, kitchen, a toilet, two bedrooms and utility as shown in figure 2.

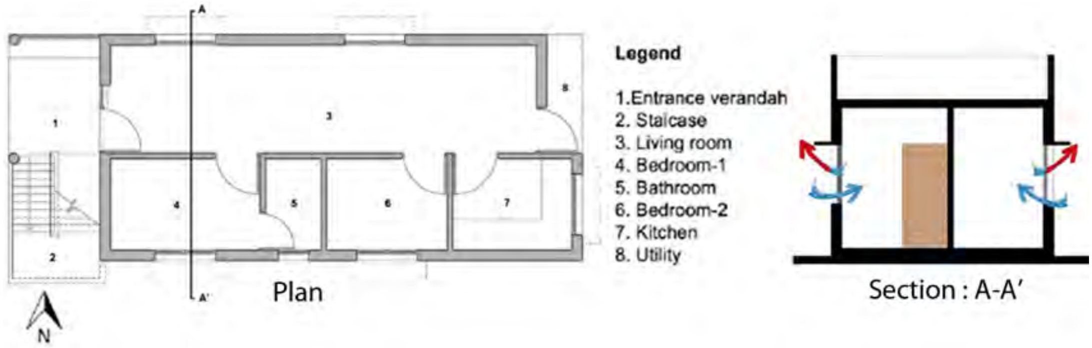

Figure 3. The Typical Present day House

The traditional housing

The traditional houses that were built around 19th century in Chennai had passive cooling strategies that responded to regional climate. For instance, Venturi effect was used to suck the hot air out with the help of mutram, an open to sky courtyard. Additionally, the deep verandahs with sloped roof inside and outside the houses were used for shading in summer. A typical traditional house (figure 3) that has been used for this research is a single storied square house that has mutram and columned inner verandahs. The house also consists of a front verandah with seating called otta that faces east direction and other services that includes toilets at the backyard (Desai, et al., 2012). Furthermore, these houses are usually constructed with red oxide flooring, country tile roofing, Burma teak rafters and lime plastering (Iyer, 2011).

Figure 4. The Traditional House

The Research Methodology

A significant method that compares the building performance of a passivhaus (Nottingham H.O.U.S.E, a case study building) with a typical present day and a traditional house of Chennai has been dealt in this paper. Moreover, the study of each house has been divided two parts namely, thermal and energy analysis. In which the thermal analysis under several cases has been carried out with Apache dynamic simulations from IESVE (integrated environmental solutions – virtual environment) software and the basic energy calculations for each house has been carried out with Sefaira architecture software. Moreover, the thermal simulation cases and general assumptions used for all the three housing assessment are as follows.

Thermal simulation cases

The first set of simulations were carried out using natural ventilation for throughout the year and the second set of simulations were done using natural ventilation but only for the summer period (April, May, June). However, with respect to Nottingham house, the second set of simulations was carried using roof light kept opened continuously to check ventilation in summer.

General Assumptions for thermal and energy simulations

- *Weather profile*: Madras/Minambakkam (Chennai) weather data was used from ASHRAE (climate zone 1) design weather database V 5.0 in IESVE.
- *Comfort and Energy*: Indoors with 18°C to 29°C were considered based on comfort zone provided for developing countries with hot climate by Givoni, (1992) and the passivhaus standards for primary energy cooling demands (Feist, et al., 2005).
- *Construction used:* Building components with respect to U-values (W/m² K) are given in table 2.

Table 2. U-Values of construction components

Types	External walls	Internal walls	Floor	Roof	Windows
Nottingham H.O.U.S.E	0.09	2.46/1.38/1.79	0.11	0.12 (internal ceiling-1.08)	0.5
Present day House	2.44	1.75	1.13	3.35	5.17
Traditional House	1.35	1.50	1.13	1.50(Slope roof)	5.17

- *People gains*: Occupancy per house was considered four with maximum sensible gain of 70 W/person and maximum latent gain of 45W/person.
- *Lighting gains*: Low energy florescent lights were considered for living (0.6W/m²), bedroom (0.25 W/m²), kitchen (0.6 W/m²) and dining room (0.6 W/m²) for both maximum sensible heat gain and power consumption inside Nottingham H.O.U.S.E. Nevertheless, Lighting gains with respect to present day house and traditional house were assumed 8 W/m2 for both maximum sensible heat gain and power consumption.
- *Equipment and appliances gains*: These gains vary according to kitchen and living with respect to each house and their usage. For Nottingham H.O.U.S.E, the gains were 60 W/m² and 5 W/m² respectively. For Present day house, they were 1.3KW and 2.5KW respectively. However, With respect to traditional House, the gains were considered as 0.69KW and 0.5KW respectively, since only fridge and TV was assumed.
- In addition, the variation profile of all the above given gains has been considered based on the daily activities undertaken by all the occupants in each house for different hours of time.
- *Infiltration*: The infiltration rate of 0.6 ACH was considered for Nottingham H.O.U.S.E, since it is an airtight building that follows passivhaus standards. However, the infiltration rate for present day and traditional house were assumed as 1 ACH.

– *Ventilation*: Natural ventilation rates were assumed as 6 ACH based on the Indian building standards given for functional requirements of buildings. An effective opening of 90% based on the daily activities of the occupants has been considered for windows.

Results

Table 3. Comparisons of Thermal and Energy performance of Houses

Description	 Case study building(Nottingham H.O.U.S.E)	 Present day house	 Traditional house
Thermal comfort (Thermal simulation - Case1)	27.30%	45.38%	60.60%
Summer comfort with roof light kept opened continuously (Thermal simulation -Case 2)	13.60%	10.78%	25.40%
Ventilation strategy used	Roof light opening (stack effect) + cross ventilation	Single side ventilation	Courtyard with stack effect + ventilation
Thriving Ventilation strategy that actually showed consistent increase thermal comfort	✓	✗	✓
Increase in comfort with respect to infiltration alone (without ventilation)	✗	✓	—
Primary energy demand	85 kWh/ (m^2 a)	210 kWh/ (m^2 a)	112 kWh/ (m^2 a)
Primary energy demand that satisfied low energy requirement (120 kWh/ (m^2 a))	✓	✗	✓
Building thermal properties and glazing typology used	Well insulated, low U-values (table 1) Triple glazing	Un-insulated, High U-values (table 1) Single glazing	Un-insulated, standard, U-values (traditional method) (table 1) Single glazing
Low energy demand with respect to building thermal properties and passive strategy used	✓	✗	✓
Specific Cooling demand	34.3 kWh/ (m^2 a)	70.1 kWh/ (m^2 a)	58.5 kWh/ (m^2 a)
Specific Cooling demand that satisfied low energy requirement (15 kWh/ (m^2 a))	✗	✗	✗
The major gains that drives the cooling demand	Solar gains from south, north and east facade	Wall and roof conduction and solar gains from south facade	Wall and roof conduction
Reason behind the high gains	No external shading device	No insulation Improper shading devices	No insulation

All the three types of houses have their unique style of design strategy and construction used. However, it is important to consider a right set of building elements (u-values, infiltration) including passive strategies to develop a house for a comfortable living in a particular climate without affecting the environment. The comparison table 3 based on comfort temperature range (Givoni, 1992) and the specific energy usage (Feist, et al., 2005) helps in defining each house, its advantages and disadvantages with respect to their specific features that responds to the Chennai climate.

Conclusions and Discussions

From the comparisons (table 3), it can be understood that the traditional house provides more percentage of comfort hours with respect to case 1 and case 2 than the present day and Nottingham H.O.U.S.E. In addition, it can be seen that, the roof light (stack effect ventilation strategy) opening in Nottingham H.O.U.S.E with respect to summer helps in increasing the thermal comfort, compared to present day house that has single side ventilation. From this understanding, it can be assumed that the combination of cross ventilation with stack effect/ venturi effect as given in Nottingham house and traditional house, proved to be a better ventilation option. However, a very low infiltration rate is not suitable for a house in Chennai with respect to passivhaus (Nottingham house) that has more airtightness leads to the very low comfort, whereas present-day house with standard infiltration rates has shown better thermal comfort.

Particularly, the building thermal properties used in Nottingham H.O.U.S.E and traditional house seemed to help in lowering the energy demand of the houses, whereas only increase in comfort through infiltration (without ventilation) is seen in present day house. Still, cooling demand seemed to be uncompromising in all the houses due to unwanted heat gains, which can be reduced by adding good levels of insulation and proper external shading devices(particularly on south side).

Developing mega cities like Chennai that faces major issues such as space constraints, increase in pollution and the high land values creating unaffordable conditions for an efficient living can be dealt with few considerations that this research seemed to contribute. In addition, this research contributes a passive design ideas that can be adapted in a national spectrum in most of the hot-humid urban and rural areas in India Originally, an integrated stack effect ventilation with cross ventilation within any house (as provided in Nottingham H.O.U.S.E) seemed to decrease space constraints and increases comfort. Furthermore, insulated building components accompanied by standard infiltration that coincides with the climate serves both thermal comfort and low energy consumption.

Abstract: In this work, finite element method was used, trough the software COMSOL Multiphisics ®, to analyses the thermal performance of a theoretical space whose main facade wall, facing south, is equipped with a glass water tank, to maximize the thermal storage and thermal mass effect. The climatic data base was incorporated from the Meteonorm® software, to which real climate data was incorporated from the National Meteorological Service (CONAGUA,2000) station of Azcapotzalco, in Mexico City, to perform the required interpolations. The main parameters used in this study were outside dry bulb temperature and solar irradiance. The inside temperature conditions were evaluated with the comfort model of Aulliciems and Zokolay (1997).
The 3D model system consists of a rectangular spaced composed of an isothermal vertical water wall and all other surfaces considered as adiabatic. The south water started with an ambient temperature *Ta* and the others surfaces at a temperature *Tf*; fulfill condition *Ta* > Tf, causing the heat transfer process. The study emphasizes the pertinence of implementing a thermal wall supplied by a rainwater harvesting system.

Keywords: Water thermal storage wall, Numerical simulation, Thermal comfort

Introduction

The term “Water walls” refers to the use of water as thermal mass in passive solar houses for heating and cooling (Bainbridge, 2005).
The actual configuration of a water wall system will depend on the location and weather condition for its application. The locations of some cases with this strategy, cover only a few places: Australia, Europe, India, Turkey, China and Africa (Ting Wu et al, 2016). Water has a high heat capacity to store sensible heat (Cengel et al, 2012) (Weiliang et al, 2012). These systems have a thermal mass effect, and considering that the thermal mass is highly effective for the climate of Mexico City, this study will determine the appropriate parameters for the water, air layer and for the whole wall thickness. The current document establishes a theoretical space that uses a thermal storage water-wall to obtain the most efficient system configuration based on temperatures and solar irradiance.

For daily amplitude of Mexico City, Mahoney (Koeningsberger et al, 1977) recommends the use of massivity above 10 °C, however, Evans (2000) indicates that this strategy is convenient from 8 °C. Mexico City presents a daily average amplitude of 11.5 °C, the minimum in September of 8.5 °C and a maximum in March of 14.1 °C. Docherty et al (1999) define three mass effects: Winter mass, Summer mass and Summer mass with night ventilation. In the case of Mexico City, the lower limit of winter comfort is 20.3 °C; for a temperature in January of 13.8 °C and a daily amplitude of 13.5 °C; it means that limit of the effectiveness of the strategy of winter massivity occurs above 14.9 ° C (20.13 - (0.4 x 14.3) = 14.9 °C).

Comfort Zone

Climatic data was analyzed according to the annual characteristics of temperature, relative humidity, solar radiation and wind. The reference parameter to analyze the temperature is the comfort zone, which is defined from the Neutral Temperature (Tn), using the linear equation of Auliciems (Auliciems et al, 1997):

$$T_n = 17.6 + 0.31 T_{med} \tag{1}$$

Where T_n is the neutral temperature and T_{med} is the annual mean temperature.
This adaptive comfort model proposes to apply a thermal amplitude of ± 2.5K on the Tn for annual periods. In this way, the Upper and Lower Limits of the Comfort Zone (ZCs and ZCi, respectively) for Azcapotzalco, are defined as follows:

T_n = 17.6 + 0.31 (16.7) = 22.77
ZC = 25.3 ° C; ZCi = 20.3 ° C

Water management

The use of technology that uses rainwater is based on rainwater harvesting systems that ensure the water supply during the rainy months, allowing its storage to be used even during the dry season. Among the elements that integrate a system of capture and exploitation of rainwater are the surface of capture, conduction, water treatment system, storage and distribution. The proposal that is mentioned in the present work is the use of water wall for temporary storage of this rainwater and to integrate it to the architectural design of a wall, at the moment it has not been approached like a temporary storage system that serves simultaneity as a thermal regulator in the built-up space.

Description of this research

The configurations and dimensions of the model are determined according to the model of Figure 1. Dimensions are set at L = 3.60, A = 3 m and H = 2.40. The floor, the ceiling and the three walls are isolated except the south side. The dimensions established correspond to the statistically most common space of a bedroom, with high thermal comfort needs. This type of composition allows to know the effect of the water wall system and its influence on indoor temperatures. The south wall is used to store and release heat. The water wall has a width of 0.07 m, and the water use is 0.168 m^3 and the air layer is 0.05 m.

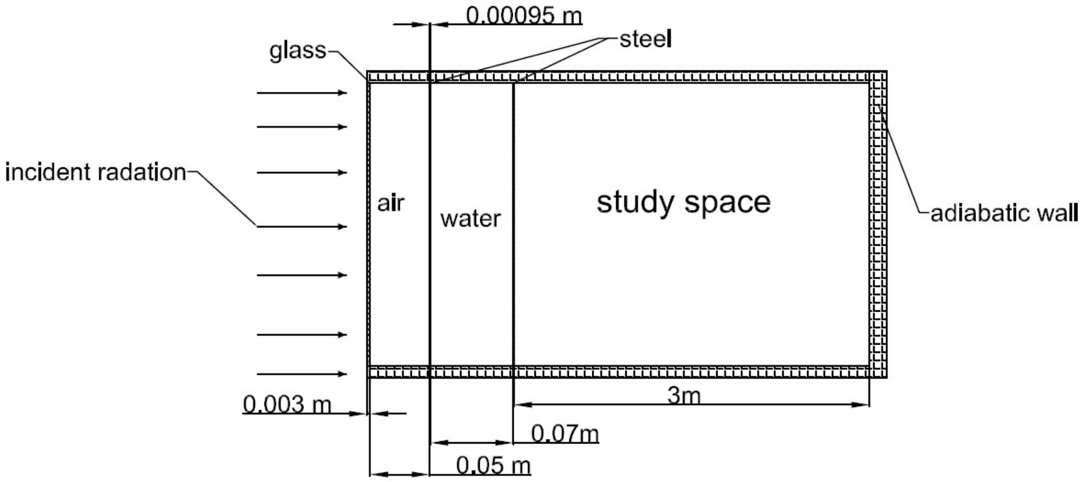

Figure 1. Sketch of a water wall.

Mathematical Approach

The physical model consists of a closed space of height H in the "Y" axis, long L in the "X" axis, and depth "Z", the water wall system starts at an initial temperature Ti, that varies over time. The upper and lower surfaces are thermally insulated, 2 configurations are handled: variation of wall thickness of water and variation of air layer.

In the formulation of convective heat transfer problems (equation 2) it must be recognized that in a moving fluid the heat energy is transported both by conduction (equation 3) and by the movement of the fluid, a body emits radiant energy with a speed given equation 4, but at the same time absorbs radiation; If this did not happen, the body would at some time radiate all its energy and its temperature would reach absolute zero. The energy a body absorbs comes from its surroundings, which also emit radiant energy.

$$Q_{conv} = H\, A_S(T - T_\infty) \tag{2}$$

Where: Q_{conv} is convection heat transfer rate, H is factor of convection, A_S is the area involved in the heat transfer process, T is the system temperature and T∞ corresponds to the ambient temperature.

$$Q_{cond} = k\, A\, (\frac{\Delta T}{\Lambda X}) \tag{3}$$

Where: Q_{cond} is conduction heat transfer rate, k is the thermal conductivity coefficient, $\frac{\Delta T}{\Delta X}$, is the temperature gradient

$$Q_{rad} = \varepsilon\, \sigma\, A\, (T_a^4 - T_\infty^4) \tag{4}$$

Where: Q_{rad} is radiation heat transfer rate, σ = 5.67x10-8 W/(m^2K^4) is the Stefan-Boltzman constant, and ε is a radiative property of the surface called emissivity, its values vary in the range 0 <ε <1, is a measure of the efficiency with which the surface emits radiant energy, depends on the material (Inzunza, 2009).

Methodology

To solve the equations of radiation, temperature, as well as the natural external convection equation governing the system together with the boundary conditions, the finite element method was used through the software COMSOL Multiphisics® Modeling Software 5.2 (2017). For these, the following methodology was used:

a) The type of analysis is selected in the software, in this case 3D model.
b) The geometry to be analyzed is drawn and the border elements are generated. In this case, the cavity was dimensioned with a height of 2.4 m, width 3.60 and a depth of 3 m. the system is formed by different layers: 3mm glass; air in different dimensions, 0.0095 m steel sheet, water which vary the thicknesses of 5 cm and 10 cm respectively; and another steel sheet 0.0095 m thick.
c) Six combinations of air and water thickness were analyzed: 1) air 5, water 5cm; 2) air 5, water 7cm; 3) air 5, water 10 cm; 4) air 10, water 5 cm; 5) air 10, water 7 cm; 6) air 10, water 10 cm.
d) The initial values are entered, which start with a temperature of 7 °C, as this is the outside temperature at the beginning of the simulations.
e) The boundary conditions are introduced and different temperature and radiation functions are handled for each day, which correspond to the external conditions to which the system is subjected, so that the software makes a variation of temperature between the walls of the cavity.
f) The interfaces solved by the program were heat transfer by radiation, heat transfer in fluids, heat transfer in solids and heat flow.
g) A cutting plane is created in the X axis, Z coordinate Y = 1.8 (figure 2), the above to export the position data to the interior of the cavity with their respective temperatures; To perform the unidirectional flow temperature distribution graph in a two-dimensional plane, a cut line is created on the X, Y (0.1549,1.2) and (3.1549,1.2) (figure 3)

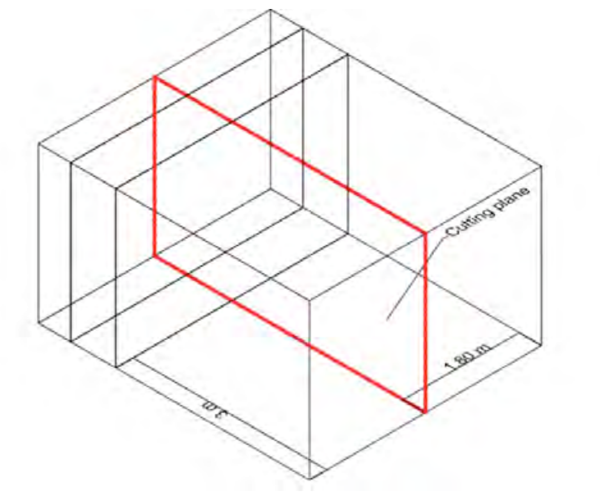

Figure 2. Cut plane in axis X, Z.

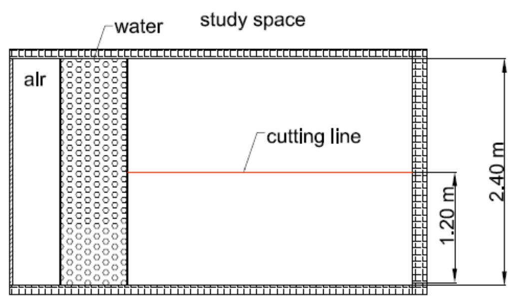

Figure 3. Cut line in axis X, Y.

Result and discussion

The interior temperatures per hour for a week in January are shown in Figure 4, where the horizontal lines correspond to the established comfort range, and the curves represent the variation of the interior temperatures as the thickness of the water wall system changes.

A total of 168 hours was simulated, these hours represent the coldest week of the year in Mexico City. The minimum ambient temperature is 3.8 °C plotted at 6:00 am, and

the maximum of 22.5 °C is at 15:00 pm, the temperature oscillation is wide, reaching up to 19 °C. The outside temperatures are located within the comfort zone 5.35% of the time, which means that 95% of time in the winter season requires spaces efficient to gain heat.
It is observed that the behavior of the heat flow between the exterior and interior space was normalized after the first 125 hours, because the test starting temperature was a theoretical temperature that was proposed equal to the outside for the same hour (7 ° C).
In order to establish the most suitable dimension for the water and air layers of the water wall, the data are taken into account after the hour 126. From this interval, the behavior of the interior temperatures is cyclical, allowing comparison of the inner and outer thermal amplitudes.

The parameters to qualify the good performance of the walls are: development within the comfort zone; close to the neural temperature; lower decrement factor; and lower temperature amplitude.

The six-proposed water-wall systems reduce the internal temperature by up to 14 °C compared to the outside temperature. They also reduced the oscillation of internal temperatures by up to 13 °C compared to the outside temperatures.

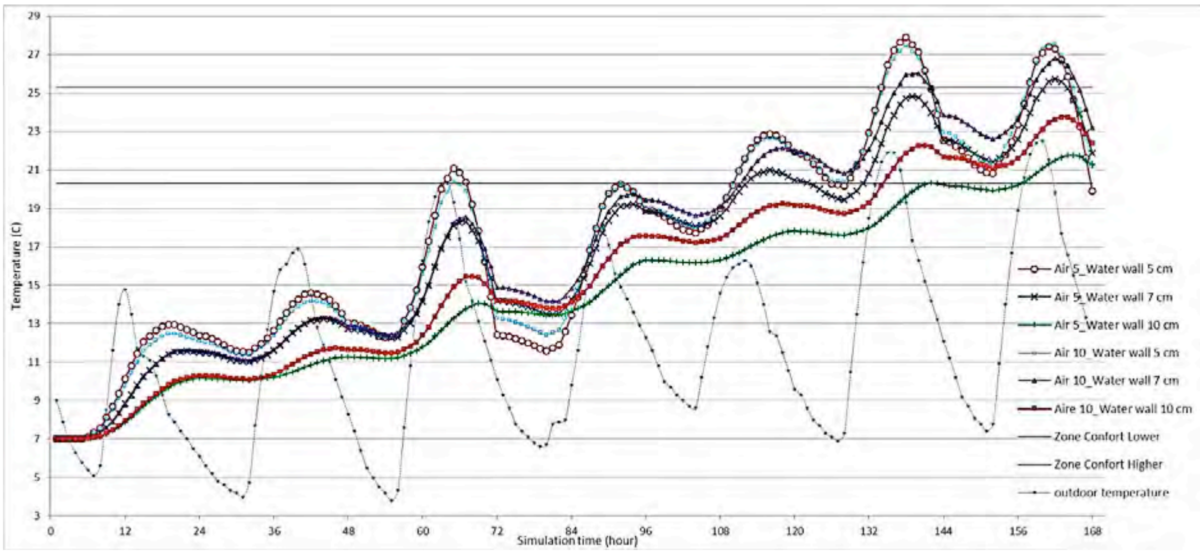

Figure 4. Behavior of indoor temperatures

Table 1. Behavior of interior temperatures according to their dimensions

System	Air gap (cm)	Water gap (cm)	Indoor amplitude (C)	Outdoor amplitude (C)	Decrement factor DFs	Time inside the comfort zone (hour)
1	5	5	7.50	15.1	0.49	16
2	5	7	4.3	15.1	0.28	20
3	5	10	1.82	15.1	0.12	12
4	10	5	6.37	15.1	0.42	17
5	10	7	4.20	15.1	0.27	17
6	10	10	2.64	15.1	0.17	24

According to the results shown in Table 1, the combination of air layer and water layer dimensions that provides the best performance of indoor temperatures are the wall of 10 cm of water and 10 cm of air (figure 5,6,7 y 8).

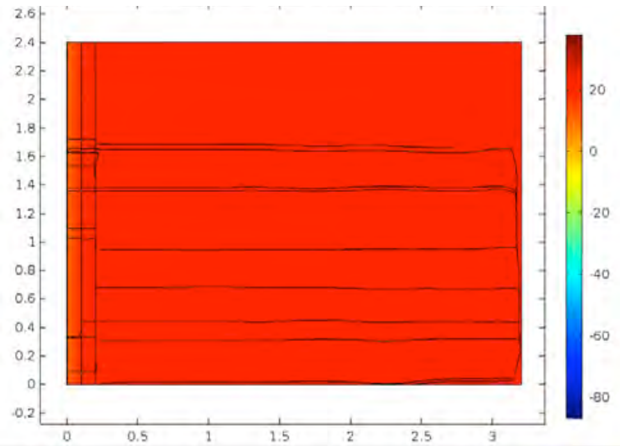

Figure 5. 8:00 h, water 10 cm y air gap 10 cm.

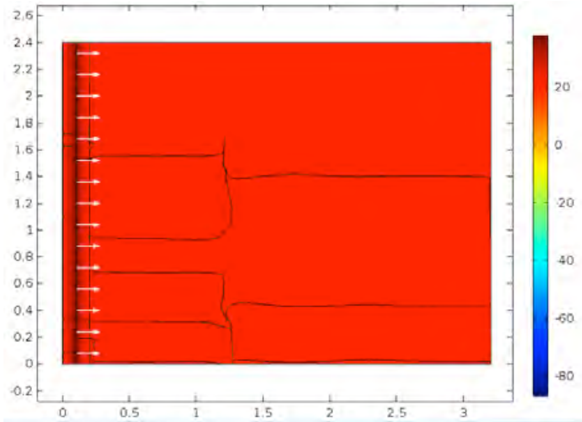

Figure 6. 14:00 h, water 10 cm y air gap 10 cm.

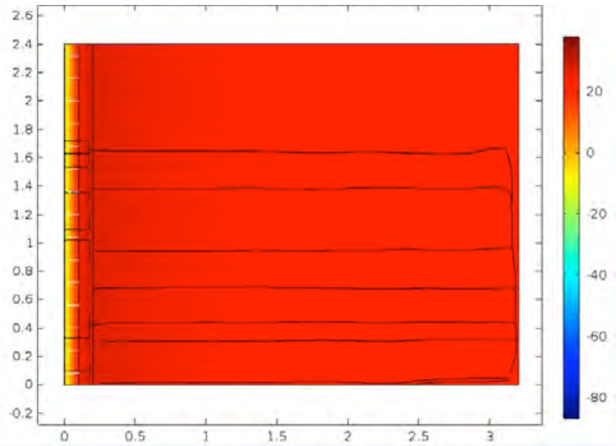

Figure 7. 19:00 h, water 10 cm y air gap 10 cm.

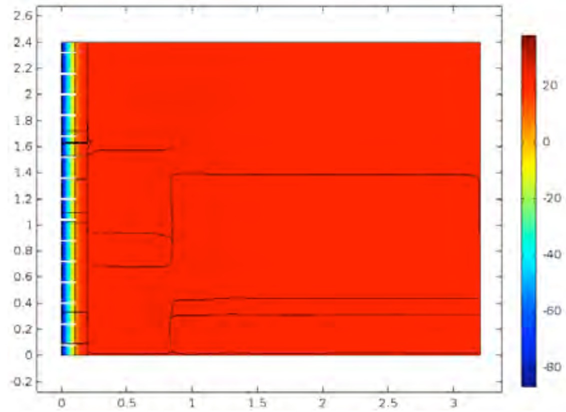

Figure 8. 12:00 h, water 10 cm y air gap 10 cm.

Conclusions

According to meteorological data and based on bioclimatic strategies, in Mexico City it is recommended the use of thermal mass, mainly in winter. According to the theoretical space evaluated with a thermal storage based on a water wall system, the following conclusions are:

The effect of air is not significant when having small water thicknesses (5-7cm), however, by increasing the wall thickness up to 10 cm, the effect of the air layer becomes more visible, staying in the greater comfort zone (air 10 and water 10) or less time (air 5 and water 10).

The indoor thermal amplitude is smaller (1.82 ºC) with the configuration: air 5 – water 10, and with a surface decrement factor (DFs) about 0.12; which represents the ratio of the thermal amplitude of the inner and outer surfaces of the wall. The lower the DFs, the better the performance of the construction system. However, this configuration, despite having lower DFs, offers comfort conditions only for 12 hours, compared to the wall water (air 10 - water 10), which remains within the comfort zone 24 hour with a DFs of 0.17.

The heat storage effect of the water wall for the coldest week of the year can increase indoor temperatures, up to 5 °C above maximum outdoor temperatures.

In winter, the water wall can increase the required heat load during night and day, regulating temperature until reach the comfort conditions. This technique of thermal storage fulfills the objective of a bioclimatic building for this climate, which is to reduce the daily amplitude of temperatures.

Materials, thickness of the different building systems and their thermophysical properties, (conductivity, density and heat capacity) determine different scenarios of heat transfer within a building. Therefore, different interior thermal conditions can be generated; spaces with pleasant temperatures or those with overheating or overcooling. An appropriate design must be based on the understanding of the properties of materials and constructive systems to create comfortable and healthy environments.

New method for choosing design strategies for sustainable buildings

Andrea Invidiata[1] and Enedir Ghisi[2]

[1]Federal University of Santa Catarina, Department of Civil Engineering, Laboratory of Energy Efficiency in Buildings, Florianópoli, SC, 88040-900, Brazil, a.invidiata@gmail.com.
[2]Federal University of Santa Catarina, Department of Civil Engineering, Laboratory of Energy Efficiency in Buildings, Florianópoli, SC, 88040-900, Brazil, enedir.ghisi@ufsc.br.

Abstract: This study shows a new method used to choose design strategies for sustainable buildings. It is based on life cycle energy assessment and life cycle carbon emissions assessment. Five design strategies were evaluated in a single-family social interest house located in three cities in Brazil: Belém, Curitiba and Florianópolis. The house was evaluated based on a 63-year lifespan. The five design strategies analysed were: white painting on the exterior walls, thermal insulation of the envelope, concrete composite slab on the roof, double glass in the windows and external window shading made of hollow concrete blocks. The EnergyPlus computer programme was used to estimate the annual energy consumption only for air-conditioning with and without the design strategies. Furthermore, the impact of climate change on heating and cooling energy demand was evaluated. Results show that not all the design strategies had a positive energy and carbon emissions balance over the life cycle of the house. Also, the different climate conditions of the three cities affected the final selection of the design strategy. This research pointed out the need of using the proposed method to assure the right selection of strategies for obtaining more sustainable buildings. Choosing design strategies based solely on the operation phase of buildings should be avoided.

Keywords: Life Cycle Energy, Life-cycle Carbon Emissions Assessment, Climate change impact, Building simulation.

Introduction

The building construction sector is considered one of the largest consumers of natural resources and energy. Buildings consume 30–40% of all primary energy and natural resources over their lifespan (construction, operation, maintenance and demolition) and respond for 30% of the emission of greenhouse gases in the world (IEA, 2016; IPCC, 2011). An appropriate choice of design strategies reduces the energy demand of buildings (Griego et al., 2012). Often, the design strategy is chosen analysing only the performance of buildings during the operation phase. But, what is the best design strategy when analysing the entire life cycle of a building? A Life Cycle Assessment (LCA) is the investigation and evaluation of environmental impacts of a given product, system or service, over its entire life cycle (ISO 14040, 1997). LCA in buildings is a complex and time-consuming process. For this reason, in the last years, many researches analysed only some, or even one, of the different impact factors. Life Cycle Energy Analysis (LCEA) is used to assess the environmental impact of buildings due to energy consumption in the life cycle. Recent studies from all over the world focusing on the LCEA in buildings have been published (Paulsen and Sposto, 2013; Hong et al., 2015). These studies have shown that the embodied energy may represent up to 30% of the energy life-cycle (Thormark, 2006; Paulsen and Sposto, 2013). In addition to LCEA, Life Cycle Carbon Emissions Assessment (LCCO$_2$A) is used for evaluating the CO_2 emissions in the life cycle of a building (Atmaca and Atmaca, 2015; Costa, 2012).

Thus, the objective of this study is to propose and apply a new method for choosing design strategies for sustainable buildings.

Method

The method is divided in three main parts, i.e., (i) evaluation and modification of the climatic data; (ii) evaluation of the design strategies through the LCEA; (iii) evaluation of the design strategies using the LCCO$_2$A. In order to analyse the operational energy consumption, the EnergyPlus computer programme was used. The method was applied in a single-family house located in three cities in Brazil: Belém, Curitiba and Florianópolis. A lifespan of 63 years was taken into account as per the Brazilian standard NBR 15575-1 (ABNT, 2010).

Climatic data and tool to assess climate change

To evaluate the design strategies through the LCEA and the LCCO$_2$A the effects of climate change on the house were studied. The tool Climate Change World Weather file Generator (CCWorld Weather Gen, 2009) was used for the A2 (medium high) emissions scenario for three future time slices, the 2020s, 2050s and 2080s. The house was evaluated under the current climate data and in the three future climate data generated for each city using the weather data file in Test Reference Year (TRY) format. Recent studies explain with more details the operation of this tool (Jentsch et al., 2013; Invidiata and Ghisi, 2016).

The House

The standard design of a single-family social house funded by *Caixa Econômica Federal* (2007), the most important financing agency for the housing sector in Brazil, was used as a base case. It is a one-storey house in contact with the ground. The ceiling height is 2.60 m. It consists of one kitchen, one bathroom, two bedrooms and one living room, with a total floor plan area of 38.16 m^2 (Fig. 1).

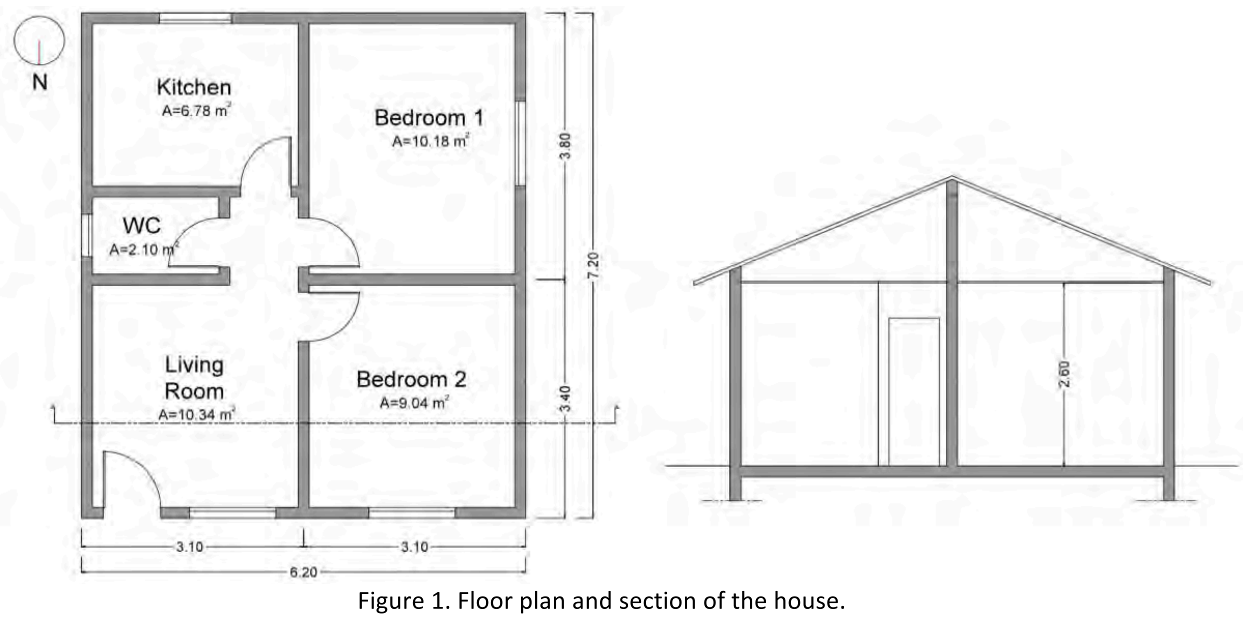

Figure 1. Floor plan and section of the house.

The internal and external walls are made of red ceramic bricks 14 cm thick and a layer of mortar 2.5 cm thick on each side. The pitched roof is made of a wooden structure with a surface of clay tiles. The ceiling is a free-hanging structure made of PVC sheets. The floor is made of a concrete layer 5 cm thick covered with ceramic tiles. The windows are composed of aluminium frames with two sliding panels of single glass 3 mm thick. Table 1 shows the thermal characteristics of the envelope of the house.

Table 1. Thermal characteristics for each component of the house.

Component of the house	Thermal transmittance (W/m^2k)	Thermal capacity (kJ/m^2k)	Solar absorptance (%)	Solar factor (%)
Roof	1.75	21	35	-
External wall	2.46	150	50	-
Floor	4.00	294	-	-
Glass	5.00	-	-	85

Design Strategies

The five design strategies analysed were: white painting on the exterior walls, thermal insulation of the envelope (expanded polystyrene − EPS), concrete composite slab on the roof, double glass in the windows and external window shading made of hollow concrete blocks. The last two design strategies were applied only in the windows of the two bedrooms and living room. It was taken into account that the single glass and the PVC-sheets ceiling of the base case were replaced, respectively, with double glass in the windows and concrete composite slab on the roof. The amount of material for each strategy was obtained from the manufacturer's catalogues. The embodied energy of the materials was obtained from ICE database (2011). The carbon dioxide emissions of the materials were obtained from Costa (2012). The five design strategies were simulated one at a time. Table 2 shows details on the five design strategies.

Table 2. Characteristics of the five design strategies analysed.

Design strategy	Material	Quantity (kg)	Embodied energy (MJ/kg)	Carbon coefficients ($kgCO_2/kg$)
Painting	Paint	8.1	79.71	0.700
Thermal insulation of the envelope	EPS	207.6	100.09	2.700
	Plasterboard	755.1	4.76	0.766

Computer simulation

In order to assess the energy demand of the house in the different cities and future climates the EnergyPlus computer programme, version 8.4, was used. The house was evaluated considering the constant use and occupation for a family composed of four persons, for the three climate data files. Details on occupation, thermal load and use pattern were taken based on the Brazilian regulation for energy efficiency in buildings (BRASIL, 2012). Equipment and lighting operated with 100% load during the operational hours. Through computer simulation it is possible to obtain the energy demand for heating and cooling the house. The house was evaluated considering only the use of an air-conditioning system; its use was defined according to the indoor occupation of the house (bedrooms and living room).

Life Cycle Energy Analysis (LCEA)

In this method, only the design strategies are analysed through the LCEA. Other materials that make up the building are not evaluated. Through this analysis, it was possible to identify the energy balance, i.e., the energy saved over the house life cycle through the use of the design strategies (Eq. (1)).

$$LCEb = OEs - (EE+ME+DE) + ELS \tag{1}$$

where LCEb is the energy balance (kWh); OEs is the operational energy saved due to the use of the design strategy (kWh); EE is the embodied energy in the design strategy (kWh); ME is the maintenance energy due to the design strategy (kWh); DE is the demolition energy in the design strategy (kWh); ELS is the energy life-cycle of the component in the base case that will be replaced by a design strategy (e.g. single glass and the PVC-sheets ceiling).

The embodied energy of the design strategies was obtained from ICE database (2011) (Table 2). For transportation of the design strategy from the manufacturer to the retailer, the distance of 250 km was adopted in the different LCEA phases. For transportation of the workers to the construction site, the distance of 50 km was adopted in the different LCEA phases. Table 3 shows the lifespan of design strategies and the other maintenance work based on the Brazilian standard NBR 15575-1 (ABNT, 2010). For transportation of the design strategy from the building to the closest landfill site, the distance of 50 km was adopted in the three cities.

Table 3. Lifespan of design strategies.

Design strategy	Lifespan (years)	No. of replacements	Maintenance
Painting	10	5	Annual cleaning
Thermal insulation of the envelope	35	1	-
Concrete composite slab on the roof	63	0	-
PVC-sheets ceiling	20	2	-
Double glass window	20	2	Annual cleaning
Single glass window	20	2	Annual cleaning
Hollow concrete blocks	30	1	Annual cleaning

Life Cycle Carbon Emissions Analysis ($LCCO_2A$)

After analysing the design strategies using the LCEA, they were evaluated through the life cycle carbon emissions assessment. Also in the $LCCO_2A$ only the design strategies were analysed. The carbon emissions balance is the CO_2 saved over the house life cycle through the use of the design strategies (Eq. (2)).

$$LCO_2b = OCO_2s - (ECO_2 + MCO_2 + DCO_2) + ECO_2 \quad (2)$$

where LCO_2b is the carbon emissions balance ($kgCO_2$); OCO_2s is the operational carbon emissions saved due to the use of the design strategy ($kgCO_2$); ECO_2 is the embodied carbon emissions in the design strategy ($kgCO_2$); MCO_2 is the maintenance energy due to the design strategy ($kgCO_2$); DCO_2 is the demolition carbon emissions in the design strategy ($kgCO_2$); ECO_2 is the life cycle carbon emissions of the component in the base case that will be replaced by a design strategy (e.g. single glass and the PVC-sheets ceiling).

The carbon dioxide emissions of the design strategies were obtained from Costa (2012), as shown in Table 2. In the operational phase, the average generation factor used to convert electricity consumption into carbon emissions is 0,137 $kgCO_2/kWh$ (BEN, 2015).

Results

Life Cycle Energy Analysis (LCEA)

First, the design strategies of the house were evaluated using the LCEA in the three cities. Fig. 2 shows the energy balance of the house with the five design strategies in the three cities. All strategies obtained a better energy balance in the hot climate (Belém). This is due to the increase in energy demand for future climate change. The results show that the concrete composite slab on the roof obtained a negative energy balance in the three cities, like the thermal insulation of the envelope in Curitiba. The painting on external walls and the double glass windows resulted in the greatest reduction of energy consumption in Florianópolis. In Belém the best design strategy was the thermal insulation of the envelope. The shading device made of hollow concrete blocks obtained a positive energy balance in all cities.

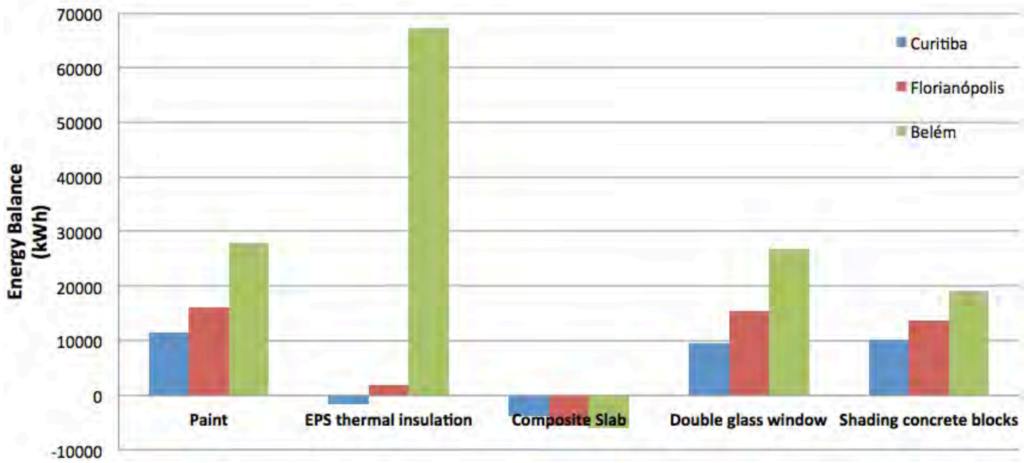

Figure 2. Energy balance for the design strategies in the three cities.

Life Cycle Carbon Emissions Analysis (LCCO_2A)

Following the evaluation of the design strategies using the LCEA, the design strategies were analysed considering their life cycle carbon emissions. Fig. 3 shows the carbon emissions balance for the five design strategies in the three cities. The results show that the concrete composite slab on the roof obtained a negative CO_2 balance in the three cities, like the thermal insulation of the envelope in Curitiba and Florianópolis. The painting on external walls obtained the greatest reduction of carbon emissions in Curitiba and Florianópolis. In Belém the best design strategy was the thermal insulation of the envelope, with carbon emissions savings over 2000 kgCO_2. Painting, double glass and shading on windows made it possible to reduce the carbon emissions in the three cities.

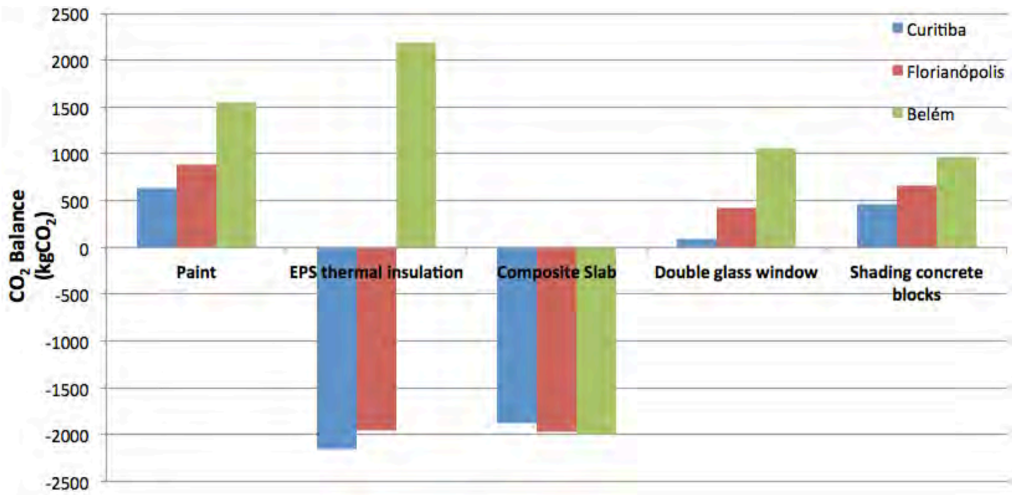

Figure 3. Carbon emissions balance for the design strategies in the three cities.

Summary

Once the design strategies were evaluated through LCEA and LCCO_2A, the relationship between the energy cycle and the carbon cycle was analysed. Fig. 4 shows the results of the energy balance and the carbon emissions balance for the five design strategies evaluated in the three cities. Each point in the graph represents a single strategy. The point at the top right position in the graph represents the best solution. The best design strategy in Curitiba was the painting on external walls, reducing the energy demand and the carbon emissions of the house. The shading and the double glass in the windows obtained positive balances, while the concrete composite slab on the roof and the thermal insulation of the envelope obtained a negative energy and carbon emissions balance. In Florianópolis the design strategies led to results similar to those of Curitiba, except for the thermal insulation of the envelope that resulted in a positive energy balance but a negative CO_2 balance. Finally, in Belém only the concrete composite slab on the roof obtained a negative result in both balances, while the other design strategies allow to decrease both energy and carbon emissions in the life cycle. The thermal insulation of the envelope was the best design strategy for Belém.

Conclusions

This paper has presented a detailed case study of a life cycle energy and carbon emissions assessment for different design strategies in three cities in Brazil. The importance of evaluating design strategies in buildings not only in the operational phase but also during the entire life cycle was observed. This is evident, for instance, if one compares the replacement of the PVC sheets in the ceiling with a concrete composite slab. The concrete composite slab reduced the energy demand during the operational phase but resulted in worse energy and carbon emissions behaviour over the life cycle of the house. Also, in the three cities, the behaviour of design strategies was different due to the several climate conditions. This method has some limitations; for instance, in the demolition phase the re-use of the design strategies was not considered. Nevertheless, through the combined analyses of LCEA and LCCO$_2$A, it was possible to identify the best design strategies to reduce the energy consumption and the carbon emissions of a house during its lifespan. The method shown herein may become a useful tool for designers to choose the design strategies with the lowest environmental impact.

Identification of the best positions of the main facades of a solar-friendly building shape as a forward problem in the building design

Stoyanka Ivanova[1]

[1] Department of Computer-Aided Engineering, University of Architecture, Civil Engineering and Geodesy, Sofia, Bulgaria, email solaria@mail.bg

Abstract: Generation of a building shape is a creative process, where some tasks are processed as forward problems and others – as inverse problems. The science defines a forward problem as a process of calculating that starts with causes and then produces the results. Contrariwise the inverse problem starts with a result and then checks its interaction with the causes. In a complex urban environment with many neighbouring shading objects, the generation of a building shape is usually decided as an inverse problem. The architect creates a new building shape and studies its interaction with the incident solar radiation. In the best case, the architect could try several building shapes and choose that with best results. This still does not mean that it could not exist another untested shape with better solar performance. The approach proposed in this paper helps the architect to find the best positions of the main facades of the designed building in a complex urban environment. This contributes to use better the solar potential of the plot.

Keywords: solar building design, building shading factor, rose of radiation

Introduction

Generation of a building shape is a creative process, where some tasks are processed as forward problems and others – as inverse problems. The science defines a forward problem as a process of calculating that starts with causes and then produces the results. Contrariwise the solution of an inverse problem starts with a result and then checks its interaction with the causes.

While an architect determines the building shape at the beginning of the design process, the following factors influence the decision:

- Approach to the building and positioning in the urban environment;
- Functions of the building;
- Compositions' considerations;
- Engineering considerations (supporting structure);
- Compactness.

For passive low-energy buildings, it is appropriate to add the efficient utilization of solar energy to the above considerations. Solar resources are critical for the passive heating, the natural lightening and the active solar systems, integrated into the building envelope.

In the architectural design, the architect usually creates a building layout and corresponding building shape and then checks how this building shape corresponds to the requirements of the building. In the solar architecture where the solar passive design is important, the designer tests the interaction of the created building shape with the available solar resources and this is an approach as to an inverse problem. In the best case, the architect could try several building forms and choose that with best results. This still does not mean that it could not exist another untested shape with even better solar performance.

Different software products that might be used to estimate the seasonal solar irradiation on building surfaces in the complex conditions of an urban environment, where many shading buildings and other objects exist, are available. However, such generated amount of numerical data is not comfortable for making decisions about the shape of a future building and assessing the suitability of one form or another.

There is a need to develop a methodology that can help to reduce the received massive amounts of calculated data to a summary assessment of a particular building shape.

An alternative approach is to develop a methodology that helps to identify the suitable positions of the building surfaces for the best use of the solar energy. This is already another kind of solution of a forward problem.

In a **simple environment** without shadings, the problem with building shape is easier to solve, following the simple rule that the larger façade should be with southern exposure, and shorter facades – with eastern/western exposure.

In a **complex urban environment** with many neighbouring shading objects, this task is difficult to solve. The articles by Robinson (2006), Compagnon (2004) and Ivanova (2015) recommend the use of the Rose of the solar irradiation as an indicator of the available solar resources on vertical surfaces. This graph, like the rose of the winds, is a vector diagram that illustrates the amount of the incident solar irradiation on vertical surfaces with different exposure for various periods of time (months, seasons, year) – figure 1a.

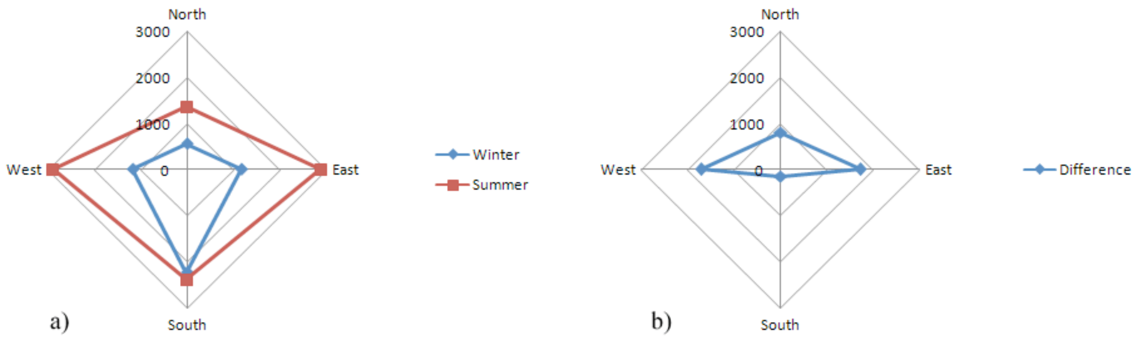

Figure 1. a) Roses of average winter (in blue) and summer (in red) daily irradiation under a non-obstructed sky in Sofia [Wh/m^2/Day]; b) Rose of the difference between summer and winter daily irradiation [Wh/m^2/Day].

Methodology

The aim of the proposed in this article approach is to support the architect to find the best exposure of the main facades of the designed building or group of buildings in a complex urban environment. This is essential for a better use of the better solar potential of the plot, as steps to create a building shape as a solution of a forward problem. For this purpose, a grid of roses of cumulative incident solar radiation and building shading factor are used.

The identification of the proper location of the designed building on the plot is one of the first design steps of the architect. Using the irradiation's roses, it is possible to evaluate the available solar resources in the nodes of a uniform orthogonal grid, placed in the plot (Ivanova, 2015), where the designed building will be situated. Such information could be guiding for the architects and urban architects in taking decision for the best position and exposure of the main facades of the designed building or group of buildings.

A simple example of a rectangular plot among tall neighbouring buildings is considered. An orthogonal grid with 3 × 3 nodes is placed over it. A virtual tall testing parallelepiped with very small square cross section is located at each node (see figure 2). Its vertical virtual walls are oriented towards the main cardinal directions (north, east, south, west). The average daily seasonal global irradiation incident to each of these 4 vertical walls of 9 testing parallelepipeds is calculated.

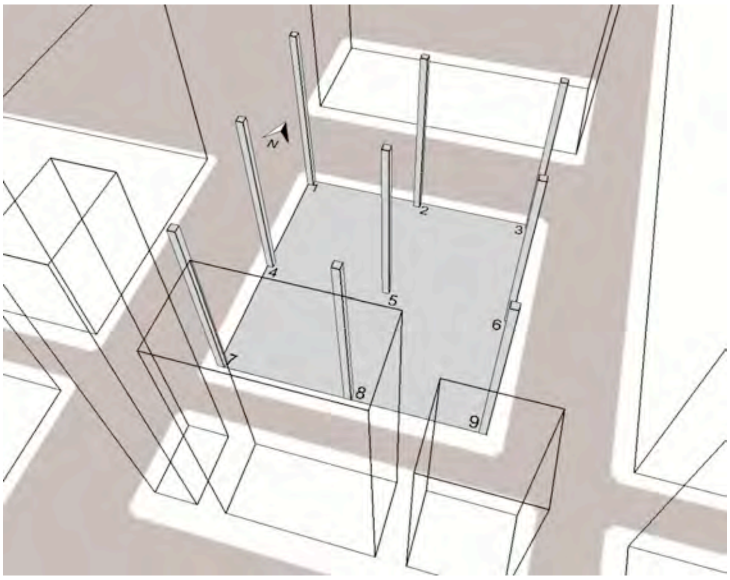

Figure 2. The composition of a considered plot and tall buildings around it.

For countries with continental climate (with cold winters and hot summers) like Bulgaria, the annual rose of solar global radiation masks and hides the different importance of solar radiation in summer and winter season. Therefore it is correct to make the calculations and analysis separately for each critical season.

For this reason, two grids of nine roses of irradiation are illustrated in figure 3. They are created using the numeric results from the program 3D-SOLARIA (Ivanova, 2014). The maximum daily winter global irradiation under a non-obstructed sky is plotted in blue (figure 3a); the maximum summer irradiation is given in red (figure 3b). The green contours in figure 3 present the incident vertical daily irradiation under the real sky, partially obstructed by other buildings and objects. The distance between blue (or red) contours and the green contours illustrates the amount of the blocked irradiation because of the urban shading.

In our previous article (Ivanova, 2015) it was explained that if we need large amount incident winter radiation and reduced amount of summer radiation, we get the best results for walls whose difference between summer and winter values of the incident irradiation is minimal (figure 1b). This means that the solar radiation incident on them is relatively permanent in the seasons. The opposite option (maximum difference between summer and winter radiation) means that there is a shortage of radiation in winter (this case needs more energy for heating), and excess of heat in the summer (it leads to additional costs for cooling).

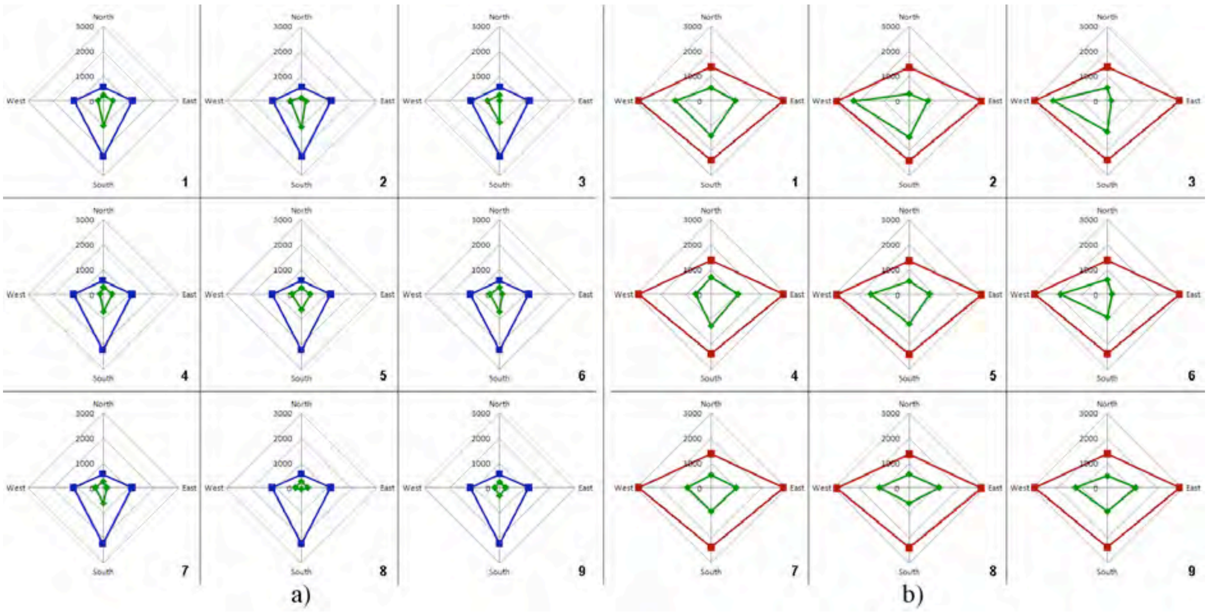

Figure 3. Roses of average daily global solar irradiation in considered 9 nodes.
The plot is located in Sofia: a) winter; b) summer.

In this article, we offer two different options to illustrate the estimated differences – with roses of solar irradiation difference (figure 4) and with 3D area charts (figure 5).

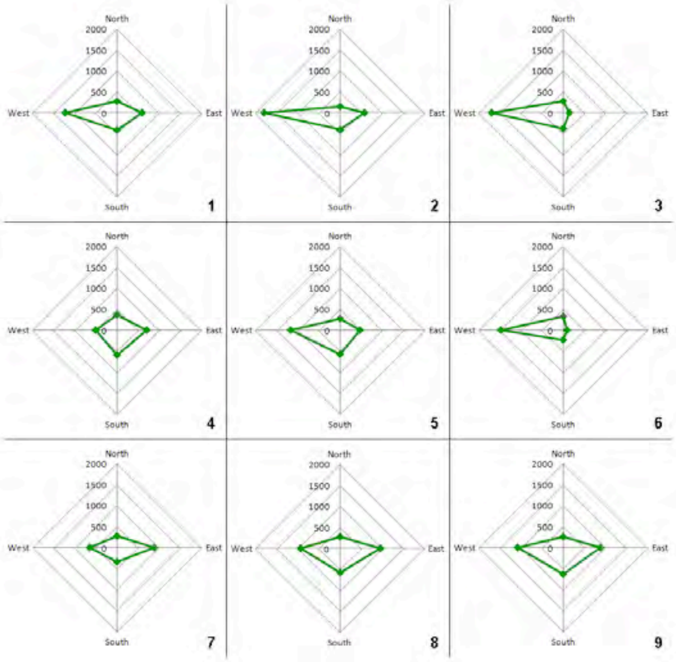

Figure 4. Roses of the differences between average daily winter and summer solar irradiation for nine considered testing parallelepipeds.

In figure 5 the left column of images displays the summer (with the lighter colour) and winter (with the darker colour) average daily irradiation on the vertical surfaces of the tested 9 virtual parallelepipeds, and the right column – the difference between summer and winter average daily irradiation. The first row of images illustrates irradiation on northern surfaces, the second row concerns the southern surfaces, the third row – eastern surfaces and last row – western surfaces.

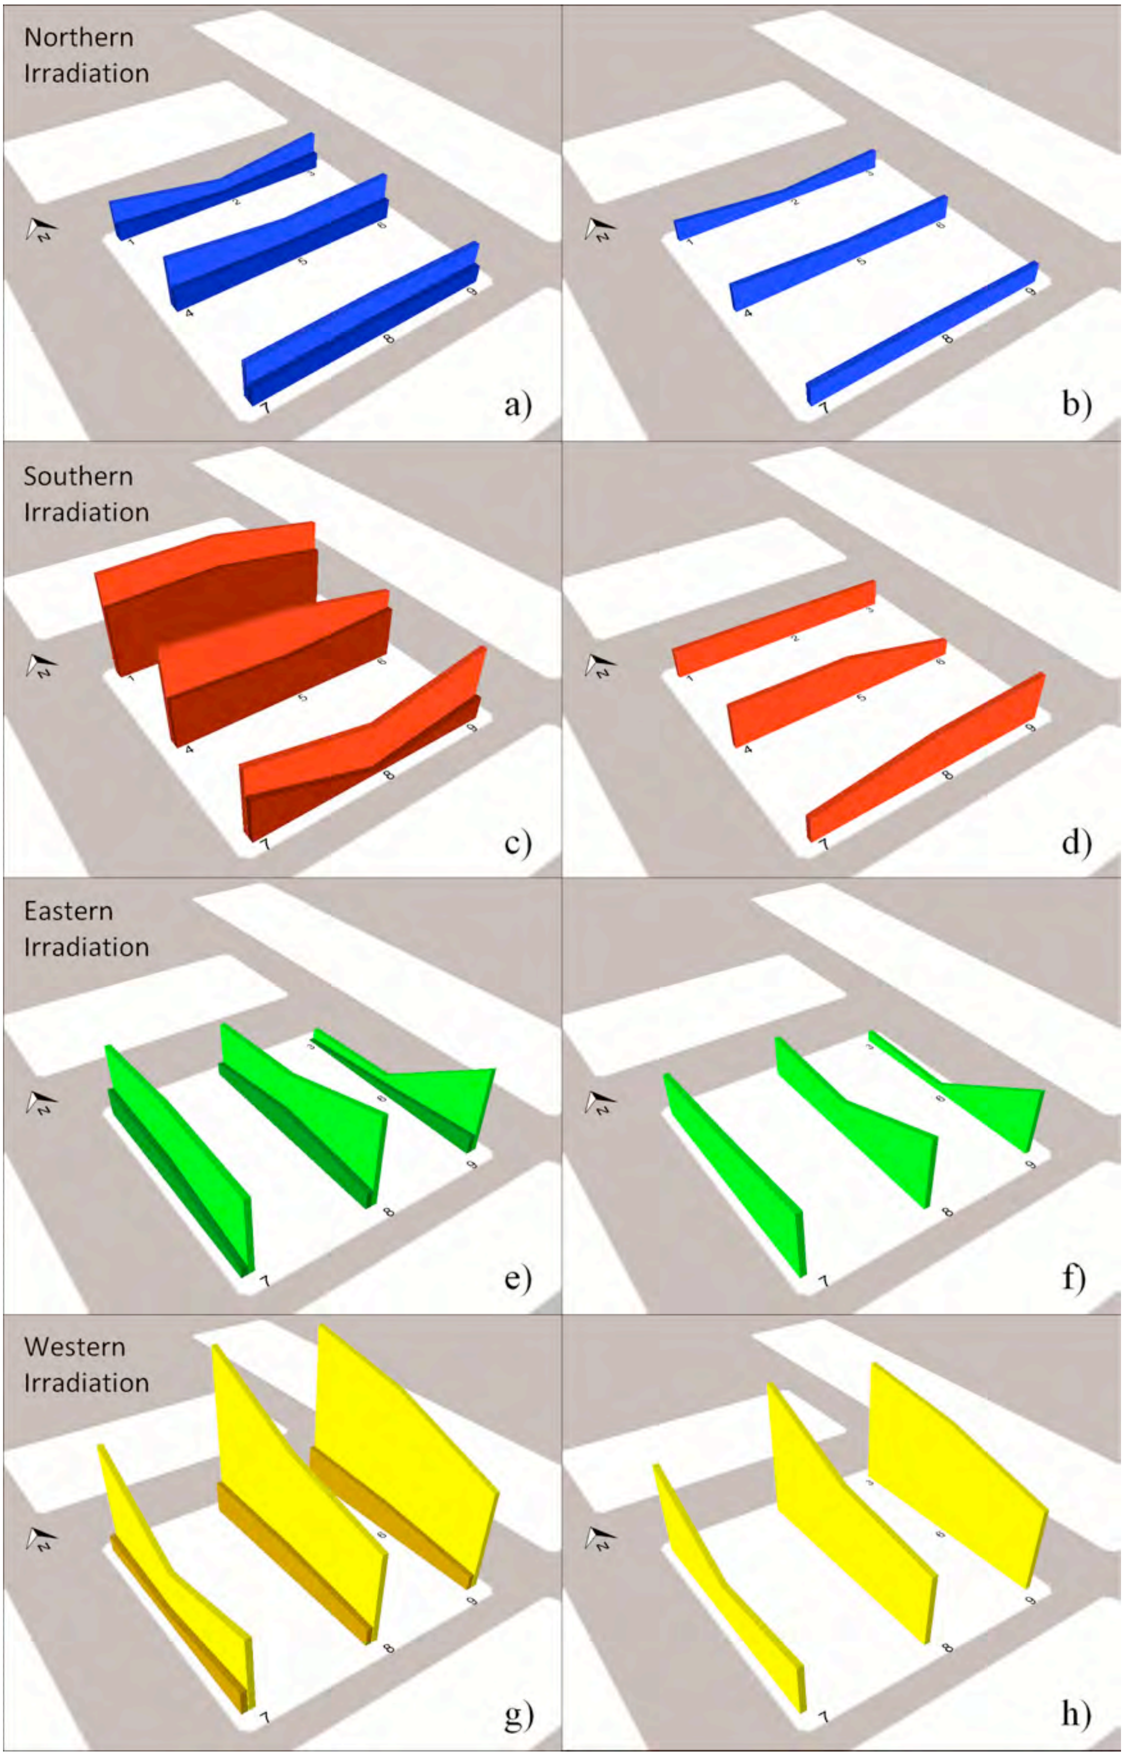

Figure 5. 3D Area charts of visualized average daily global solar irradiation on vertical surfaces:
a, c, e, g) summer and winter irradiation; b, d, f, h) difference between summer and winter irradiation.

The desirable positions for building facades on the plot are the locations with minimal differences (figure 6a, b). Such position for easterly exposure exists in the north-eastern part of the plot. A minimum difference for westerly exposure exists in the southwest part, and for southerly exposure – in the central or the northern part of the plot. The difference for the northerly exposure is nearly constant everywhere.

Based on these guidelines, we can suggest a building form composed of 3 units as it is shown in figure 6c. The largest unit has southerly exposure and is sufficiently distant from the buildings to the south of the plot. Thus it is capable of getting more direct solar radiation. The western unit is lower because of the unfavourable difference for the eastern wall in the southwest corner of the plot. The same consideration is valid for the height of the eastern unit.

Another suitable shape of the building might be the form of the Cyrillic letter "Г" (figure 6d) situated in the western and northern part of the plot, but it will be too close to the building north of the plot and would cause too large shadows on it in winter.

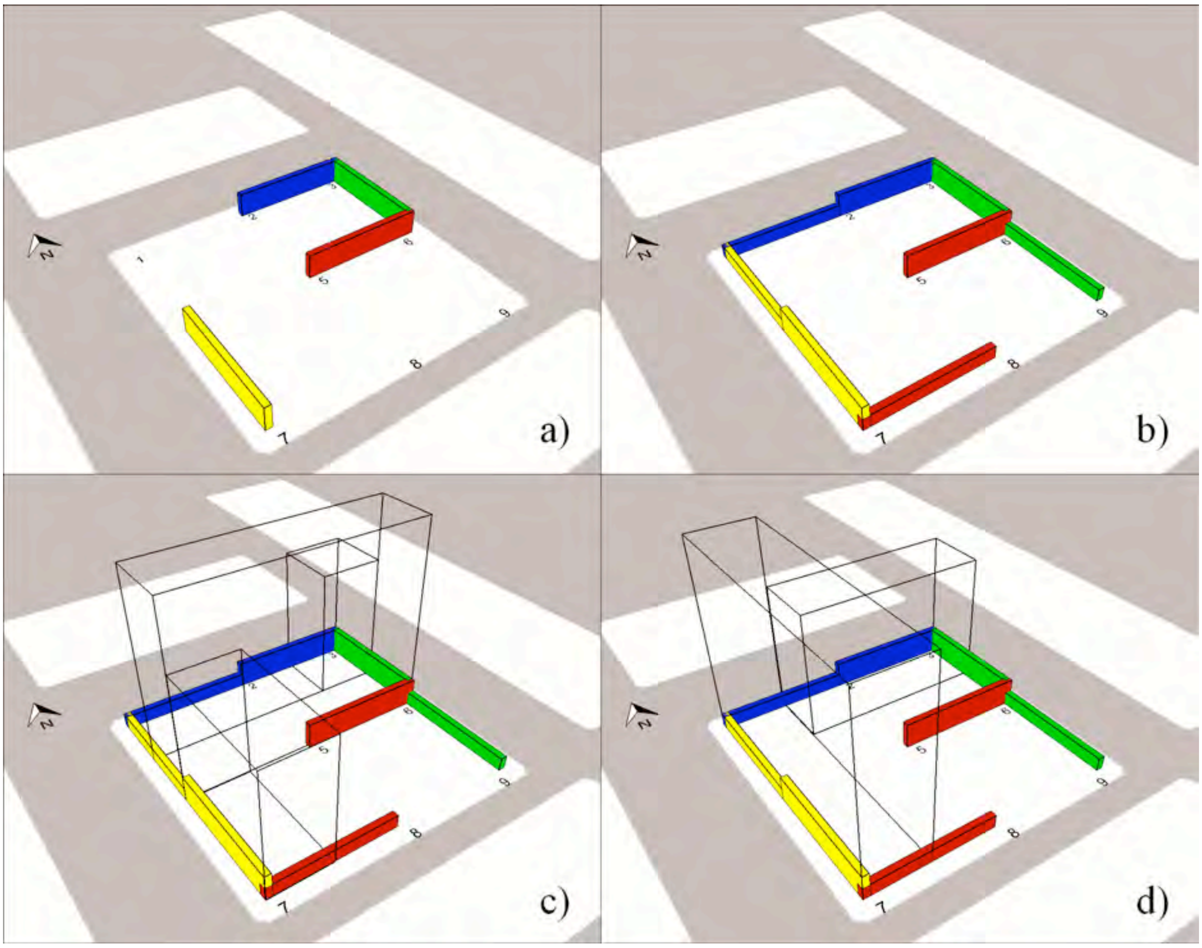

Figure 6. a) positions with smallest differences between summer and winter irradiation; b) positions with the two smallest differences between summer and winter irradiation; c, d) two proposed building shapes according to this analysis.

The proposed shapes reflect both the normal expectations for shading in the environment with tall buildings and the irregularity in the shading due to the uneven locations of neighboring buildings and their various heights. The two proposed building shapes have to be checked in the next stage with a detailed calculation of their building shading factor.

Evaluation of building shape with Building Shading Factor

The interaction between the available solar energy, the shape of the future building and the obstructing objects in the surrounding urban environment can be evaluated quantitatively with the help of a **Building Shading Factor** (*BSF*). It represents the ratio of the blocked solar energy that fails to reach the explored building surfaces and the maximum possible incident solar energy on these building surfaces under the non-obstructed sky (Ivanova, 2014). Architects can use the calculated numeric value to assess the shading effect caused by surrounding urban environment and the self-shading effect caused by building elements participating in the composition of the studied building. The methodology is implemented in the computer program 3D-SOLARIA.

The building shading factor has a different meaning in winter and summer. The higher values in winter are due to low sun. Therefore, lower value of the factor indicates better building shape. *BSF* in summer has lower values than in winter due to high sun. Logically, higher *BSF* values correspond to better building shapes that offer better shading. There are buildings and complexes with seasonal use (for instance summer and winter resorts), and buildings that are used all year round. In these buildings the sought compromise between winter and summer shading factors is different. For buildings for summer living the architect seeks a maximum value of BSF, while for buildings for winter habitation a minimum *BSF* is targeted. In buildings for permanent habitation, the best solution is characterized by minimal difference between winter and summer values of *BSF*.

As an example, three buildings variants (figure 7), placed in the same considered plot, are evaluated. Their volume is equivalent V=18000 m^3; the external surface is A=4900 m^2. The calculated values of their form factors are equivalent also: $FF=A/V$= 4900/18000=0.2722.

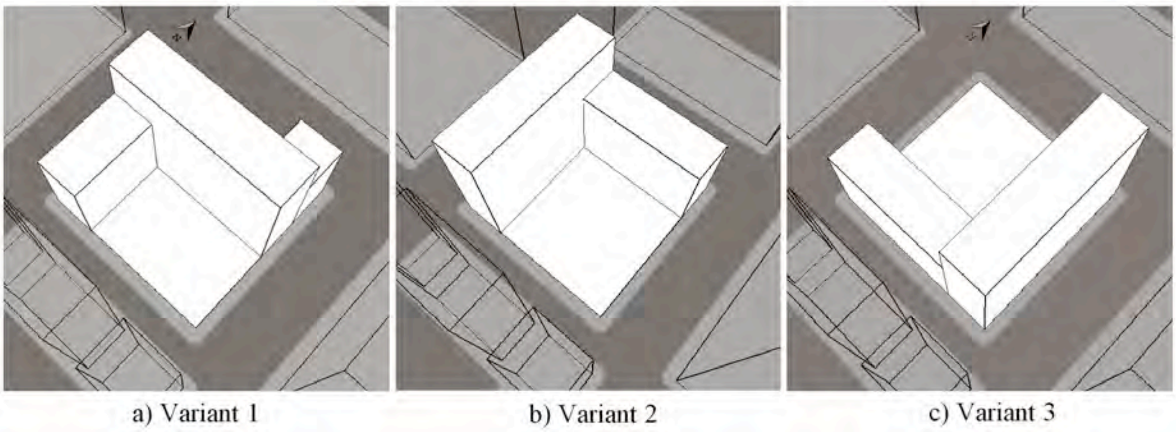

Figure 7. Three variants of building shapes with equivalent values of volumes, external areas and form factors

The first variant (figure 7a) is proposed after the performed analysis (see figure 6c). The second variant (figure 7b) was the other configuration recommended due to the same analysis. The third variant (figure 7c) has a shape, equivalent to the second shape, but rotated at 180°.

After the estimation of the incident solar global radiation on the building surfaces the following results were calculated and illustrated in figure 8:

- Variant 1 – BSF_{winter} = 0.715; BSF_{summer} = 0.553; difference 0.162;
- Variant 2 – BSF_{winter} = 0.712; BSF_{summer} = 0.546; difference 0.166;
- Variant 3 – BSF_{winter} = 0.743; BSF_{summer} = 0.534; difference 0.209.

According to these results, the first of the considered three building variants is the best one because it has a minimum difference between the winter and summer values of *BSF* (0.162). The second variant is estimated as very close to the first one (difference 0.166). The third variant, even if it has the same shape as the second but rotated, is the worst (difference 0.209).

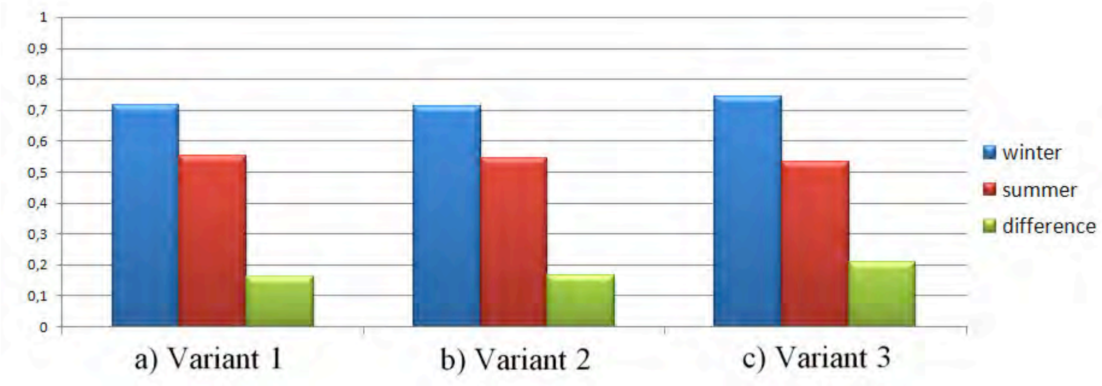

Figure 8. Values of BSF for winter (in blue), summer (in red) and the difference between them (in green) for the considered three variants of building form.

The first building variant will receive the most relevant seasonal amount of solar energy on its surfaces in comparison with two other considered variants, as it was assumed after the analysis of the estimated difference between summer and winter irradiation.

Conclusions

The solar resources are very important in the passive low-energy architecture. In this article, we recommend a new approach to identify the positions on the building plot which are most suitable for the building facades. This information could help the architect to create solar-friendly building shapes as a solution of a forward problem. The proposed approach uses a grid of roses of vertical solar global irradiation, which nodes are regularly placed on the plot. The increasing of the number of the grid nodes will be suitable for buildings with a more sophisticated shape. Then the proposed variants of building shapes have to be ranked with a calculation of their building shading factors. The variant with most relevant energy resources is the one with the largest difference between winter and summer values of *BSF*.

Design to Thrive

Improving Thermal Performance of Traditional Cabins in the High-Altitude Peruvian Andean Region

Cecilia Jimenez, Martin Wieser and Susana Biondi

Pontificia Universidad Católica del Perú PUCP, Lima, Perú

Abstract: Communities in the high-altitude region of the Peruvian Southern Andean Mountains are located over 4200 meters above sea level. Communities organize in isolated cabins dispersed in an extensive area surrounding the community center. The harsh natural environment and poor living conditions affect people's health and increase child mortality, especially in winter. Daytime solar radiation is of high intensity. At night exterior temperatures are -10^{o}C, while indoor temperatures of cabins barely reach 0^{o}C. This research sought to improve the thermal performance of these cabins with passive design strategies and local resources. The methodology included: a) collection of weather data versus indoor thermal performance, availability of local resources and understanding domestic organization patterns; b) definition of comfort temperature range and analysis of local materials; c) technology transfer by involving the population in the construction of a prototype. Simple passive strategies of air tightness and solar gain with local available materials (adobe for walls, totora reed (Schoenoplectus tatora) and sheep wool for insulation, and stone and wood to waterproof the floor) improved night thermal performance in these isolated areas. Although local people are starting to implement these techniques in their own cabins, this is just the starting point towards appropriate thermal comfort.

Keywords: Thermal Performance, Passive Solar Design, Totora Insulation, Vernacular Architecture, Tropical high altitude climate

Introduction

The high-altitude Southern region of the Peruvian Andean Mountains is located in between 4000 and 5000 meters above sea level. The main economic activity of communities in this region is alpaca breeding, which organizes the community in isolated cabins dispersed in an extensive area surrounding the community center and market. Agriculture is not feasible; only "ichu" grass (Stipa ichu) grows everywhere, which is the main food for alpacas. People live in extreme poverty and poor living conditions, with neither electricity nor water system. These circumstances affect people's health and increase child mortality, especially in winter, when "heladas", nighttime frost, are frequent; young alpacas' mortality also increases during this season thus affecting their main income.

The typical cabin in this region has three separate modules: bedrooms, kitchen and storage room, made of stone walls and occasionally with adobe bricks, earth floor, small or no window holes, metal doors and roof, and no insulation. Originally the roof was thatched with the local "ichu" straw, but currently it has been replaced by tin metal roof sheets over thin wood rafters, given that it is more economic, it is more "modern", and nowadays it is not feasible to get "ichu" straw with the required length. This change worsened the thermal performance of cabins. Field measurements during the coldest months showed indoor temperatures around 0^{o}C at night.

Figure 1. Quella-Quella, a typical cabin and landscape of the high altitude region

According to weather data collected for three months in one of these communities, Orduña, average air temperature during the day is 12.5°C and -4.1°C at night. There is not a significant seasonal variation and the diurnal thermal range is moderate to high (around 16°C). However, due to climate change, climatic conditions are unstable, unpredictable and there are more frequent frost events at night. Relative humidity has significant variation during the day and day after day. However, on average, relative humidity is low at midday, in between 10% and 40%.

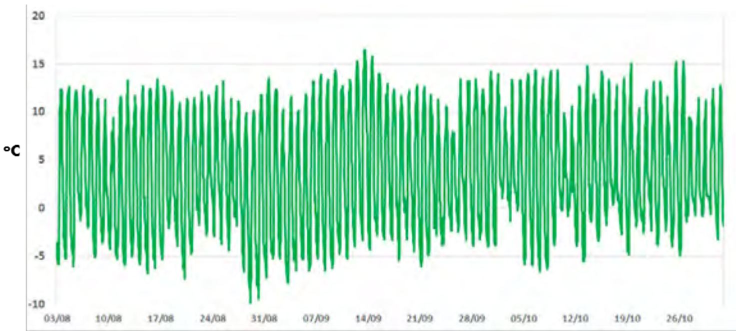

Figure 2. Outdoor Temperature in °C

Solar radiation is constant and very high throughout the year. The average daily total of the three months of measurements is 6kW/m^2. However, maximum daily total can reach 8kW/m^2, and minimum daily total is around 3.5kW/m^2. It is important to note that 75% of the time solar radiation was over 5kW/m^2, while only 5% of the time solar radiation was below 4kW/m^2. Winds are constant, with moderate speed and coming from diverse directions. Maximum speed is in the range of 3 and 5 m/s at noon, and decreases significantly at night, becoming completely calm at dawn, when it is also the moment of the day with the lowest air temperature.

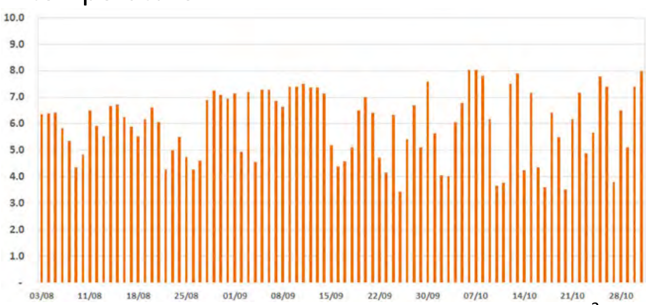

Figure 3. Global Horizontal Solar Radiation (kW/m^2)

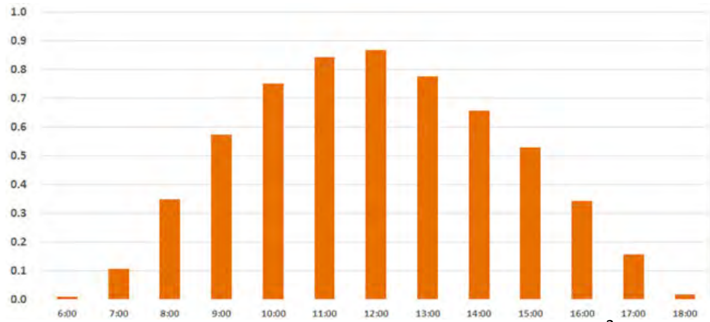

Figure 4. Daily Average Solar Radiation (kW/m^2)

Given these conditions, this is a proposal to improve the thermal performance of the dwellings in these isolated communities, by means of bioclimatic design strategies, local resources available in the region and active participation of the local people.

Methodology

The research focuses on Orduña and is a section of a multidisciplinary project on technological transfer in high-altitude communities (Rodriguez Larrain et al, 2016). Orduña is a characteristic community of this region, at 4800 meters above sea level. It has the typical climate of the high altitude region: cool during the day and very cold at night. In addition to collecting weather data, there was a previous study on the habitat, the typical dwellings and the living practices and patterns of its inhabitants.

A portable weather station, Davis Vantage PRO2 Plus, was used to register exterior information, and data loggers ONSET Hobo H08-003-02 and Extech registered air temperature and relative humidity within the cabins. Actual air temperature data was collected in different months from 2014 to 2016, with a total of 150 days of measurements. Only 7 of the 150 days air temperature at night was above 0^{o}C, giving an average minimum temperature of -5^{o}C. It may be concluded that frost occurs throughout the year, and is not related to a particular season, but rather is a constant condition in Orduña.

There are no specific studies on thermal comfort in high altitude tropical climates. Therefore, the adaptive comfort method of Nicol and Humphreys (2002) was taken as reference to calculate and define a thermal comfort range for Orduña, based on the monthly average outdoor air temperature. From the air temperature data collected, the calculated lower limit of the comfort zone is around 12^{o}C, which is much higher than the indoor temperature registered in the cabins, generally in between -2^{o}C and 2^{o}C.

Representative cabins were measured and occupation patterns and users' needs were defined in group sessions with local people.

The proposed bioclimatic design strategies focuses on increasing heat generation/gain and reducing heat losses with local resources and materials, especially the "totora" reed mattress as insulating material. The "totora" is abundant in the high Andean lakes, and for a 5cm thick mattress the average R-value is 0.74m^{2}K/W (Ninaquispe Romero et al, 2012). The strategies were evaluated with Design Builder software to select those which best improve thermal performance and are economically accessible to local people. Conductivity of selected local materials was evaluated at the laboratory to select the thermally best combination.

Basic concepts on climate and thermal performance of buildings were deployed to local people in group sessions. They were also trained in the selected bioclimatic design strategies and construction techniques by applying them in remodeling some sections of their own cabins.

A prototype cabin applying the bioclimatic design strategies was built by the local people in the communal center town with the supervision of the project team members. Once completed, the weather station and data loggers were installed to register new measurements. ONSET Hobo data loggers were placed in the three rooms of the bedroom unit (two sleeping rooms and one distribution room in the middle) to register air temperature and relative humidity. Two data loggers were placed in each room at 0.40 and 1.40 meters above floor level. Data was registered every hour from August 3 to October 31, with a total of 2160 data per item. Given that the prototype cabin was more hermetic than the standard cabin, interior air quality was also measured, specifically the CO_2 concentration with Sper Scientific 800050 equipment.

Traditional Dwelling Design and Practices

The organization pattern of the cabins has a "U" shape: the bedroom unit on the East side has two rooms with doors facing West, towards a central patio. On the North side is the kitchen unit, usually the only building with a thatched "ichu" roof; and on the South side is a storage room. The West side of the central patio has a "pirka" stone fence. One family or extended family (grandparents and/or oldest son's family) lives in a cabin.

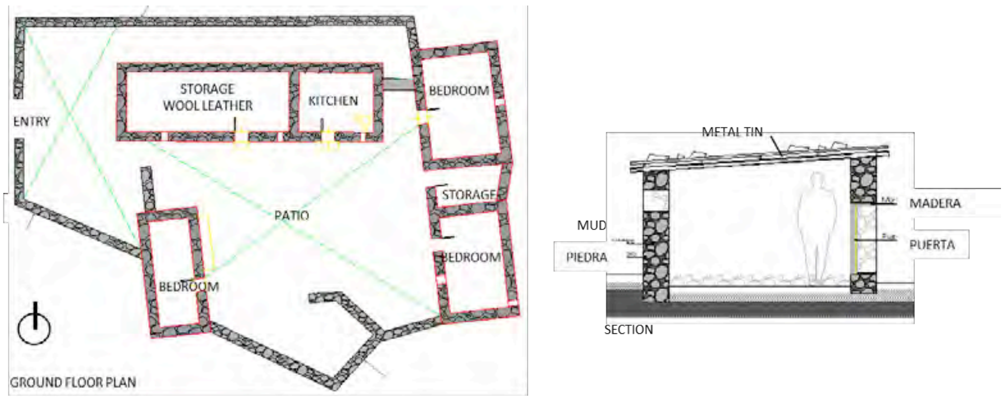

Figure 5. "Quella-Quella" Plan and section of traditional cabin in Orduña

During the day men and women are in the field pasturing the alpacas; only small children, pregnant women and elderly members of the family stay in the cabin. They usually sit in the kitchen, which is warmer, or in the sunny area of the patio. They all gather in the kitchen at about 5 to 6 in the afternoon for supper and then go to the bedroom unit. Usually two to four members of the family sleep in one room. At 5 to 6 in the morning they gather again in the kitchen for breakfast, before leaving for their daily activities.

Most of the cabins and fences are made of dry stone, which is the material readily available in the region. In the cabins, the holes among stones are covered with mud. Floors are just earth without any treatment, thus usually they are damp and increase the cold sensation within the cabin. The gaps left by the rafters in between the stone walls and the metal roof remain open. The door of each room is poorly built with cracks all around the border. The little heat generated by the people in the bedrooms, escapes from the room through the materials by conduction and through all the gaps and cracks.

Proposed Design Strategies

The bioclimatic design strategies recommended for Orduña to reduce heat loss were: materials with lower U-value, elimination of cold air infiltration through cracks and gaps, small windows to allow solar heat gain and natural light, insulated doors and window shutters. Regarding heat gain, solar radiation became the main source available, especially via skylights. These strategies are congruent with those of other authors (Olgyay, 2008) (Szokolay, 2014) (Givoni, 1998).

The base module selected to evaluate the recommended strategies was a sleeping room of 3.00 by 4.00 meters with stone walls, metal tin roof, earth floor and metal door. The longer sides of the wall face East and West. Two windows were located on the West wall, with single pane glazing and wood frame. Results from simulations with Design Builder software proved that insulation of walls and roof with 5 cm thick "totora" reed mattress was the most effective strategy to improve the thermal performance of the room (Figure 6), and to determine the following materials (Table 1):

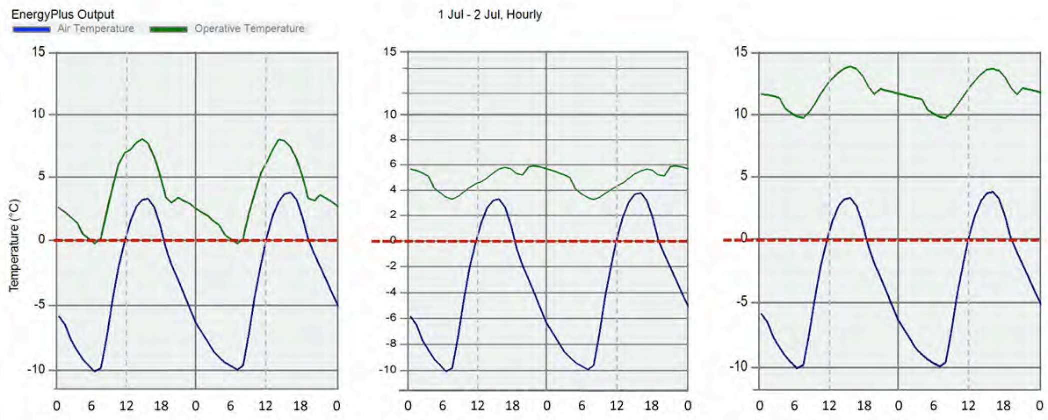

Figure 6. Results of simulations with Design Builder

Table 1. Recommended materials to improve thermal performance in Orduña cabins

Element	Materials	U-value W/m^2 ^{o}K
Roof	Metal tin sheets in the exterior for rain protection; 5 cms of a mix of mud with straw; 5 cms of insulation made of "quesanas de totora" reed mattress; wood rafters, and gypsum plaster in the interior	0.979
Walls	Adobe 40 cm thick, 5 cm of "totora" reed mattress on the exterior, and 2.5 cm of clay coating on both sides of the wall	0.581
Floor	Three layers of stone of different sizes totaling 25 cm thick, 5 cm of a mix of mud with straw, and 3 cm of hardstand earth to reduce sub-soil damp reaching the surface	1.516
Windows	Single glazing with wood frame, facing West, with 2.5 cm thick shutters made of two layers of plywood with sheep wool in between as insulation	1.370
Entry Door	Wood frame with a layer of metal sheet in the exterior, 2.5 cm thick of sheep wool insulation and a layer of plywood in the interior. It should not open directly into bedrooms but rather to an intermediate room	1.164
Skylight	Wood frame and a transparent plastic sheet. Only in the room with day-activities	5.995

Some modifications were done for the construction of the prototype cabin. The "quesana de totora" reed mattress was placed in the interior instead of the exterior of the adobe wall, due to practical purposes of maintenance and durability. Windows were open on both sides of the room, facing East and West, and the floor was completed with wood planks (Figure 7). The skylight was 0.80 x 1.00 meters and located in the distribution room Local people painted the walls white and bought furniture (beds, small tables and chairs) for the cabin bedroom unit.

Figure 7. Proposed site plan of prototype and built cabin (bedroom unit and kitchen)

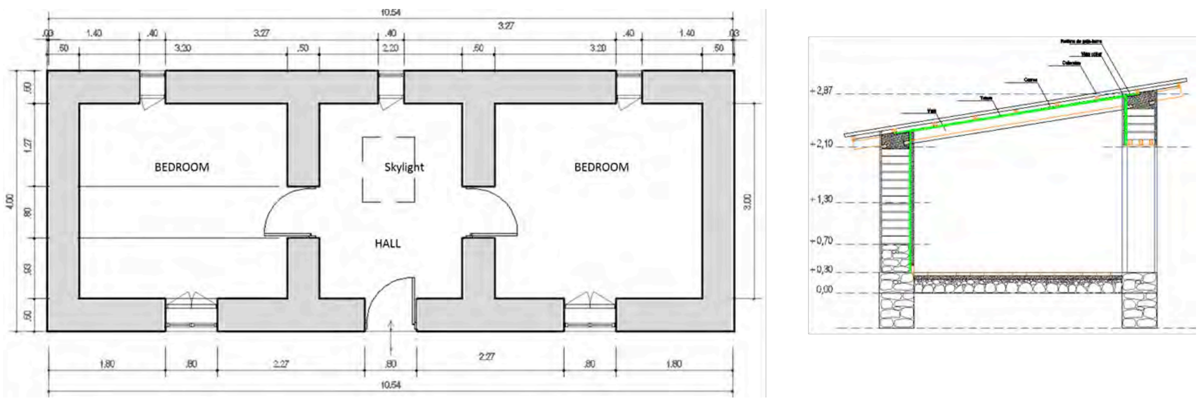

Figure 8. Floor plan and section of bedroom unit

Results

It is important to note that rooms were not consistently occupied during the three months of measurements. Results are the hourly average of the three months of registered data. In the case of the distribution room with the skylight, data was valid only for one month (August). The CO_2 concentration data was registered for 24 hours in one sleeping room with two people, who made sure the room was hermetic at night.

As indicated before, the exterior thermal range is 16°C with cold nights and cool days (Figure 9). The interior thermal range of sleeping rooms is only 4°C to 5°C, while in the distribution room with the skylight the thermal range is 12°C. During the coldest hours of the night, interior temperature of the prototype sleeping rooms are 8°C above exterior temperature and 4°C above temperature of traditional cabins, which is an improvement, but still not high enough to reach contemporary comfort standards, as previously defined.

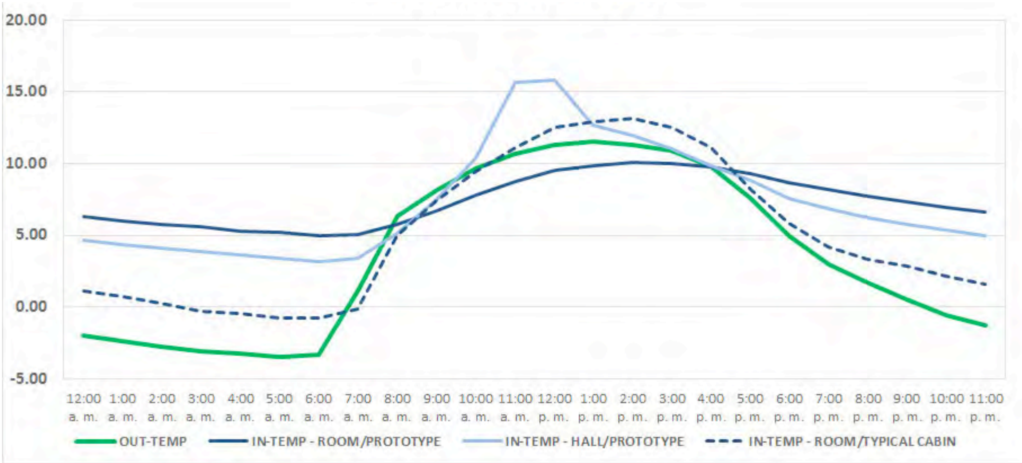

Figure 9. Air temperature in ^{o}C, of prototype bedroom unit compared to traditional cabin and outdoors

Air temperature in the distribution room is 5^{o}C higher than the sleeping rooms, but also 1^{o}C to 2^{o}C lower at night. The difference of the air temperature registered in the sleeping rooms at 40cm and 140 cm above floor level is greater when the temperature in the distribution room is the highest. This demonstrates that warm air from the distribution room enters the sleeping rooms by convection during the day. Concentration of CO_2 was slightly above 1000 ppm but still within an acceptable range.

Discussion

The results show progress towards thermal comfort in Orduña cabins, but also that it is necessary to consider further improvements and additional strategies to achieve a better thermal performance of the cabins. The "quesana de totora", reed mattress worked well as insulation on the roof and walls; however they could work better on the roof by adding a layer of clay mixed with straw to guarantee there is no infiltration through interstices among reeds.

The skylight in the hall proved useful for solar gain, which is potentially the most effective strategy to improve the thermal performance of the prototype. It could work even better if all the roof of the hall is transparent and become a hot-room to transfer heat to the sleeping rooms by convection through the open doors during the day, and to collect heat on the walls adjacent to the sleeping rooms and transfer it by conduction in the evenings. The option of adding skylights in the bedrooms would require shutters that guarantee hermetical closing at night, and also that are economical, and easy to use and maintain.

Insulation of doors and windows shutters with sheep wool worked well. The only consideration would be to make sure the frame has no gaps or grooves. The insulated floor would prevent it to becoming a source of heat loss, as long as the interior air temperature rises above the exterior mean air temperature. This is especially important at night.

The floor to ceiling height of the prototype could be lower thus reducing the volume of air in the rooms to warm up and the exterior surface exposed to cold winds. It also would allow the warm air to be closer to users due to thermal stratification of the air. The color of exterior walls should remain dark to reflect the least incoming solar radiation. This has to consider the possibilities of natural clay and the acceptance of users of the cabins.

Despite CO_2 concentration is within an acceptable range, it might be required to include a simple control system for fresh air intake, when more than two persons occupied the bedrooms.

Conclusions

The implementation of basic bioclimatic concepts of thermal comfort with local resources can improve the thermal performance of cabins in isolated areas of Andean high altitude regions of South Peru. The first objective must be to make the dwellings more hermetic and insulated to prevent heat loss by conduction and infiltration. Given that Peruvian Andean regions are within the tropics, solar radiation of high intensity is the main and most effective source of heat gain, specifically through skylights.

The “quesanas de totora”, reed mats, have proved to be a good insulation material; however it is only available in the southern part of Peru.

The recommended strategies could satisfy the thermal comfort requirements of current inhabitants, but they still do not satisfy contemporary international standards of thermal comfort. It might be necessary to consider complementing the passive strategies with active ones or even with conventional heating systems. However, current economic constraints make difficult the broad implementation of non-passive systems.

Impact of added convex windows on heating energy need and peak load in different climatic zones

Attila Kerekes

Building Engineering, Faculty of Engineering, University of Debrecen, Hungary, kerekesa@eng.unideb.hu

Abstract: Windows have a dominant role in the energy balance of buildings. Added convex windows compound the features of additional insulation, mass wall, double skin façade and the form of bow windows. They facilitate the energy conscious retrofit of existing buildings without replacing the original windows thus lower operational energy consumption can be achieved with less embodied energy and without the garbage of demolition. Heating energy consumption can further be decreased by preheating the fresh air or recovering considerable energy of the exhaust air in the added zone. The operational energy saving obviously depends on the climate and on the orientation. Detailed dynamic simulations have been carried out for three climatic zone and different orientations. Calculated results have been checked with measurements of custom made cabins in Hungarian conditions. The investigations prove the considerable energy saving potential of added convex windows. A problem has been discovered and analysed. To achieve low energy consumption a higher built-in capacity of the heat source is required to meet the increased glazed ratio. This reveals the problems of many building regulations, which encompass the peak output of the heat source although the final goal is the low primary energy consumption and the related emission.

Keywords: glazed ratio, added window, heating energy need, peak load

Introduction

Windows in general are the weak points of the energy balance of existing buildings – obviously most energy conscious retrofits begin with changing windows, which is accompanied with serious disturbance of inhabitants and the problem of demolished material.

The “added” convex windows are put on the façade from outside whilst the original windows remain in place. The contour of the added windows is optional: polygonal, curved, asymmetric or symmetric. The form (from outside) is similar to that of the bay or bow windows: a traditional architectural feature in the UK. The area of the façade covered by the added window is greater than that of the original window: it means that all constructional joints, edges, bearers, windowsills: in one term all thermal bridges around the original windows are covered: thermal bridge losses and risk of fabric damages decrease. In the buffer zone (between the original and the added windows) the temperature increases due to the modest greenhouse effect, the covered massive wall around the original window acts as a mass wall. A further side effect is that the air tightness of the façade is improved. The ventilation air can be channelled through the buffer zone facilitating heat recovery from the transmission heat loss (in case of inlet) or from the leaving air (in case of exhaust). The schemes of different states and the model are shown in Fig. 1.

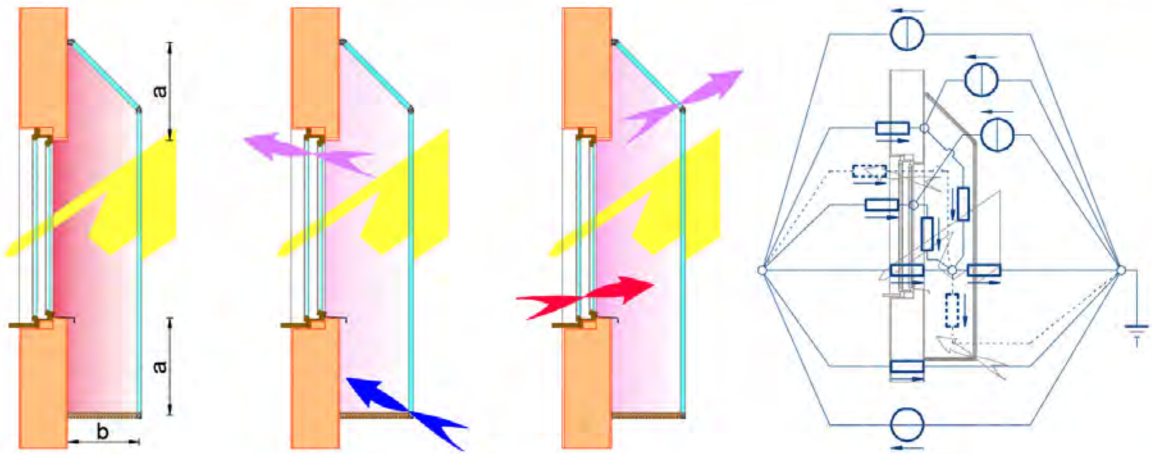

Figure 1. Scheme of added windows: buffer and greenhouse effect, fresh air preheating, exhaust air heat recovery and simplified model.

The width of the wall covered by the added window around the original window (as shown in Fig. 1, size "a") and the depth of the added window (as shown in Fig. 1 "size b") should be chosen between 20 and 40 cm for convenient installation and use. In our calculations the dimensions "a" and "b" were therefore taken into account as 40 cm.

Measurements have been taken, which show that using shades (to reduce upwarming) are the same effective in the case of using external shades on the original window, and in the case of using interior shade in the added window.

Methodology

Different combinations of walls and original windows (U and g values), glazing of added windows (single and double) have been analysed in the function of the glazed ratio (the last relates to the original windows) for three orientations. Dynamic simulation has been carried out using Energy Plus v.8.4.0 software for different climatic zones: the model is a room of five adiabatic boundaries and the varying façade. Air change rate 0.5/h and 55 W internal gain were considered. Heating energy need and net peak load of heating system have been calculated. Some of the results are shown on Figs 2-5. Three zones have been selected: the home location Debrecen {N 47° 28'} {E 21° 37'} Dfb (climate type in Köppen classification based on Kottek et al (2006)) in continental zone, a location close to Edinburgh: Leuchars {N 56° 22'} {W 2° 52'} Cfb and Bergen {N 60° 17'} {E 5° 13'} Cfb.

The following two base cases will be analysed in detail. The first one is an old façade of masonry wall and a low quality window. The effects of added windows are shown in Figs. 2. and 3. – it is important to notice that the refurbishment of the façade is restricted exclusively to the use of added windows.

Obviously a complex refurbishment includes the thermal insulation of the massive wall too. This is the second case, where the thermal insulation of the wall is improved up to the level of nearly Zero Energy Buildings, however instead of replacing the old windows they are kept and added windows are applied.

Three states have been considered. 1. Buffer and greenhouse effect, when no air flow passes the buffer zone (ventilation is provided via another intake). 2. Preheating of fresh air. 3. Heat recovery from the leaving air.

The results are shown in Figs. 2-5.

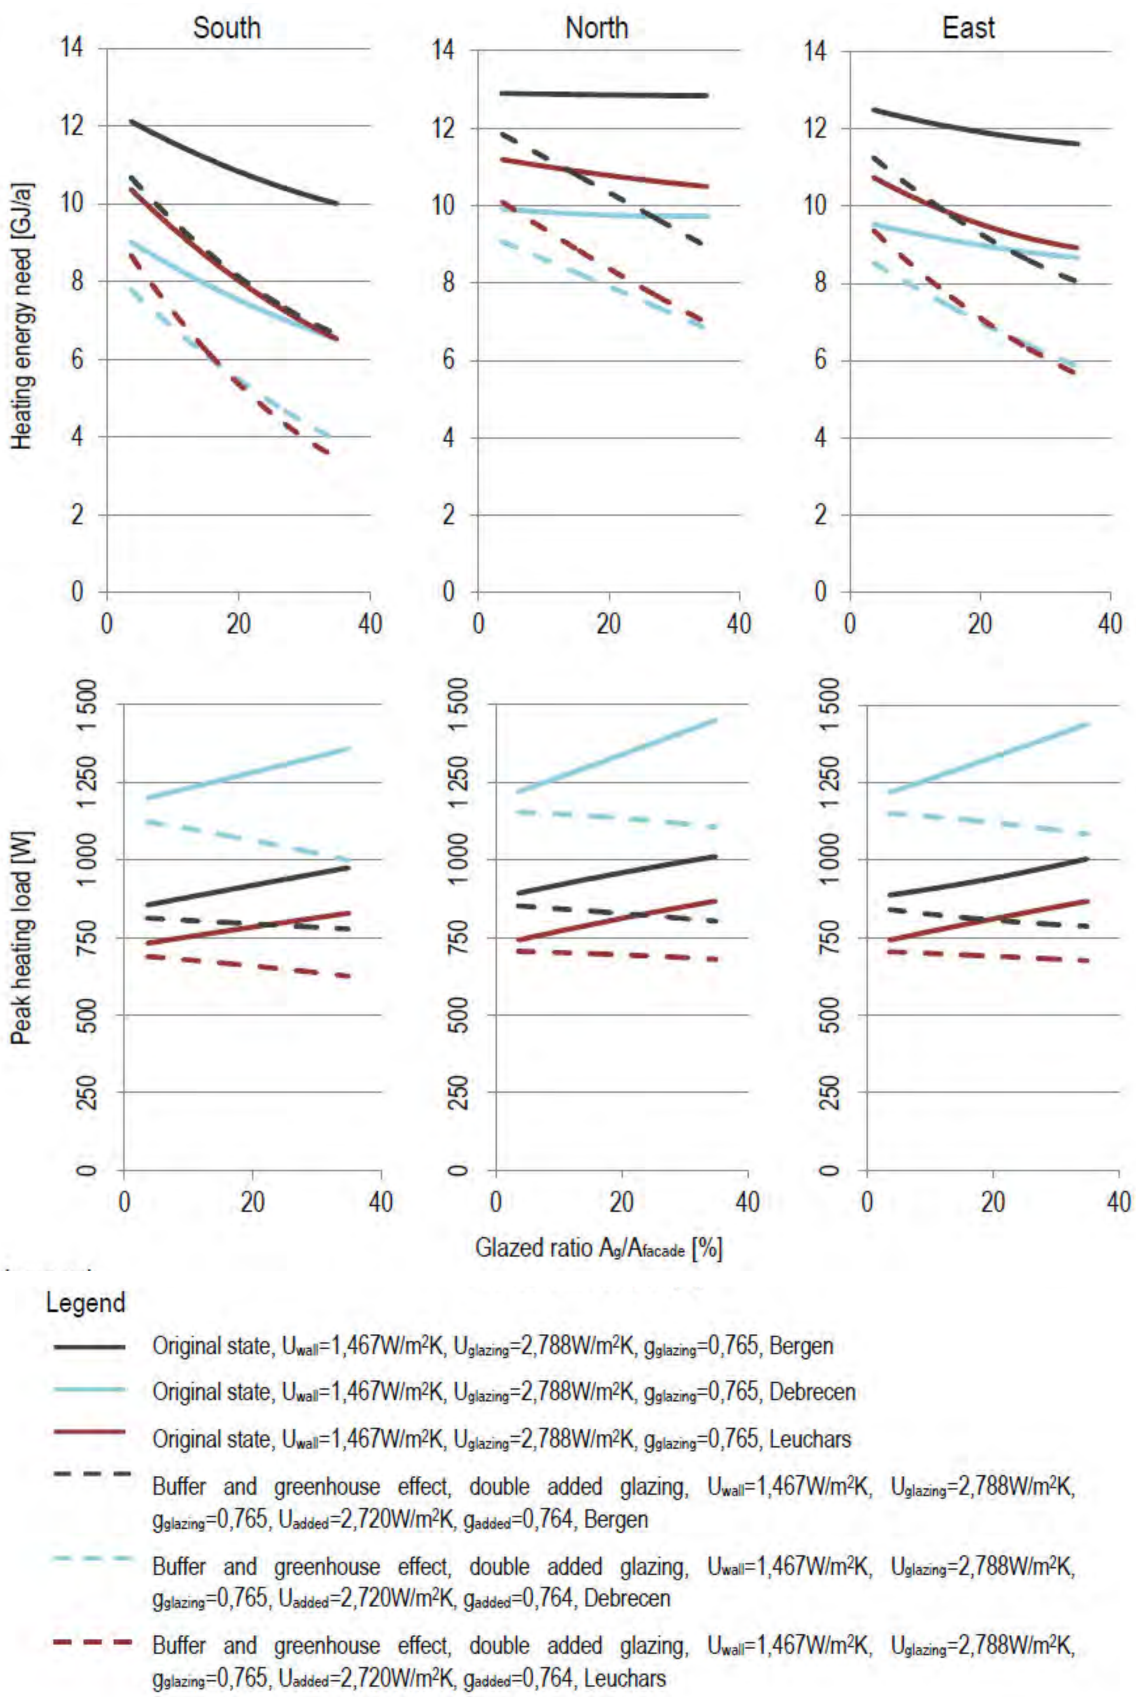

Figure 2. Heating energy need and peak load – original window, buffer and greenhouse effect with added window.

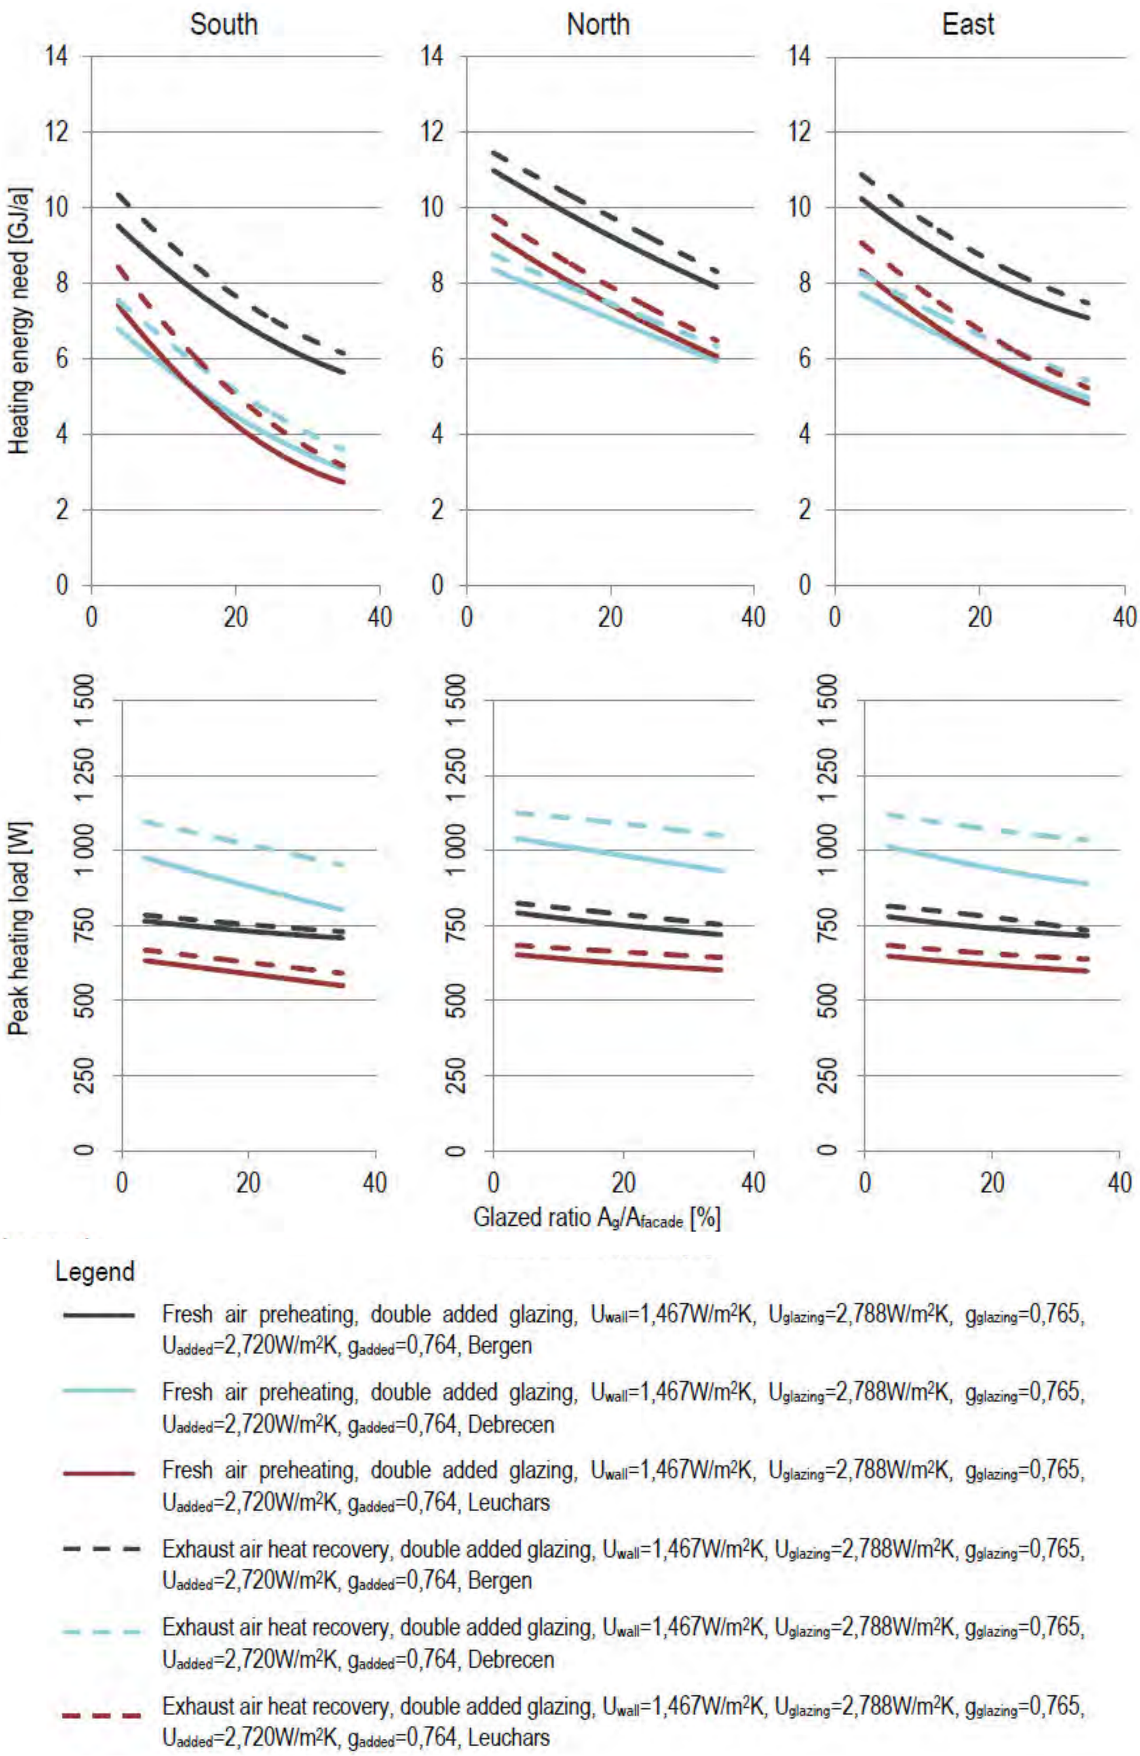

Figure 3. Heating energy need and peak load with different ventilation modes.

Discussion

As far as the latitude is concerned the order of the heating energy need (Fig. 2.) fits the expectation. Positive effects of increasing the glazed ratio of well oriented façades is partly the consequence of the poor thermal insulation of the wall. In the case of the North facing façade the glazed ratio does not practically influence the heating energy need.

Added windows radically decrease the heating energy need. The positive effect of the glazed ratio is more considerable due to several phenomena: the buffer and greenhouse effects, as well as the mass wall gain around the perimeter of the original windows. The higher the glazed ratio is – providing a continuous surface – the less the shadow of the reveals is.

Not surprisingly, the increased glazed ratio is accompanied with higher peak load. This fact traces back to a basic problem: elementary requirements of regulations (U-values, heat loss coefficients) as well as the everyday design practice encompass the low heating peak load although the most important goal is the low heating energy consumption.

Channelling the ventilation air flow through the buffer zone results in a considerable decrease of heating energy need and peak load. Certainly in the case of natural ventilation the air change rate depends on the users' habits: to facilitate the comparison in each case the conventional minimum ACH has been taken into account. In a building of more rooms and storeys it is impossible to say definitely the direction of the air flow since it depends on the wind and temperature difference, therefore both options have been considered. Their average or as a conservative estimation the less favourable one can be taken into account.

The second building option exhibits slightly different features. The effect of the glazed ratio is less radical – this fact is due to the better thermal performance of the façade and the lower U-value of the wall. Here the heating energy need tends to, or exhibits, a minimum at a given glazed ratio whilst in the case of North facing façades the glazed ratio either has no practical effect or shows a moderate negative tendency. Nevertheless the advantage of the added window is clear in each case.

Regarding this option it is worth mentioning that following the common routine of refurbishment (added external thermal insulation on the wall and change of original windows) the reveal become very deep which results in considerable shading. An added window "collects the passive gain" in front of the outer surface of the insulated wall and makes use of solar energy which does not enter the room directly through the original window.

Conclusions

The concept of ventilated window and double skin façade is not new. Its combination with mass wall and application as an effective refurbishment measure maybe considered as a further contribution, which is free of the problem of demolition and facilitates minimal disturbance of inhabitants.

The performance of ventilated windows is analysed among others by Carlos et al. (2010), Appelfeld-Svensen (2011). Simulations, measurements on site and in laboratory prove that the use of a passive elements like the added convex window as a heat recovery is promising. Certainly, the referred authors did not analyse the influence of different climatic zones.

Mainz and Menti (2012) investigated the thermal performance of different glazings itself under different conditions, illustrating the wide variety of positive and negative seasonal balances. They implemented a “climate severity index” – which is the ratio of the degree days and the global radiation income for the same interval. (it is considered a simplified version of that implemented by Santamouris (2010)).

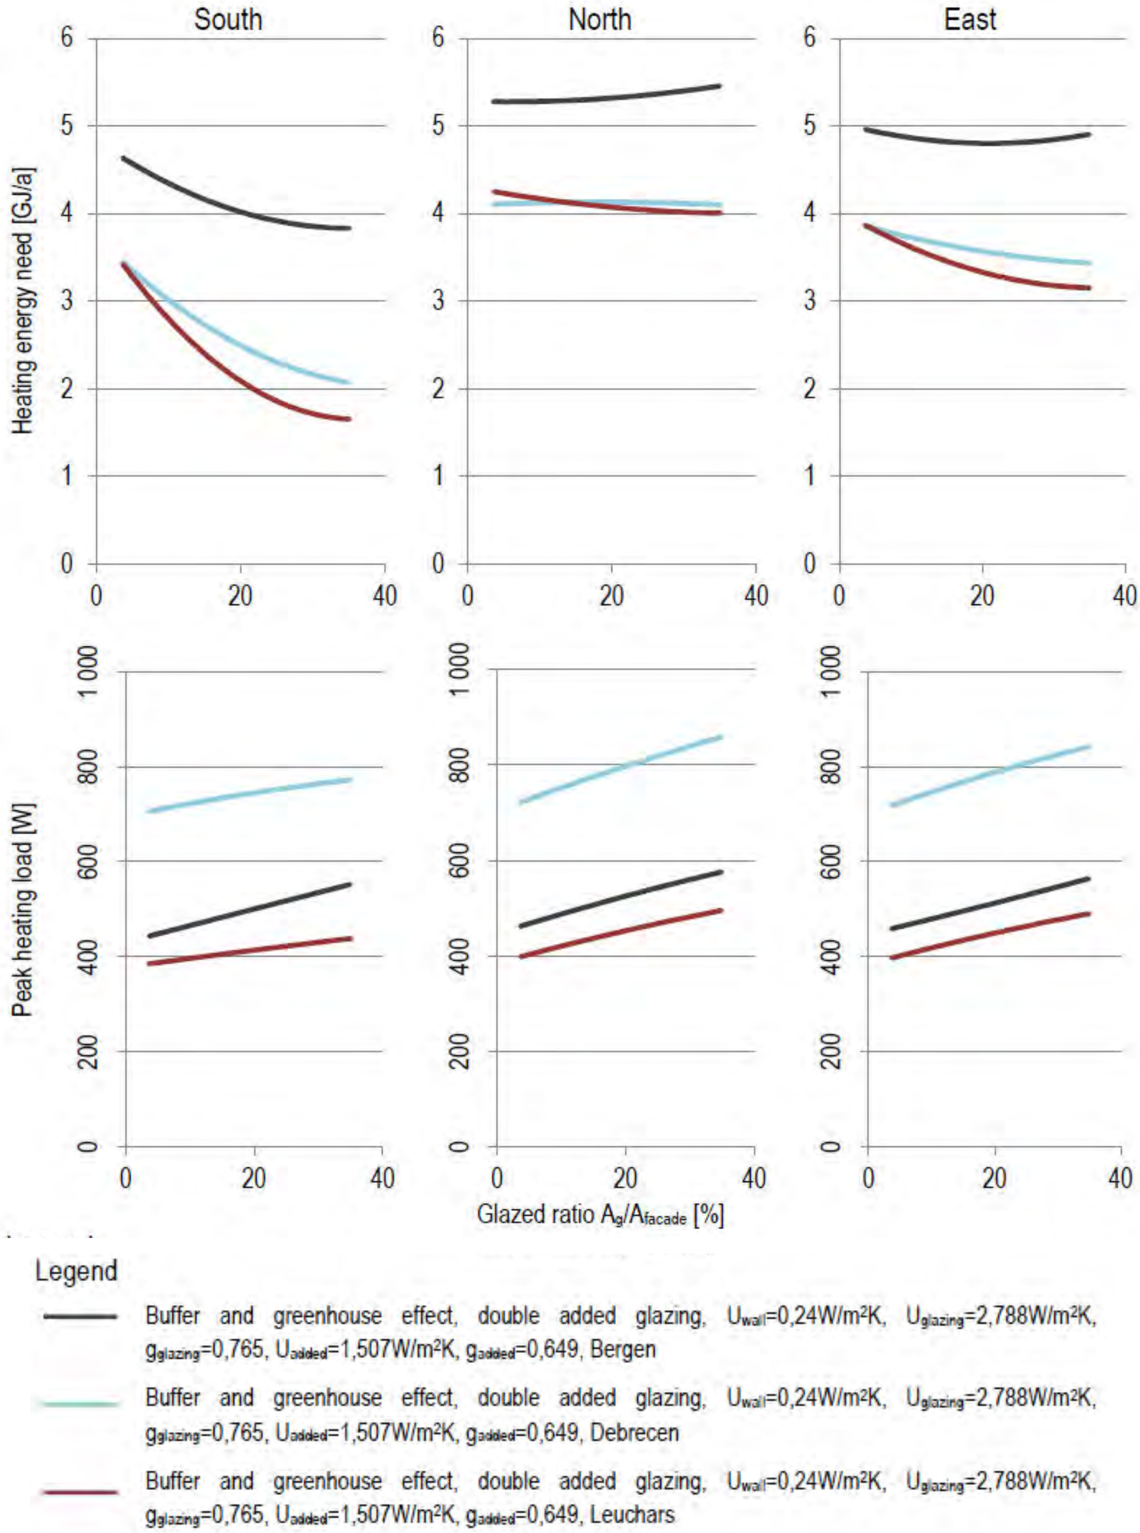

Figure 4. Heating energy need and peak load – buffer and greenhouse effect.

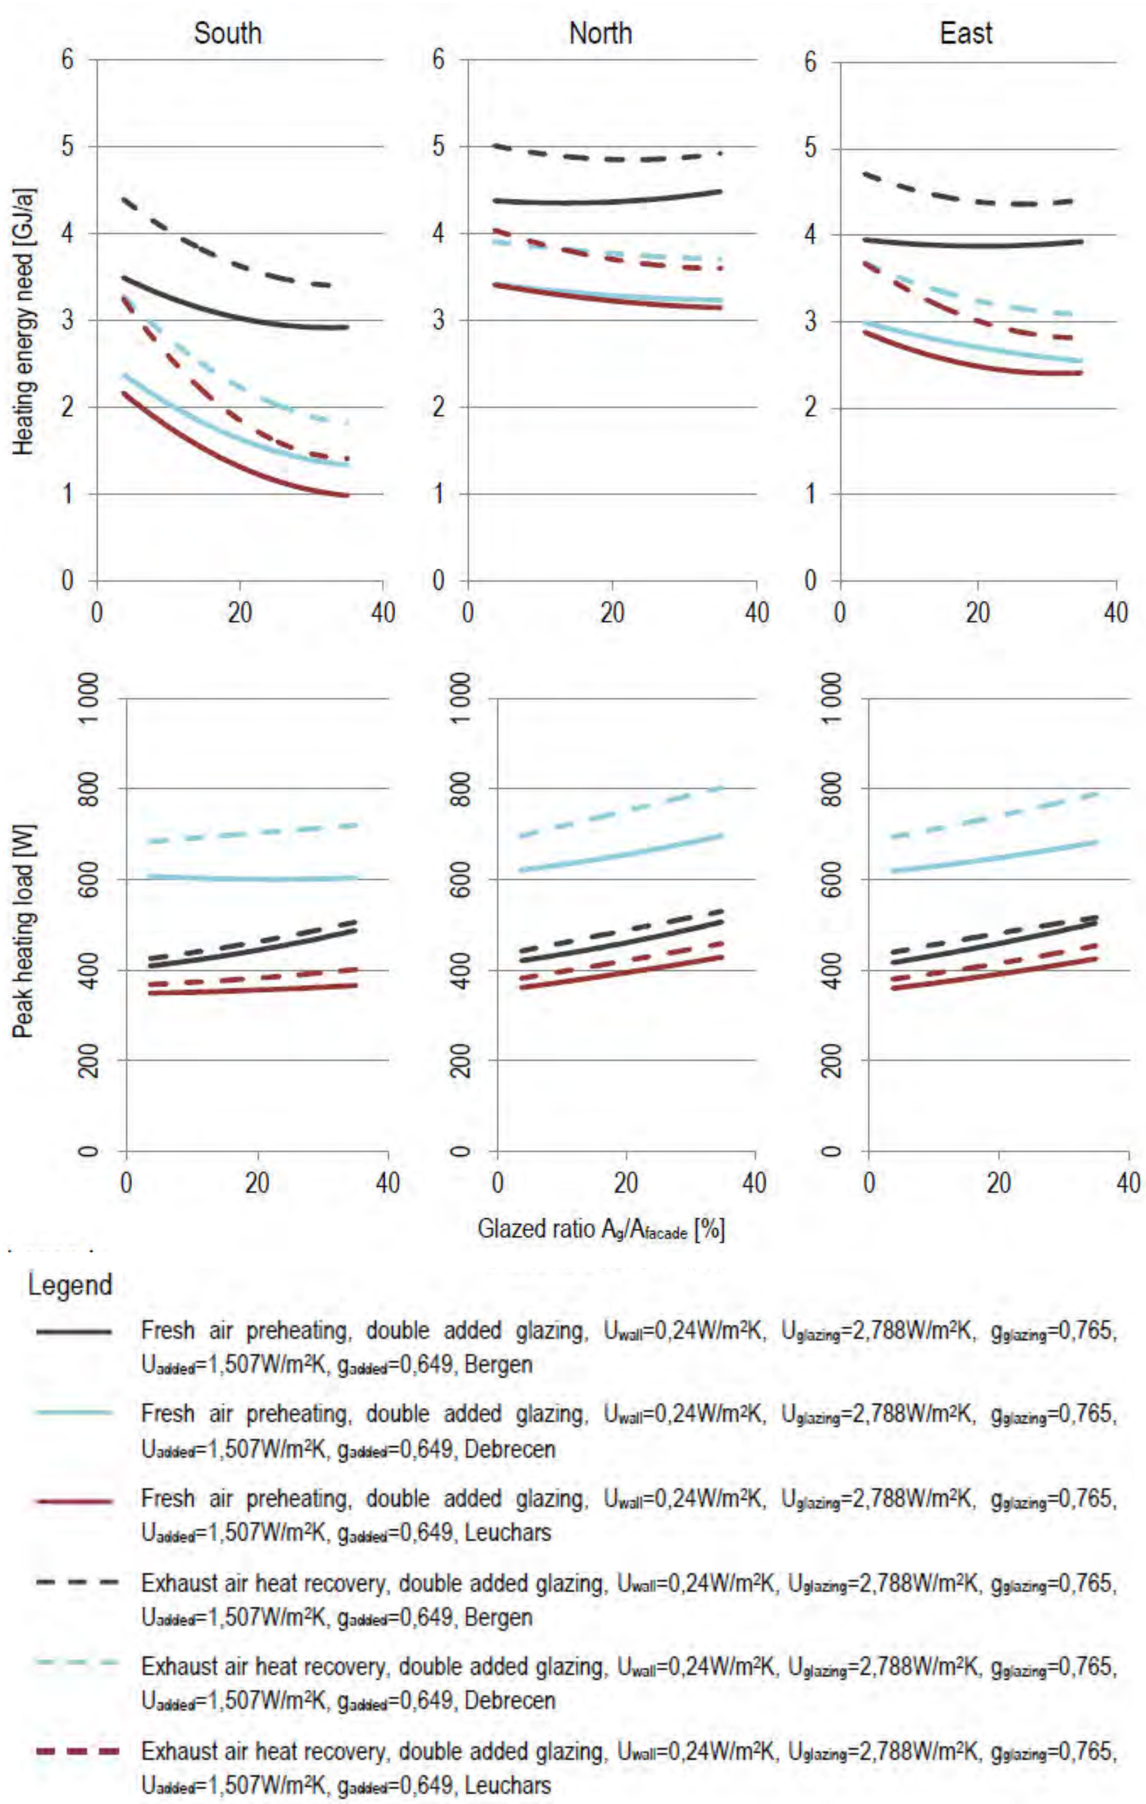

Figure 5. Heating energy need and peak load with different ventilation modes.

The simplified climate severity index does not reflect the many radical or fine differences between the climatic zones proved in our results. Therefore we must take into consideration the following aspects:

First of all for the same location different indices should be applied for different orientations if vertical façades are spoken of.

Secondly if the degree-days are the same for two locations their “length” (from date to date of the traditional heating season) as well as the minimum outdoor temperature can be different (compare Debrecen in Dfb zone and Bergen in Cfb zone). With a mild minimum temperature the longer the “heating season”, the more solar gain can be utilised. The same applies to the effect of the internal gain.

Thirdly further fine differences can be due to the sunpath: the higher the latitude is the closer is the angle of the direct solar beam to the wall azimuth: the higher is the transmitted solar energy and the less is the shadow of the reveal. Another fine side effect is the albedo of the surrounding environment with or without snow.

The results illustrate the potential of passive solar measures. Even if the new concepts of “Passivhaus” and its mutations from passive to active buildings offer new materials and technologies the classic passive solar architecture is not outdated at all. Moreover, if low operational energy consumption is achieved with more and more embodied energy it is worthwhile to set new systems and materials with their embodied energy against the thorough pondering of form, glazed ratio, orientation, to set demolition and replacement against added passive elements of long physical lifetime.

To prevent any misinterpretation the author does not deny the necessity of contemporary technology: the well balanced alloy of old and new ideas offers the best solution.

High-level EU documents neglect utilised passive solar gain. Whilst the Energy Performance of Building Directive encompasses the low operational energy need and requests the utilisation of renewable energy the positive contribution of passive solar systems is not acknowledged in the energy balance as a part of the renewable share.

Abstract: This paper aims to examine the potential for improving thermal comfort for a location under composite climate zone in India through bioclimatic analysis. A new bioclimatic tool has been developed for the investigation of the potential of passive heating and cooling strategies. A modified thermal comfort zone is proposed for a composite climate based on a review of the recent thermal comfort field surveys carried out in India. The comfort zone of the chart was then extended to define the control potential zones (CPZ's) or passive design zones based on the calculations of the effects of passive heating and cooling strategies. The hourly weather data based on TMY (Typical Meteorological Year) was used for the climate analysis. The bioclimatic potential of three passive strategies, namely Natural Ventilation, Direct Evaporative Cooling and Passive Solar Heating have been analyzed for their thermal comfort potential. Results show that Natural ventilation has the maximum potential (71 %) for achieving comfort in a composite climate of India. Location specific passive strategies can be developed using this tool based on the severity of the climate with in a composite climate zone in India.

Keywords: Passive strategies, Passive design potential, Bioclimatic chart, Composite climate, India.

Introduction

One of the primary goals of a sustainable built environment is to design buildings which are sensitive to the local climate. A full understanding of the local climate provides the designer with the opportunity to explore the possibilities of a range of passive design strategies which are contextual to the location of the building. In this study a simple tool is developed for climate analysis, tailor made for people living in the composite climatic zone of India. The presently available climate analysis tools like weather tool (Ecotect weather tool, 2011) and climate consultant (Climate consultant, 2011) are primarily designed for temperate and cold climates where people are acclimatized to such climates and hence tend to employ HVAC systems more frequently to achieve indoor comfort. In contrast, people in tropical climates mostly live in naturally ventilated buildings where varying range of indoor conditions are experienced due to changing outdoor conditions. The occupants in such climates adapt themselves through behavioural, psychological and physiological controls to achieve acceptable comfort conditions indoors. The adaptive model of thermal comfort, used in international standards like ASHRAE Standard 55 2013 is based on this fundamental premise. It is hence logical to expect that the comfort requirements of occupants are also likely to vary significantly in these climates when compared to temperate and cold climates. This paper presents a simple and easy to use climate analysis tool which can be used by architects and building designers to get an overall picture of the potential for comfort achievable and the passive strategies appropriate for a location under composite climatic zone in India. The city of Bhopal, which is classified under the composite climatic zone (NBC, 2005) is taken as a case study. The proposed method for developing the tool was carried out in the below mentioned steps:

i) Analysis of comfort requirements and definition of an appropriate thermal comfort zone on the bio climatic chart for people living in the composite climate of India.

ii) Definition of control potential zones (CPZ) or passive design zones as extensions of the base comfort zone.

iii) Quantitative analysis and assessment of thermal comfort, heating and cooling potential of different passive strategies. This will be done for the whole cumulative year and individual months.

Thermal comfort zone for people living in composite climate of India

International standards like ASHRAE (ASHRAE Standard 55, 2013) in their 'Graphical comfort zone method' section propose a conventional comfort zone on the psychrometric chart uniformly applicable to all climates in the world. This is based on the PMV-PPD index. Particularly the upper humidity ratio limit of 0.012 Kg (water vapour)/kg (dry air) is very restrictive for tropical climates. However some earlier studies (Nicol, 1974) in tropical regions and recent field studies on thermal comfort in India (Indraganti, 2010), (Dhaka, 2015) particularly in a composite climate, have questioned the applicability of the ASHRAE thermal comfort Standards in these regions. These studies have shown that people have higher thermal acceptability or tolerance than what is defined in the international standards like ASHRAE Std 55 (ASHRAE Standard 55, 2013). This is due to the adaptation of the subjects to higher temperatures in a warm climate. Hence the international standards may not be directly applicable to Indian conditions.

The computer weather tools like Ecotect weather tool and climate consultant also fail to predict the comfort periods for Indian conditions because they use comfort boundaries which are defined by ASHRAE standards or comfort models suited to temperate and cold climates. For example Figure 1 shows the comfort prediction by two weather analysis tools, namely climate consultant and Ecotect weather tool.

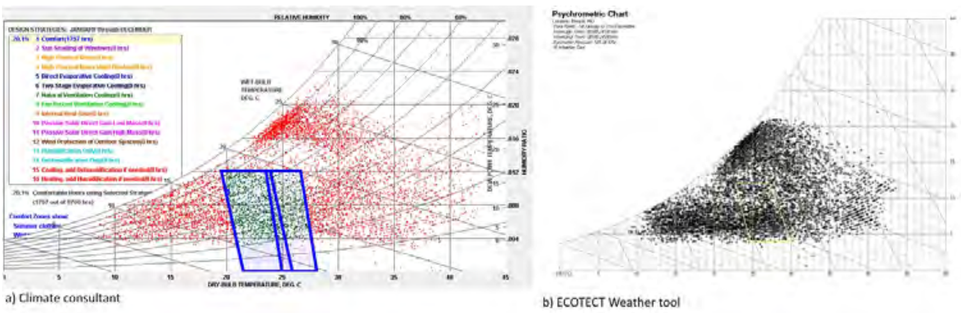

Figure 1. Comfort predictions for Bhopal by a) Climate consultant and b) Ecotect weather tool.

The comfort zone proposed for Bhopal using climate consultant tool is based on the ASHRAE standard 55 2004 and it shows that it is only possible to achieve comfort conditions for 20 % of the total time in a year. A similar prediction is shown by the weather tool, which indicates that only 20 % of the total time in a year is comfortable. But according to certain recently conducted thermal comfort field surveys in India (Dhaka, 2015) it was found that more than 80% of the people living in naturally ventilated buildings voted with in the comfort band (-1,0,+1) which represents 80 % acceptability according to the International standards of thermal comfort. These comfort percentages of satisfied people in the tropical climate of India indicate that the predictions of computer tools significantly underestimate the actual comfort potential of composite climates in India.

Table 1 gives a summary of the recently conducted field studies on thermal comfort in India. The studies show that occupants living in naturally ventilated buildings in a composite climate of India adapted themselves to the varying outdoor conditions and kept themselves comfortable through various adaptive actions like opening of windows, turning on fans, change of clothing as per season, changing of activity levels, etc in a wide range of comfort temperature between 17 °C to 35 °C, relative humidity between 15 % - 90% and air speeds between 0 – 1.5 m/s. This indicates a wider comfort band higher than what is defined in the international comfort standards as well as Indian standards.

Table 1 Thermal comfort field studies in composite climate-India.

Methodology

In this paper, a revised thermal comfort zone is proposed on the building bio climatic chart for people living in the composite climate of India. This comfort zone is defined as the Adaptive comfort zone (ACZ) which defines the acceptability limits of comfort for people living in naturally ventilated buildings in a composite climate. This ACZ also takes into account the various behavioural adaptations like acceptable operative temperature limit, humidity limits, clothing, activity and air velocity preferences for people living in a composite climate in India. Figure 2 shows the newly defined (modified) thermal comfort zone (thick lines) for a composite climate. The comfort zone applies for normal healthy

Indians for sedentary work (Standing, relaxed- 1.2 met – 70 W/m^2), under still air conditions (0.2 m/s). The clothing insulation values vary from 0.5 clo -1.0 clo reflecting the adaptation of people as per change of seasons, from summer to winter. The thermal conditions inside this comfort zone is expected to satisfy 80 % occupants based on 10 % predicted whole body dissatisfaction and 10 % dissatisfaction due to local discomfort like cold floors, draught and radiant temperature asymmetry. The lower limit of humidity is set at 20 % because Indian people living in composite climate do experience dryness of skin, nose, throat and eye irritation during the hot-dry months (April and May). This has also been substantiated through the recent field surveys (Indraganti, 2010). The upper humidity limit for this comfort zone is fixed at 80% for still air conditions (0-0.2 m/s), because at humidity levels higher than this, lack of air movement may cause stuffiness and cause discomfort due to skin wettedness, especially at temperatures higher than 32 ^{o} C limit or the skin temperature (Indraganti, 2010). Moreover under still air conditions (0-0.2 m/s), it was found that the occupants in naturally ventilated buildings were comfortable up to a lower temperature limit of 18 ^{o} C and a higher temperature limit of 32 ^{o} C for 80 % acceptability (Kumar et al, 2016). Thus, based on the review of thermal comfort surveys (Table 1) it is found that the occupants living in naturally ventilated buildings in a composite climate of India are comfortable in a range of operative temperature between 18 °C to 32 °C, at relative humidity between 20 % - 80% under still air conditions (0 – 0.2 m/s). This defines the adaptive comfort zone for a composite climate of India.

Control potential zones for passive cooling and heating strategies

This study considers only the *direct* passive cooling and heating strategies namely, *Natural ventilation, Direct evaporative cooling* and *Passive solar heating*, as they are directly related to the climate variables, namely *wind speed*, *humidity* and *solar radiation*. The indirect strategies like thermal mass and mass with night purge ventilation, indirect passive solar heating and indirect evaporative cooling are not considered, as these are highly influenced by parameters like building envelope thermal properties, occupancy and equipments.

Passive cooling by Natural ventilation

The two most important functions of air movement are to enhance convective and evaporative heat loss. Convective heat loss by air movement is effective when the air temperature is near to or less than the skin temperature at lighter clothing levels (0.5 clo). Above skin temperature, air movement causes discomfort due to heat gain on body surface. This phenomenon was observed in Hyderabad (Indraganti, 2010). Evaporative heat loss is most effective at medium humidity levels between 40-50% and at air temperatures near or below skin temperature (32 °C). At higher air temperature, higher humidity levels (> 80%) impede evaporation and hence cause discomfort. In such a case higher air velocities (1.0 m/s or higher) are favourable in reducing discomfort. As discussed before, it has been observed especially during summer months (Kumar et al, 2016) that subjects wearing lighter clothing (mean 0.3 clo) adapted themselves comfortably by opening windows and using ceiling fans at lower speeds to achieve moderate air movement of up to 0.5 m/s at temperatures as high as 33 °C and relative humidity between 20- 80%. Further it was also observed that the subjects' desire for higher air speeds increased with increasing indoor operative temperatures. At temperatures higher than 33°C and up to 35 °C, the subjects' preferred an air speed of 1.0 m/s or higher. Figure 2 shows the extended passive zone through natural ventilation as dotted lines. The upper limit of this zone extends up to an operative temperature of 35 °C. At higher humidity levels thermal comfort sensation is experienced at lower operative temperatures. Hence this is shown along a tilted line which follows the SET temperature line on the Bio climatic building chart. This corresponds to an air velocity limit of up to 1- 1.5 m/s. Beyond this limit air movements cause discomfort due to heat gain on body surface, draughts and paper blowing.

Passive cooling by direct evaporation

Evaporation is the process which converts sensible heat into latent heat by increasing the water vapour content in dry air. The most important parameters which govern this strategy are the Wet bulb temperature (WBT) and the wet bulb depression i.e. the difference between the maximum dry bulb temperature and maximum wet bulb temperature. The higher the wet bulb depression higher is the cooling effectiveness of evaporation. But during this process the wet bulb temperature remains unchanged. In a composite climate in India, humidity is generally low (30 % or less) during the day time in the hot dry season (Latter half of March, April and May). Hence this strategy is most effective during this season. The cooling performance of a direct evaporative cooling system is measured by the air temperature exiting the evaporative cooler and is given by the following relation:

$$T_{EC} = T_{DBT} - T_{WBD} \times \varepsilon \qquad (1)$$

Where T_{EC} – is the Air temperature exiting the cooler (in °C); T_{DBT} – is the Ambient inlet dry bulb temperature (in °C); T_{WBD} – is the wet bulb depression (T_{DBT} - T_{WBT}) (in °C); ε is the efficiency of the evaporative cooler. In a direct evaporative cooling system the ambient air temperature is reduced by nearly 70-80% of the wet bulb depression (Givoni, 1992). Based on this the maximum limit of outdoor ambient air temperature for achieving comfort by means of direct evaporative cooling is fixed at 42 °C for hot dry climates. The corresponding wet bulb temperature would be a maximum of 22 °C. This would give an indoor cooling temperature from the evaporative cooler between 26-27 °C at a mean indoor air temperature of 27-29°C (Givoni, 1992). The maximum limit up to which dry bulb temperature can be lowered by direct evaporative cooling is about 11°C (Szokolay, 2004). Thus the upper comfort limit for the evaporative cooling zone is extended by 11 °C along the wet bulb temperature line.

Passive solar heating

This strategy is applicable in the cooler season of the year. It relies on direct solar heat gain through fenestrations. To get an approximate idea of the effectiveness of a passive solar system, a building energy balance and steady state heat transfer model is used. Assuming a typical south facing wall of area 35 sq.m. (10 m x 3.5 m) of an office building on a middle upper floor having a floor area of 100 sq.m, with window area of 10 sq.m (2 m x 5 m) with no internal heat gain or heat exchanges with adjacent spaces, the heat flow through south wall, window and infiltration (ventilation) heat gain is given by the below equations:
Heat flow through south wall is given by:

$$Q_{wa} = U_{wa} * A_{wa} * (T_i - T_{so}) \qquad (2)$$

T_{so} is the Solar air temperature, which is given by: $T_{so} = \mathrm{To} + \frac{\mathrm{Is \times \alpha}}{\mathrm{ho}}$ (3)

Heat flow through window opening is given by (ASHRAE handbook of fundamentals, 2009):

$$Q_{wi} = (SHGC * I_s * A_{wi}) + [U_{wi} * A_{wi} * (T_i - T_o)] \qquad (4)$$

Heat gain due to infiltration is given by:

$Q_v = \rho * C * V_r * (T_i - T_o)$ (5)

Where,
U_{wa} is Overall thermal transfer co-efficient (U value) through the south wall in W/m^2 º C,
A_{wa} is the area of south external wall in m^2,
α is the solar absorption coefficient of the external wall,
h_o is the outside surface film heat transfer co efficient of the external wall surface,
SHGC is the Solar Heat Gain Coefficient of the window glazing (dimensionless),
I_s is the mean daily solar irradiance on the south facing wall in the coldest month in Bhopal,
U_{wi} is Overall thermal transfer co-efficient (U value) through the window,
A_{wi} is the area of the window in m^2,
ρ is density of air in Kg/m^3,
C is specific heat of air (J/ kg ºC),
V_r is ventilation rate (m^3/s) and T_i is the Indoor air temperature, T_o is outdoor ambient air temperature. The steady state heat transfer equation for energy balance of the space is given by (omitting evaporation heat loss on roof surface):

$Q_{wi} - Q_{wa} - Q_v = 0$ (6)

Assuming a conventional construction in India which is made of an RCC framed structure with: i) External wall: 190 mm modular brick with 12 mm plaster (outside and inside) with a U_{wa} value of 2.35 W/m^2 º C with α = 0.6, h_o= 22.7 W/m^2 º C
ii) Window: Aluminium framed with 6 mm single glazing having a U_{wi} value of 5.7 W/m^2 º C and SHGC of 0.7
iii) For ventilation, considering an air exchange rate of 2 hr^{-1} and volume of space-V=350 m^3 (10m x 10m x 3.5m)

The indoor air temperature at the lower limit of the comfort zone is 18.0 º C at 50% Relative humidity. The average daily solar irradiance on the south facing wall in the coldest month in Bhopal is 207.5 W/m^2. On calculation, this gives a T_o value of 13.9 º C, which is the lowest outdoor temperature at which the heat delivered by a passive solar system can compensate to maintain indoor comfort temperature. Below this temperature, active heating systems would have to be used. It is important to mention that the actual efficiency of the passive solar system depends on the building design and envelope specifications, type and design variables of the passive solar system. Therefore the above model considers standard conditions and hence is only for a reference.

Plotting of hourly climatic data on bioclimatic chart

Figure 2 shows the hourly conditions for a typical meteorological year for Bhopal. This chart is created using a newly developed bio climatic analysis tool in an excel spreadsheet. Each point represents its x-coordinate (Dry bulb temperature) and y-coordinate (Humidity ratio). The number of data points were identified with in each of the boundaries (comfort and passive design) using IF-AND logic in the excel spreadsheet. Based on the number of points identified with in a given boundary, the potential for comfort and passive heating and cooling was calculated.

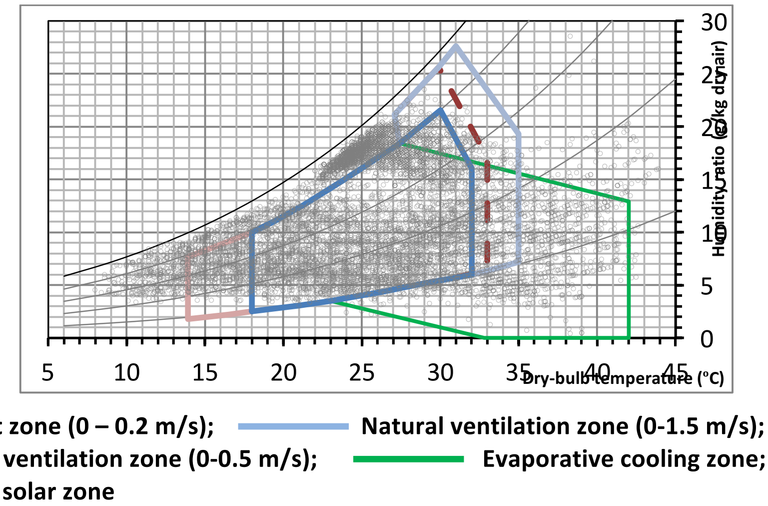

Figure 2. Plot of hourly weather data points for Bhopal at standard atmospheric pressure (101.325 kPa)

Results

Cumulative whole year assessment

The cumulative comfort potential of different passive design strategies (in percentages) for the whole year is shown in Figure 3. Natural comfort, *without* the use of any passive strategies can be achieved for nearly about 49% of the total time of the year. The percentage of comfort improvement for each passive strategy is also shown in Figure 3. Natural ventilation proves to be the *most effective* passive technique for comfort improvement (21.5 %). This correlates well with the field studies (Indraganti, 2010), (Dhaka, 2015) where occupants used adaptive measures like opening windows and turning on ceiling fans to achieve comfort. The comfort period can be increased by this strategy and it provides a cumulative comfort (70.6 %) for more than half period of the total time during a year. Passive solar heating (6.3 %) (Cooler season) and direct evaporative cooling (4.2%) (Hot-dry season) are less effective because they are season dependant. Nearly 81% of the total time during a year would be thermally comfortable if *all* three strategies are combined.

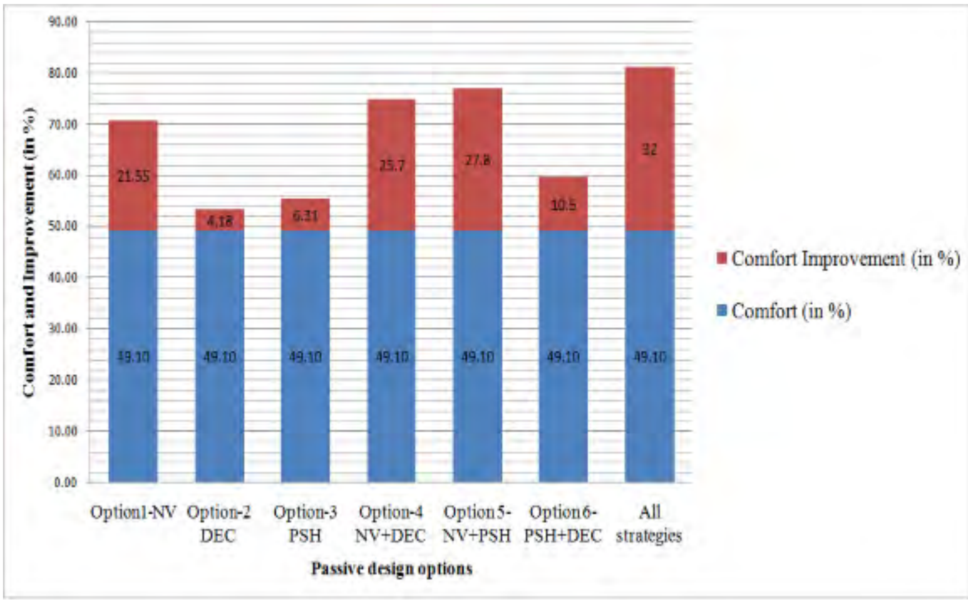

Figure 3. Cumulative and Potential for comfort improvement for each passive strategy and their combinations for the whole year in Bhopal (in %).
Natural Ventilation (NV), Direct evaporative cooling (DEC) and Passive solar heating (PSH).

Conclusions

This study illustrates through a simple tool, a method to analyze the composite climate in the preliminary stage of climate responsive building design. This method gives reliable results and is very useful for the architects and building designers to get a very quick summary of the climate of any location within a composite climate zone in India. It is important for architects using software tools to have a thorough understanding of the local climate for designing climate responsive buildings. Three passive strategies related to the climate were explored in this study. But relying completely on these passive strategies to maintain thermal comfort is not feasible, although still there is a significant potential for improvement of comfort. The actual comfort conditions achieved will be contextual and depend on the building typology and its building envelope design specifications. Natural ventilation proves to be the *most effective* passive design strategy for achieving thermal comfort in a composite climate of India. This correlates well with the recently conducted thermal comfort field studies in a composite Indian climate. Being a low and cost effective strategy, its applicability must be explored through more detailed studies particularly for free running (unconditioned) buildings. More such locations need to be analysed under a composite climate in order to investigate the applicability of a particular passive strategy based on its climate severity.

Abstract: This study aims to investigate and compare the performance of a heat exchanger using water and sand in a hot and humid climate of Indonesia. The heat exchanger consists of copper cooling coil with a size 3/4' of diameter that arranged and buried as deep as 10 cm in an acrylic container measuring 1 x 1 x 0.2 m, which filled with water or sand. Water from the zinc roof surface after spraying was accommodated in the gutters then flowed to the heat exchanger. The comparison of performance from a heat exchanger using water and sand shows that both water and sand has not much different performance to decrease the water temperature through it. The heat exchanger using either water or sand as cooling medium can decrease the temperature of the incoming water after being sprayed on the roof surface by about 0.8°C in average. As the cooling medium, the mean temperature of the water and sand is not much dissimilar from each other, each about 27.5°C. It is necessary to mention that the power of the heat exchanger using water to cool the incoming water is more effective in the forenoon, while the sand being effective occur at noon and afternoon. Essentially, this system has demonstrated its usefulness and capacity as a passive cooling strategy for improving thermal comfort in the humid tropics.

Keywords: passive cooling, evaporative cooling roof, heat exchanger with water or sand, roof surface temperature

Introduction

Buildings face the problem of excessive heating as an upshot of the pressing of hot and humid climate. This condition will result inconvenience of occupants and a waste of energy for cooling the room if not taken seriously. Energy consumption will increase when the construction was designed unconsidered environmental conditions, use of construction materials inappropriately and ignores the protection from direct sunshine. Building on average in humid tropical climates face the problem of how to maintain comfortable conditions in the buildings.

The passive cooling strategy is a scheme for economising energy consumption and achieving thermal comfort that needed for a tropical humid climate condition. The evaporative cooling that being ignored in the region is as one of the passive cooling strategies. Implementation of this plan will be able to conserve energy needs of the building and make a comfortable space condition and efforts to lower the cooling load drastically. It is essential for creating a comfortable place that will increase the productivity of the occupants of the buildings.

The evaporative roof spray cooling system is not a new idea; studies have been done since early 1939. Because of the energy crisis, roof spray cooling methods have recently become acceptable and desirable (Carraso et al, 1987). The operation of roof spray cooling is a straightforward and fundamental one; the basic concept aims to wet the hot surface and cool it down with sprayed water. Maerafat et al. (2010) have studied the role of the evaporative cooling cavity in residences; they reasoned that the application is successful and get a broad impact on cooling strategies. Givoni (2011) and Joudi and Mehdi (2000) examine the indirect evaporative cooling with a cooling load varies for housing, they have concluded that the passive cooling system can reduce the room temperature, but this system will differ from one another depending on the particular climate. Kim et al. (2011) have examined the potential energy savings with direct or indirect evaporative cooling by using the outdoor breeze and concluded both these strategies could be utilized for the energy conservation.

Jain et al. (2008) have tested the insulation along the roof of the building that can be customized for the intention of cooling by using an indoor air or not which demonstrated this arrangement can work in the right way. In 1977, they had also experimentally investigated in some detail the issue of roof pond and roof spray at the roof surface of a thick reinforced concrete roof exposed to a hot-day sunny climate. It was found that, by roof shower, the peak roof temperature decreased from 55°C to 28°C as compared to a reduction from 55°C to 32°C in the case of roof pond. The condition was obviously due to more efficient evaporation of water at the roof surface. The roof surface temperature was observed to undergo a drop of the order of 15°C as compared to 13°C in the case of the water pond.

Kettleborough et al. (1981) have conducted research on how the wet plastic plate as a heat exchanger was performed for indirect evaporative cooling. Likewise, Costelloe and Finn (2003) stated that the passive cooling with the air-water system is potentially applied in temperate or moderate climates. Tang et al. (2005) have described that the cooling with a puddle on the roof using a floating bag had good performance compared with movable insulation. Wongsuwan et al. (2006) have conducted an experimental study on the roof pond house under tropical climatic conditions; they concluded that the system could reduce 2-4°C indoor temperature lower than the outdoor.

Spanaki (2007) had reviewed the literature of some studies on the different type of roof ponds for cooling purposes; she reported that spraying system is usually preferred for larger cooling loads. The usefulness of roof spray-cooling was found to be most useful in buildings with lightly constructed, poorly insulated roofs. In relatively the same line with research of Zhou et al. (2004) that studied the effect of the difference between a grass roof and the roof by spraying water in a building with reinforced concrete (RC) construction. The conclusion is that the roof by spraying water is not suitable for an RC building with a high level of insulation in the roof. Kindangen (2016) has reported that water spraying can reduce the zinc roof surface temperature by an average of 5°C and to gain a greater advantage of the roof temperature reduction is needed to spray water in approximately 10-15 minutes and carried on continuing.

All of these studies as described, they noticed generally how evaporative cooling was applied to the roof of the building, but this brings up another problem: how to make the water after being sprayed being cooler for reuse. Water after being sprayed will be hotter, to reuse it required the cooling process in order to cooling by spraying more effective. Re-cooling can be answered by applying a heat exchanger. The purpose of this paper is to compare the performance of a heat exchanger using water and sand.

Methods

The experiment has taken out in Manado city, it is situated in the state of North Sulawesi in Indonesia, at latitude 1.4583°N and longitude 124.8260°E, has a humid tropical climate. The hottest month is August with average temperature 27°C and the coldest one is January with average temperature 25.9°C. In general, the temperature difference between the hottest and the coldest month is not too much; their amplitude is low. The rains' period occurs from November to February, being the rainiest month January (452 mm).

A cell test was constructed with a 1.5 m of length, 1.5 m of width and 2.5 m of height with plywood for the walls and floor and the roof made of corrugated zinc sheets. The floor cell test made of plywood that raised about 80 cm from the ground. This construction does not have a ceiling; roof tilted only in one direction. The cell has openings measuring 30 x 40 cm on the right and left sides (North and South) as presented in figure 1. The house test is placed outdoors, in the garden, as efficiently as possible exposed to direct sunlight in the morning until the afternoon.

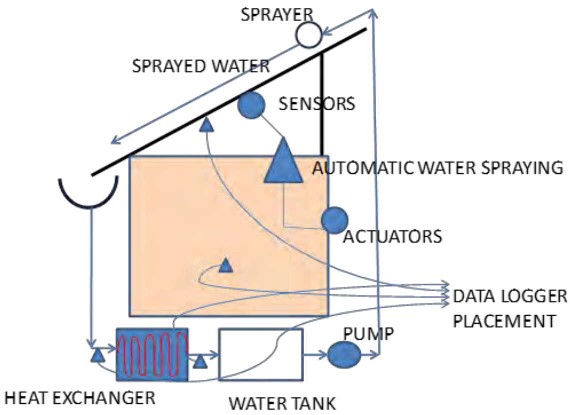

Figure 1. A cell test and schematic design of cooling roof device.

Measures were taken to check the performance of the heat exchanger using RC-4HC data logger that measures temperature and relative humidity. We use 5 pieces RC-4HC data logger with the appropriate placement. One data logger is placed in roof gutters that take in water after spraying, is given as a reference temperature of incoming water where the temperature must have been hotter. One data logger is ready at the end of the copper pipe to record changes in water temperature coming out of the heat exchanger. A data logger to record the temperature of the water or sand in the heat exchanger as a cooling medium. A data logger is placed in the cell test for recording the temperature in the room and other data logger is placed and affixed to the inside of the zinc roof to measure and record the temperature of the roof surface.

A heat exchanger made of acrylic plates with a size of 1 x 1 x 0.2 m. The copper pipe is used as a cooling coil with a size 3/4' of diameter and 6.5 m of length mounted in an acrylic box. An acrylic box filled with water or sand as a coolant in which the copper pipe buried as high as about 10 cm from the surface of the water or sand. At the terminal of the copper pipe where the water will be provided with a plastic hose to the tank. The circulation water is pumped out of the tank with a submersible pump capacity of 4000 l/h. Water is pumped into the perforated PVC pipe on one side that will squirt water onto the entire surface of the roof.

An automatic roof spraying device was designed and it consists of a controller, sensors, and actuators. The microcontroller Arduino UNO and SSR 25-DA require a supply voltage of

12V to the electrical current of 3A, while DHT11 and DS18B20 sensor probe and a 2x16 LCD need a supply voltage of 5V. The DHT11 sensor is applied to observe the roof surface temperature while the DS18B20 sensor probe is utilized to assess the indoor air temperature. These sensors are really easy to use with the microcontroller Arduino, and they have an excellent point of stability and very precise calibration.

The device is set at a certain temperature as a parameter of the roof surface temperature limit. If the limit exceeds, then the controller will activate the actuator and the pump will work to spray water on the roof. Exactly the same, if the temperature of the roof is less than or equal to the limit, the controller will turn off the actuator.

Figure 2. The heat exchanger designed: water and sand as media cooling.

Results and Discussion

The temperature parameter was adjusted at 38°C; it means the motor will turn on when the roof temperature reaches 38°C and water will be sprayed. Measurements were carried out in the period of July and October. For the day, the average indoor temperature is lower than the outside temperature. The roof surface temperatures get down to go drastically up at 09:00 and fluctuate until 13:00, and the temperature can shoot from 50 to 56°C. The phenomena caused by the proprieties of metal like zinc: it is easier and faster to absorb and emit the heat. After 15:00, the internal temperatures go down less than the outer ones. The roof surface has always maintained less than 38°C, and given effectively benefits for the daytime. It caused the indoor air temperature is lower than the exterior during the day. In fact, an automatic spraying water onto the roof surface can significantly cut the roof surface temperature, even go down to 14°C.

The next step is investigating the performance of heat exchanger using either water or sand as a cooling medium to reduce the temperature of the water to be reused after spraying the roof surface. Measurements performed at the time the water out of the gutter and into the copper pipe in the heat exchanger, it is called a water-in; while the term of water-out is water that has passed through a heat exchanger, which will be forwarded to the water tank. An expected process occurs in the heat exchanger is cooling the water after the cooling process by spraying the roof surface.

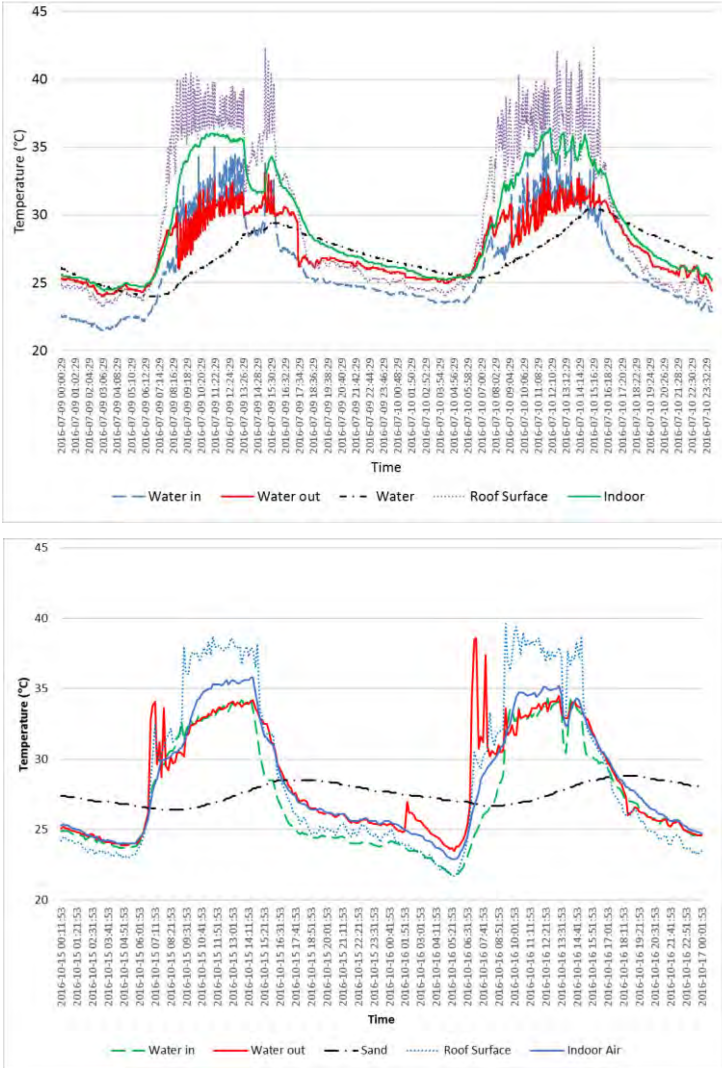

Figure 3. The performance of heat exchanger designed: water and sand as a cooling medium.

Figure 3 shows the state of the water temperature when entering and exit to and from the heat exchanger compared to water or sand temperature in the box of a heat exchanger, the roof surface and indoor temperatures. The roof cooling occurred effectively at 8 am to 3 pm, where the spraying of water occurs not continuously depend on whether they have passed the temperature threshold set or not; the process of cooling water by a heat exchanger also depends on the presence or absence of spraying occurs, thus curves for water-in and -out should not be continuous.

Comparison of water and sand temperature as the cooling medium in the heat exchanger indicates that the water temperature reaches a minimum at 25°C at 06:00 and a maximum of around 30°C at 15:00. While the sand temperature reaches a minimum value at 26°C at 08:00 and a maximum of around 28°C at 17:00. Both characteristics of the two materials, thereby resulting in an average performance are almost similar in the cooling water sprays; but the performance of cooling by water is more optimal occurs at 08:00 to 11:00 compared with the performance by the sand. Performance of cooling by sand more optimal occurs at 11:00 and so on, as presented in figure 4. This phenomenon is also reinforced by comparing the indoor air temperature between the cooling by water and by sand as illustrated in figure 3. The decreasing of roof temperature, on average, it is more effectively occurred in the cooling by sand.

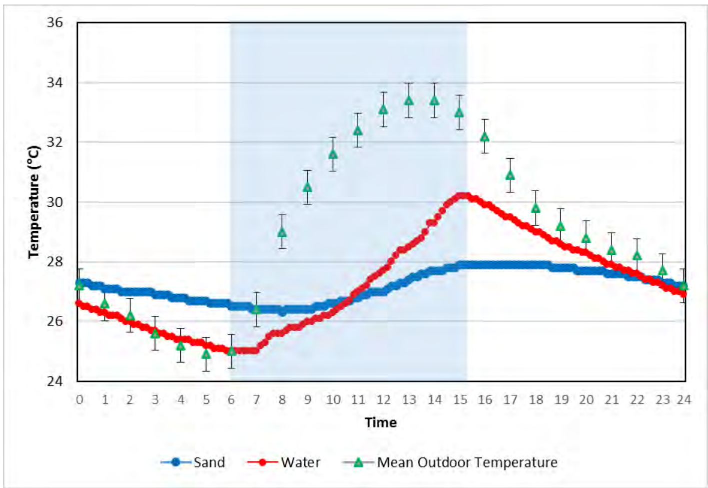

Figure 4. Sand and Water temperatures as water cooler of heat exchanger vs mean outdoor temperature

For more details, we sort out suitable data as in figure 5, it demonstrates the comparing of the temperature of the water-in and -out from a heat exchanger; the difference between them amounted to an average of 0.8°C for cooling by water and sand. This condition explains that the heat exchanger using either water or sand as medium cooling works well to lessen the temperature of the incoming water after being sprayed on the surface of the roof.

It shows as well the ability of the heat exchanger using water as cooling medium to cool the incoming water is more effective at the time of the morning from 8:00 to 11:00, while using sand as cooling medium more effective occur from 11:00 to 15:00. The average reduction in temperature between the water in and out of 0.83 with a standard deviation of 1.2. If the cooling medium in the heat exchanger was replaced with sand, it will be found an average reduction in water temperature is almost the same as that before the 0.81 with SD 0.89. The tendency of cooling is effective in the morning until noon.

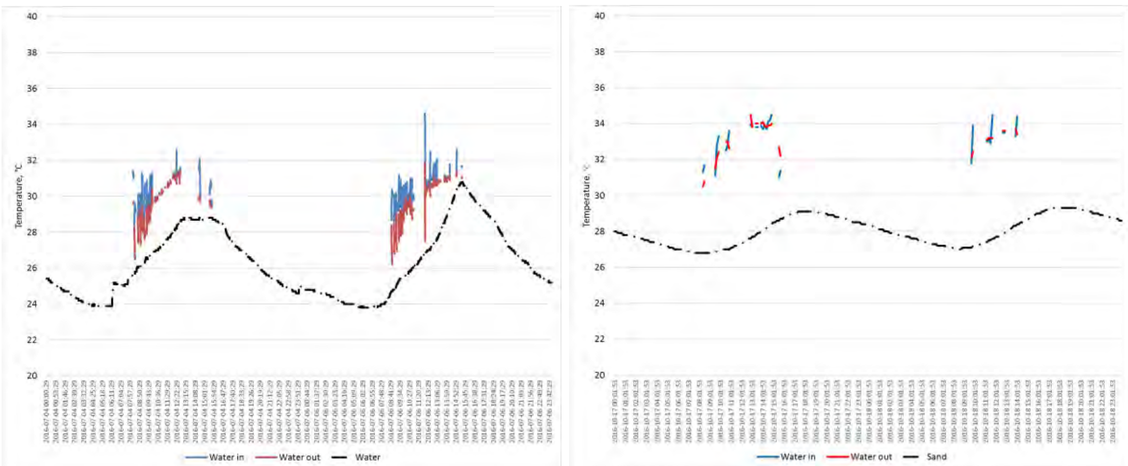

Figure 5. Roof surface, indoor and water-in and -out temperatures.

We assume the thickness of copper pipe is very thin. It signifies that the temperatures inside the copper pipe are the same with the outside and they are equal to the temperature of water. Based on the average temperature of 0.8° C and the effective length of copper pipe of 6.5 m, the mass flow rate and the rate of heat flow can be calculated by the forced convection in tube principles. The estimated values of them approximately are 1.106 kg/h and 515 Watts respectively.

Conclusion

Comparison of the performance of the heat exchanger using either water or sand has been carried out. Heat exchangers are used to cool water that has been sprayed onto the roof surface in the test cell using the automatic water spraying device. This device can work well to run water pump to spray the surface of the roof when it reaches 38°C or more. The water spraying onto the roof surface uses significant amounts of water, for that the attempts to reuse the sprayed water is the focus of this paper. Spray water flowed into the heat exchanger where the cooling medium using water or sand, their cooling performance was measured and compared.

The role of heat exchangers can lower the temperature of the water from spraying the surface of the ceiling, which has become a hot, down an average of 0.8° C using either water or sand. The ability of the heat exchanger using water as cooling medium to cool the incoming water is more effective in the morning, while using sand as cooling medium more effective occur at noon and afternoon. This exemplifies the benefits derived when using either water or sand as a heat exchanger as the cooling medium. The further work is to investigate from a mathematical model of the performance of the heat exchanger when comparing the different cooling medium. This design can be employed as a means to lower the temperature within the edifice in a humid tropical climate.

The Influence of façade design on the optimum window to wall ratio and overheating rate in UK Passivhaus dwellings for current and future climates: A Parametric Design Method

Yahya Lavafpour and Steve Sharples

School of Architecture, University of Liverpool, Liverpool L69 7ZN, United Kingdom

Abstract: Many researches of overheating in buildings have focused on the optimisation of the window to wall ratio (WWR). However, the physical form of the building envelope has not been widely considered as a factor in optimisation investigations. This study examines if the optimum WWR might vary in response to slight geometrical changes to a façade's design. An evolutionary parametric design method was used to generate a range of inverted pyramidal shaped envelopes with different inclination angles for each façade. This was implemented for an existing UK Passivhaus. The WWR was set as the main variable along with a sub variable of different weather data (both current and future climate scenarios). This paper, in particular, focused on minimising the overheating during the summer while reducing the primary energy use of the building. These two parameters were set as the objectives to be optimised using the parametric tool in the dynamic thermal simulation software DesignBuilder. The calculation used batches of Energy Plus simulations using a genetic algorithm. The results showed that the optimised WWR varied significantly when implementing different façade arrangements. Optimum self-shading shapes could allow more glazing to be used while still achieving thermal comfort in summer climate.

Keywords: overheating, WWR, self-shading, warming summer

Introduction

In the mid-20th century the core principle of modernist architecture was that the shape of a building should be primarily based on its function – hence the phrase *"Form Follows Function"*, which was coined by the American architect Louis Sullivan. At that time, a building's intended use and its function were the most important criteria in designing the form of a building. The integration of the form and its relationship to a building's energy consumption means that the whole issue of a building's use needs to be considered differently in a sustainable context (Cody, 2006). A new architectural language introduced by Cody (2010) emphasised that the design of the building envelope was one of the key drivers for achieving energy efficiency in the built environment ('*Form Follows Energy*'). He argued how energy will become a new design parameter for future architecture. Research has demonstrated that buildings with different external envelope areas but similar internal floor areas can have different energy demands (Zerefosa, et al., 2012; Capeluto, 2003; Loonen, et al., 2013). Zerefosa et al, (2012) believed that the energy consumption of two buildings with the same materiality, volume, wall area, openings and operating programmes, displayed difference only due to the shape of their external envelopes. They examined the energy behaviour of a case study in Athens with polygonal and prismatic envelope shapes. The research pointed out that the prismatic formed building had lower solar gain compared to its orthogonal counterpart and consumed less energy in an annual cycle. (Gupta & Gregg, 2012; Laouadi, 2010) showed that shadings was the most effective single intervention for reducing overheating in homes for the future UK warming climate. Monitoring results from the Camden Passivhaus in London showed that summer overheating occurred between 15.00-19.00, with the maximum at 17.00 (Ridley, et al., 2013), suggesting that the overheating happened perhaps due to unnecessary solar gain.

Large south facing windows are common in Passivhaus designs as they provide free solar heating and daylight utilisation. Research has underlined that the optimum window to wall ratio (WWR) is around 25% for the Passivhaus standard. However, some Passivhaus buildings employ up to 60% south facing WWR (SF-WWR). This has raised the concern that the large areas of glazing would lead to increased discomfort hours under UK future climates, especially in London. By contrast, other façades have a very small percentage of windows, and there often is no windows on east or west Passivhaus elevations. Although this will alleviate unwanted solar gain, it will also potentially reduce cross ventilation, daylighting and view. Many researches have focused on the optimisation of WWR, while the form of the building envelope has not been included in the optimisation process. This study aims to investigate if the optimum WWR would vary as a result of slight amendments to the geometry of a façade's design. In particular, this study examined the concept of self-shading geometries.

Building shape and solar exposure

The greatest source of internal heat gain is usually from solar radiation, which enters the building directly through windows. In addition to various commonly used shading approaches, inclined facades have also been implemented to create a self-shadow on the building's glazing and envelope. The incidence angle between the direct solar beam and the building's surface changes as a result of changing the orientation of the building or the inclination of a façade, resulting in different values of solar gain. With no obstacle and shading factor, solar heat gains ($\Phi_{\mathrm{sol}}^{check}$) on a flat surface with a given tilt angle and orientation can be calculated using Equation 1:

$$\Phi_{sol}^{check} = \bar{\alpha}_s AT[I_d \rho(1 - cos \sum) + I_d(1 + cos \sum) + \frac{1}{\pi} I_b(cos \sum cos\, L^s + cos\, \psi\, sin \sum cos\, L^s + \sqrt{Sin^2 \psi Sin^2 \sum + (cos \sum cos\, L^s + cos\, \psi\, sin \sum cos\, L^s)^2})]$$

Equation 1

where A (m^2) is the area of the flat surface, $\mathrm{I_b}$ and $\mathrm{I_d}$ are the direct and diffuse solar irradiation (W/m^2) respectively, $\sum$ is the tilt angle of the surface, ψ is the orientation angle, ρ is the reflection coefficient from the ground, and $\mathrm{L^s}$ is the equivalent latitude, which depends on the specific month. This study used a computer-modelling tool, which makes it relatively straightforward to calculate and evaluate large numbers of design alternatives for solar gain.

Thermal discomfort

In the UK there is no universally agreed overheating criterion for residential building. This is perhaps because in the UK the retention of heating has been the main focus of thermal design and so overheating has not historically been a concern (Lomas & Porritt, 2017). The Housing Health and Safety Rating System from the Housing Act 2004 (Health and Safety Rating System , 2006) stated, "*a healthy indoor temperature is around 21°C. As temperatures rise, thermal stress increases, initially triggering the body's defence mechanisms such as sweating. High temperatures can increase cardiovascular strain and trauma, and where temperatures exceed*

25°C, mortality increases and there is an increase in strokes. Dehydration is a problem primarily for the elderly and the very young".

The Passivhaus standard requires that indoor air temperatures should not exceed 10% of occupied hours above 25°C for living spaces. CIBSE TM36 (2005) set the 'warm' and 'hot' temperature thresholds of 25°C and 28°C for living rooms and 21°C and 25°C for bedrooms respectively. CIBSE Guide A (2007) said operative temperatures should not exceed 10% of occupied hours above 25°C for living spaces (both living room and bedrooms). Operative temperature also should not exceed 1% of occupied hours above 28 and 26°C for living rooms and bedrooms.

Methodology

To generate a proposed self-shading form a parametric design method was used to generate a range of reversed pyramidal shape envelopes with different tilts on each façade. The form generation was carried out using evolutionary parametric tools Grasshopper and Galapagos (Rhino Plug-ins) to create an extensive range of façade inclinations to achieve a desirable fitness. A simplified box building (9m long x 7m wide x 3m high) was created as a base case for an initial pilot study. Eight points were formulated to create this box in different X, Y, and Z axes. The four points that created the base were kept fixed throughout the parametrisation analysis. The other four points (Figure 1), which were located at 3m high in the Z direction, were created using the number slider to manipulate the points parametrically. Each façade was divided into grids and the sum of the solar radiation received by each grid was calculated.

The Galapagos evolutionary computing tool was used to find the best fitness to minimise the solar radiation from 1 June to 30 August while choosing the optimised forms that received the higher solar radiation between 1 October and 30 March. Data analysis derived from the pilot study hypothesised inclination angles of 115° and 122° to be an effective shading intervention for the south and west walls respectively. The east-facing wall had a more complex shape, where the inclination angle for point D was steeper (117°) than for point B (103°). For the north facade the wall leant inward slightly at 87°. This geometry was then implemented in to the case study.

Implication to an existing Passivhaus case study

According to the Passivhaus Institute, the frequency of overheating increases sharply with a WWR of more than 20%. However, larger windows are often recommended (Schneider, 2006). The study used the design of an actual Passivhaus built by bere:architects called Larch House (Figure 2), which employed a SF-WWR of 55% (Bere, 2014). This house was modelled using the advanced dynamic simulation software DesignBuilder. Selected tilted walls from the pilot unit replaced the original vertical walls of the Larch House case study. Dynamic thermal simulations were used to examine the impact of these inclinations for the Passivhaus dwelling to make use of the self-shading that this form created. A sensitivity analysis of internal temperatures and thermal comfort conditions in the dwelling as a function of building facade inclination and prevailing climatic conditions was undertaken. The simulations were calculated for the living room and main bedroom. Windows assigned to the living room and the main bedroom on relevant facades were subject to the parametric analysis of WWR. This paper focused on minimising the thermal discomfort overheating during the summer while reducing the primary energy use of the building. These two parameters were set as the main objectives to see if the optimum WWR would vary by manipulating the façade geometry. The Optimisation Tool in DesignBuilder v5 was used to identify the optimum combination.

Figure 2. Existing Larch House (bere:architects) and 3D model of the case study and modified geometry.

Weather data

This study used probabilistic climate change scenarios from the UK Climate Change Projections to determine the overheating risk in an existing Passivhaus dwelling under a high emission 50-percentile scenario in London. The PROMETHEUS team (Eames, et al., 2011) have developed future weather files in EnergyPlus format (.epw) using a UKCP09 weather generator. These hourly weather data files are available under low, medium and high emission scenarios with different percentile probabilities for both Test Reference Year (TRY) and Design Summer Year (DSY) weather data. They are available for three future intervals i.e. 2030's, 2050's and 2080's. DSY tend to give warmer summer days while TRY is more representative of the whole year. For the modelling in this study a high emission 50 percentile probability (A1F1 50%) was chosen. Since this study considered a whole year's energy performance it was felt that the Test Reference Year (TRY) data would be more representative of the year. London (Islington) weather files were used in the simulations as London is projected to experience the greatest temperature rise due to climate change and the impacts of the urban heat island (GLA, 2006).

Overheating criteria

There are two ways of assessing summertime thermal comfort – static and adaptive. This paper used CIBSE guide A (2007) static criteria, defined as overheating when indoor living spaces hit the 'warm' benchmark of 25°C for more than 10% of the occupied time and exceeds the 'hot' threshold of 28°C in the living room and 26°C in the bedroom for more than 1% of the annual occupied hours. Assessing thermal comfort based on the static criteria allows a focus on one specific parameter i.e. in this case the geometrical implication of the house. However, in reality, individuals will also adapt their behaviour to changing temperatures.

Results and Discussion

Table 1 shows a breakdown of the simulations, indicating the total hours that operative temperatures exceeded the static CIBSE Guide A threshold. This study used a generic UK household occupancy schedule. The bedroom was occupied (with different fractions) from 22.00 to 08.00 weekdays and from 23.00 to 09.00 at weekends. The living room was occupied from 17.00 to 23.00 weekdays and 09.00 to 23.00 weekends. In the current London climate, a similar house to the Larch House case study would experience warm indoor temperature (Lavafpour and Sharples, 2015). Considering the 55% WWR, the house with the original form in London current climate experienced 35% of the occupied hours equal or over 25°C ($h_{\vartheta} \geq 25$°C) in the living room, and 30% in the bedroom. Overheating in the living room was reduced to 12% using the optimised self-shading geometry. Tilting the façade on the south elevation, and the prismatic shape of the east façade, eliminated the 28°C/26°C overheating threshold but slightly exceeded the 25°C threshold limit. However, by reducing 5% of the WWR (i.e. down to 50%) the proposed geometry eliminated overheating in both rooms. Because of changing the façade angle, the average operative temperature dropped for both summer and winter periods. There was a slight increase in heating load for the optimum shape, which is greater in the current climate. Despite this increase, heating demand always remained within the Passivhaus limitation of 15 kWh/m^2 while assuring the minimum indoor temperature of 20°C.

The optimum shape building with 55% of glazing has almost the same Indoor operative temperature as the original shape with 25% WWR. The overheating percentage for the future climate also had a similar trend. A larger WWR on the optimum shape had an equal overheating risk than the original building shape with smaller WWR (Figure 3). The gap between the curves indicating overheating rate for different façade forms grows when the WWR exceeded 35% (Figure 4). The impact of the self-shading geometry is more apparent in the future weather scenarios. It can be seen that the original shape with more than 35% glazing area will experience a high risk of overheating even in the current climate. The optimum shape with 40%WWR had an acceptable overheating rate until 2050s weather projections; however, the proposed geometry could not eliminate overheating.

Table 1. Impact of form on WWR and the annual warm threshold hours for London current and future weather

WWR		Current		2030s		2050s		2080s

Conclusion and future work

Optimal form of a building can significantly reduce direct solar gain without reducing the total solar heat gain needed for mild and cold regions, in particular for buildings with large glazing areas. The results from this study showed that the WWR varied significantly when implementing different façade arrangements. Self-shading facades allowed a greater window to wall ratio on the south and east facades and a steeper inclined wall for the west façade of the case study house, which originally did not have any windows, allowed for a small area of windows and potentially could increase cross ventilation cooling during the summer. The study was not trying to generate a complete optimal building form and cannot define finite performance criteria. However, the extent of a small design changes can be estimated using the result of the paper.

The shape of the external building envelope will also affect the daylight and airflow patterns. Future work will investigate the consequences that the proposed geometry may have on natural ventilation and daylighting.

Thermal mass analysis of geometrically modified concrete ceiling using computational fluid dynamics

Daniel Sang-Hoon Lee[1]

[1] High-Performance Simulation Laboratory, Institute of Architecture and Technology, School of Architecture, The Royal Danish Academy of Fine Arts, Schools of Architecture, Design and Conservation, Daniel.Lee@kadk.dk;

Abstract: Often thermal mass applications of concrete floor/ceiling for indoor comfort have seen active developments around load shifting control strategies, in conjunction with direct/indirect thermal storage systems using hollow core concrete slabs. The main agenda was to increase the temperature difference between the cooled ceiling and the surrounding air for greater energy absorption by the thermal mass. In addition, there are recent developments in application of phase change materials (PCM), for increasing specific heat capacity of concrete. Meanwhile, a different direction of investigation can develop towards searching for geometrical forms of exposed ceiling, which may enhance the airflow for more efficient heat transfer between the air and the ceiling.
At centre of the current research is geometrical design of structural elements, which will guide the indoor airflow to increase the heat transfer efficiency. Thus the research addresses not only the heat transfer related design parameters, which include convective heat transfer coefficients, total surface area in contact as well as the temperature difference between the materials, but also the characteristics of indoor airflow. There, in application of computational fluid dynamics (CFD), the efficiencies of heat exchange through the concrete ceiling with specific geometrical profiles have been examined.
The current investigation adopted the authors' office space as a basic study model; however, the model includes more generalised space layouts including the furniture. The environmental scene was set to a peak summer day in Copenhagen, Denmark. The CFD simulations compare between more conventional flat, arched and ribbed ceilings and the comparison of the results between the ceilings were made based on the resultant indoor temperatures.

Introduction

Energy efficiency of buildings are often measured in respect of the consumed embodied energy. Embodied energy in building analysis can be commonly discussed in two parts. Firstly, it is the initial embodied energy, which is related to the calculated energy consumption for the actual construction of the building. Secondly, it is the operational embodied energy, which refers to the energy consumption for the building's service period for heating, cooling, ventilation etc. In response to the global agenda to reduce the amount of carbon emission in construction industry, researchers have investigated to reduce embodied energy in both initial and operational parts.

The increasing number of researchers in structural and construction engineering fields have been investigating to optimise building structures for reduced initial embodied energy.

The optimisations are commonly achieved through innovations in high-strength low-density materials and the structural forms with the aim to design and construction of structures with the least amount material with extended life span and minimised maintenance. In regard of the operational embodied energy, there have seen active developments with the goal to reduce the level of energy consumption for the operation of mechanical building services, and for more increased use of passive systems in innovative applications of renewable resources. However, the above expertise can be developed for more synergetic research, where the design and construction methods of building structures are further investigated for possible reductions in both the initial and operational embodied energy.

The global research interests in thermal mass applications for energy efficient building design have seen steady growth. The research in thermal mass applications have been very appealing to the global researchers, for the investigations develop the ways to utilise the built structures, which have the initial purpose to resist the loads, for energy storage that can also release back the stored energy when required. Based on the material's thermal mass characteristics and for the wide applications, there have been active research for concrete thermal mass. The main areas of research include the development of efficient night ventilation and load shifting control strategy (Blondeau, et al., 1997) (Kolokotroni & Aronis, 1999) (Braun, 2003) (Yang & Li, 2008) (Sun, et al., 2013), and direct and indirect thermal storage system with exposed soffit and hollow core airflow respectively (Barton, et al., 2002) (Barnard, 2006) (Corganti & Kindinis, 2007). However, most of the research have been in the realm of incorporating the existing structural systems and develop either more passive ventilation strategies or mechanical systems; with the aim to reduce the starting temperature of the building structure and elements in the beginning of the daily thermal loading cycle.

In addition to the above, there have been interests of how geometrical forms of building elements affect the indoor environments. For indoor thermal comfort, it is considered that the geometrical configurations of structural and non-structural exposed elements of indoor space would affect the thermal conditions through their effects on indoor airflow and surface-to-surface radiative heat transfer. Therefore, the currently presented investigation was taken as a part of research, which explores the relationship between geometrical forms of building elements and resultant indoor thermal conditions. However, such research must be followed by in-depth understanding in the characteristic convective heat transfer behaviour based on slow indoor air movement and the radiative energy exchange. Therefore, the investigation was carried out based on computational fluid dynamics simulations, which would provide numerical data of three-dimensional indoor airflow and energy transfer.

3D Computational Model

There are first three models, which were constructed and analysed to examine the effect of three ceiling geometrical profiles on indoor temperature. The three profiles are 1) Flat ceiling, 2) Ribbed ceiling and 3) Arched ceiling. In the paper of Lee and Naboni (Lee & Naboni, 2017), it was mentioned that, despite the increased surface area of the ribbed ceiling, the hindrance to the air movement caused inefficient heat exchange between the air and the ceiling. Thus, in the current investigation it is proposed to make a comparison study between geometrical ceiling in other conventional forms such as flat and arched ceiling. The simulation models are constructed based on the actual meeting area (Figure 1&2) in the Institute of Architecture and Technology, School of Architecture in Copenhagen.

Figure 1. the meeting area at the Institute of Architecture and Technology which is used for the simulation.

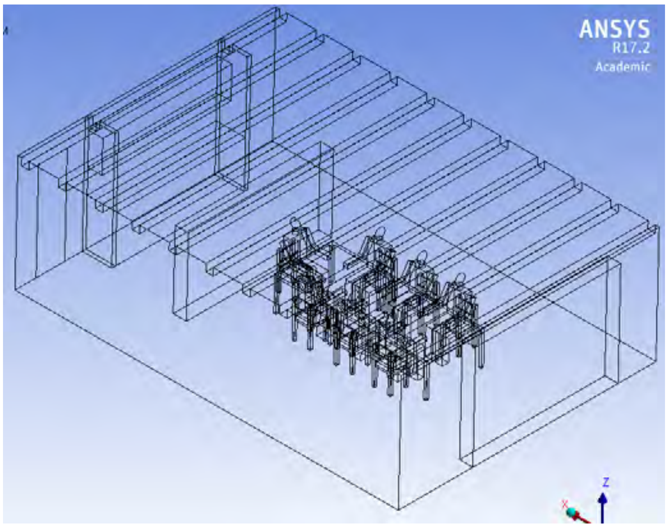

Figure 2. ANSYS Fluent 17.2 Simulation model (Ribbed ceiling) constructed based on the meeting area.

CFD Simulation Model and Set-up

The computational models were imported and meshed inside ANSYS. The furniture, partition walls and mannequins were modelled as individual volumes, which are placed inside an air domain, and all the elements were conformal meshed.

The assigned material properties of each volumetric units are defined in Table 1. It is to note that the material definitions for mannequin are actually ineffective for the simulations, as the boundary conditions were applied on the outer walls of the mannequin volumes. The material is created simply to give material definitions to the mannequins. All the volumetric elements were meshed with tetrahedron elements, which range from 2.0 to 4.0 cm in the sizes. In result, there are minimum 18.3 million finite elements for each simulation model.

Table 1. Material Definition

	Density (kg/m3)	Specific Heat (j/kg-k)	Thermal Conductivity (w/m-k)	Viscosity (kg/m-s)
Air	1.225	1006.43	0.0242	1.7894e-5
Wood (Furniture)	18	2310	0.173	-
Gypsum (Wall)	2320	1138	0.5	-
Concrete	2400	880	0.7	-
Mannequin (Human)	1062	3470	0.209	-

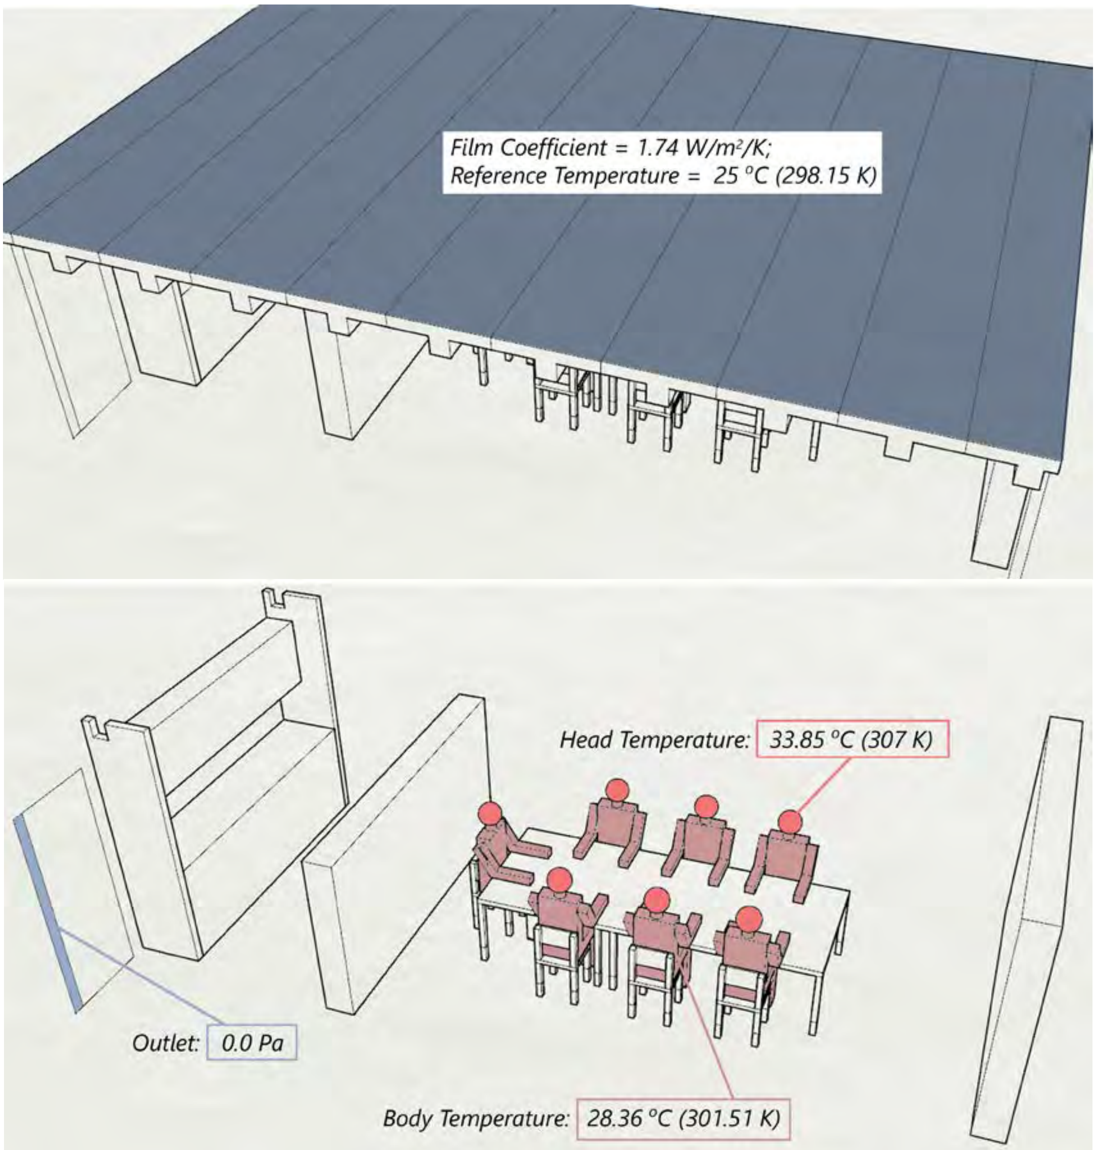

Figure 3. Assigned boundary conditions

The assigned boundary conditions for the simulations are described in Figure 3. The head and body temperatures of the mannequins are based on the measured mean temperature with summer clothing (Lee, et al., 2016). The heat transfer coefficient value was extracted from CIBSE Guide A; the transmittance U-value based on the construction description of 'vinyl floor covering, 50 mm screed 150 mm cast concrete'.

The steady state, pressure-based incompressible fluid CFD simulations were ran in ANASYS Fluent 17.2. The simulations adopted realisable k-ε turbulence model, and the energy transferred by radiation was considered using Surface-to-Surface (S2S) radiation model. All the simulations were ran equally for 500 iterations.

Results

The main interest in the current study is on whether different geometrical profiles for a fixed volume could give different indoor room temperature. Thus, the temperature data are extracted from results and compared between the cases of three ceiling profiles. The data extraction locations are described in Figure 4, and the average temperatures along the x-locations/m are plotted and compared for the three ceiling profiles in Figure 5.

As it can be seen from Figure 5, there is a clear pattern of the indoor temperature increasing when the ceiling geometrical profile varied from Flat to Ribbed. Please note that the high peak temperatures around 4.8 m location is for the data extraction points coincide with the mannequin's location. This result is in contrast with the statements by Lee and Naboni (Lee & Naboni, 2017), however, there could be a number of discussions around such contrast. As it can be seen in Figure 6, the ribbed ceiling has higher temperature distribution in comparison with the flat ceiling, and as described by Lee and Naboni (Lee & Naboni, 2017), the ribbed ceiling has higher efficiency of taking in the heat. However, the ribbed ceiling does not necessarily lose the heat more effectively than the flat ceiling, as the upper geometrical condition is the same. Thus, the stored heat remains in the ceiling and prevents any indoor heat to enter the concrete thermal mass. In result, as the current investigation is based on steady state solver, the indoor temperature rises until the system reached pre-defined energy balanced state, which gives higher indoor temperature than the case of flat ceiling. It would be more relevant to simulate based on transient solver, however, it would be greatly computer intensive to run for the current models with significantly large number of finite elements.

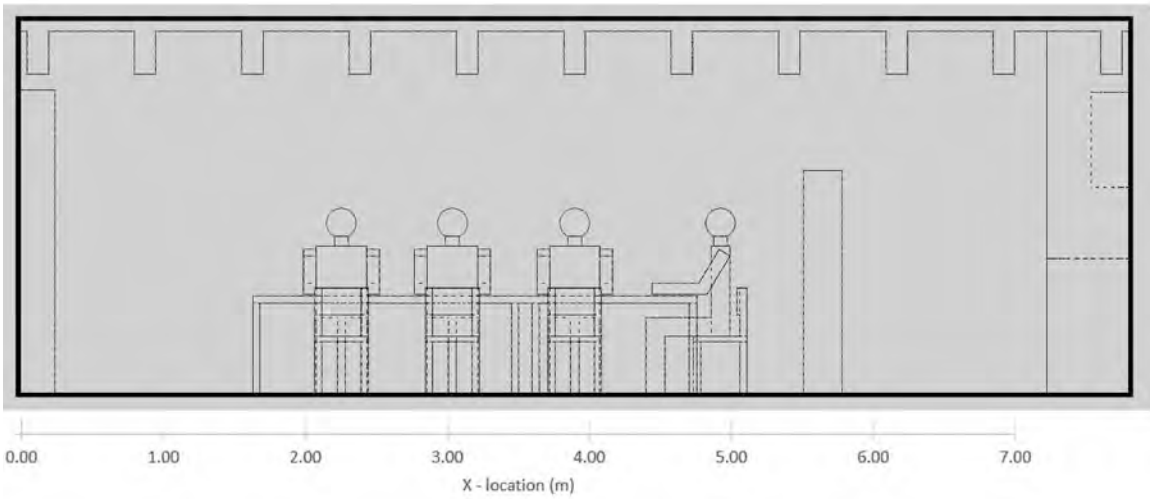

Figure 4. X-location for data extractions.

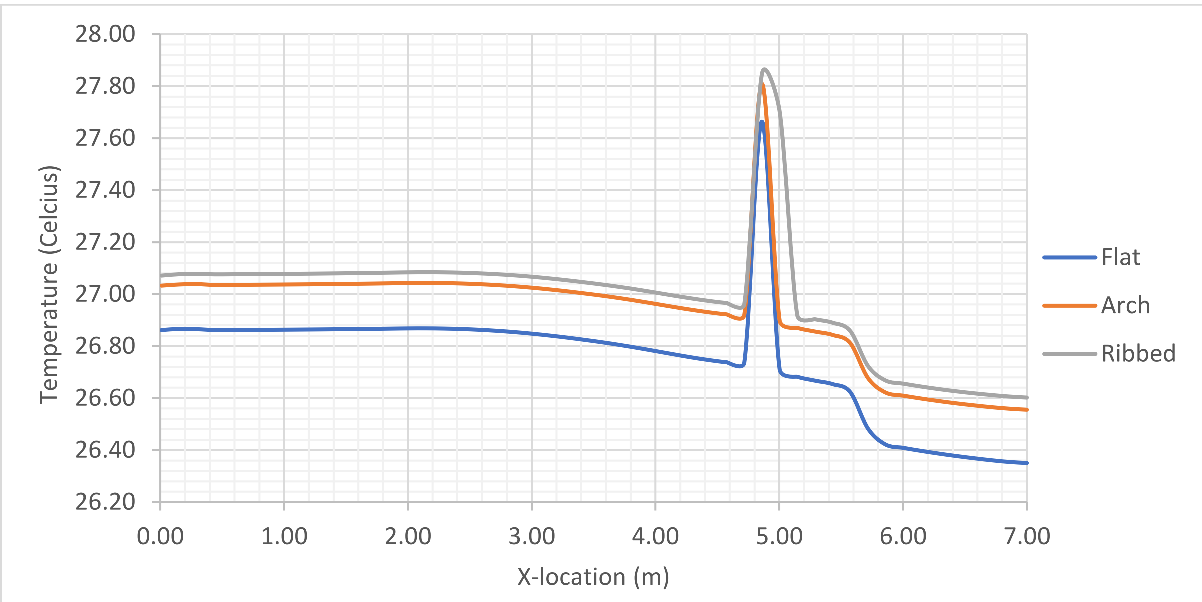

Figure 5. Comparison of average Indoor temperature for three ceiling geometrical types.

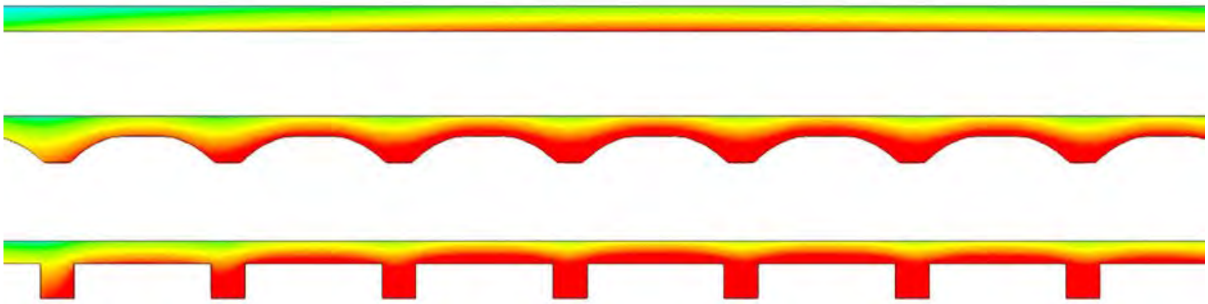

Figure 6. Comparison of temperature distribution inside Flat (Top), Arch (Middle) and Ribbed (Bottom) ceiling

Conclusions and Discussions

The current paper presented an investigation, which explored the relationship between the geometrical profiles of the exposed soffit and the ambient temperature. The investigation was carried out based on the numerical method using CFD, which was developed based on the site-specific context.

The simulation results showed that, based on steady state simulation the ribbed ceiling geometry resulted in highest indoor temperature. The mainly discussed reason for such result was that, the greater heat absorption efficiency of ribbed ceiling increased the overall ceiling temperature to higher level. This seems prevented further absorption of indoor heat, causing the indoor air temperature to rise. Thus, in order to design a concrete ceiling for efficient thermal mass performance, the geometrical optimisation must consider for both heat absorption and heat dissipation characteristics. Another obvious option would be to add more mass to the ceiling, for example, by increasing the depth of the web of ribbed ceiling.

In respect of the actual magnitude of the temperature rise, the impact of ceiling's geometry seems to have relatively minimal impact on the indoor temperature; even when the total mass of the arched and ribbed ceilings has increased in comparison with the flat ceiling. It is thought that such result is for the physical scale of the difference of three ceiling profiles are minimal in scale of the indoor space. It would be an interesting investigation to explore the effective scale of building elements, which would start to have significant influence on the indoor thermal environment. In addition, the possible transient simulation might provide better and more specific time-lapsed results.

Abstract: The use of natural ventilation is an excellent strategy for achieving passive cooling in buildings, especially in hot and humid climate areas like in Southern Texas. The architect James Riely Gordon (1863-1937), after ten years of architecture practice, originated specific typologies of plans, extremely innovative in court house architecture to respond to South Texas climate, reinterpreting the period's attention in mechanical systems' innovations for ventilation and cooling and heating. Gordon designed seventeen courthouses in Texas, twelve of which are still existing and functioning at this time. From analysis of his work, we can identify a typological metamorphosis in the design development of courthouses, which evolved over time to become more technologically sophisticated and climatically efficient. This study investigates the design and construction features and climatic response strategies of these types of court houses, identifying the step by step evolution process in the development of these typologies, and specifically examines and assesses their natural ventilation effects. This step by step process developed by the architect for creating the best typological system intends to suit, simultaneously, style, function, technological innovations and mostly, environmental thermal comfort. These systems, now no longer in operation due to the adoption of mechanical ventilation systems, are rediscovered and reinterpreted as core elements of sustainable architecture, and could form valuable lessons for the contemporary sustainable design in hot humid climates.

Keywords: natural ventilation, hot-humid climate, Texas courthouses, signature plans, sustainable design

Introduction

Interest in passive design for either heating or cooling has re-emerged as a part of a movement towards sustainable architecture. Applying passive cooling means utilizing natural forces and design characteristics to achieve indoor thermal comfort, improve indoor air quality and make the building a better environment to live or work in.

This study shows how a climate-responsive approach, together with an interest on technological advancement, was one of the main foci in 19th century American architecture movement, as indicated by some architectural journals of that time. The architect James Riley Gordon (1863 -1937) in the design of Texas courthouses strongly contributes to the architectural debates of his time, when much effort and thought were devoted to the 'quest' an American style (Meister, 2011), associated to the adoption of modern technical and typological innovations, to create climate-responsive buildings. This paper also demonstrates, through the use pf performance simulation, how Gordon's courthouses can be considered effective climate-responsive structures, where comfort zone temperature is achieved during hottest periods of the year with the adoption of passive cooling strategies only.

James Riely Gordon (1863-1937) was San Antonio's most acclaimed architect during the final decade of the nineteenth century, despite his lack of formal education. The first major break in Gordon's career occurred in 1886, at the age of 23, when he was selected to supervise the construction of San Antonio's new federal courthouse and post office. Although his job description focused on project management and did not include design input, this project may have been the incubator for Gordon's interest to developing a courthouse design which effectively addressed the oppressive Texas heat by maximizing natural ventilation. Gordon brazenly suggested alterations to the building's orientation and room layout to the Supervising Architect of the United States Treasury, intending to make the building more responsive to the local climate, in particular to take advantage of San Antonio's prevailing south-easterly winds. The federal courthouse experience may also have cemented Gordon's affinity for the Richardsonian Romanesque style of architecture. Romanesque, with its fortress-like appearance of permanency, was a popular choice for civic architecture during the nineteenth-century's age of eclecticism. Gordon associates this architectural style to modern technical and typological innovations, as ventilation systems which inform the buildings' layout. Gordon was awarded his first courthouse commission in 1889, eight years after a legislative act allowing counties to finance their courthouses through bonds and taxes launched a building boom in county courthouse construction throughout Texas. Although the prolific architect's oeuvre includes extensive work in residential, commercial, and religious buildings, as well as the Texas Building at Chicago's Columbian Exposition, Gordon is best known as an architect of courthouses. In a note which appears to have been written around 1930, Gordon claims to have "nearly seventy successful court houses to my credit" (Gordon, ca. 1890-1937).

Technology versus Typology: Heating and cooling systems in the second half of 19th century and the development of climate-responsive typologies

Heating and cooling systems in the second half of nineteenth century: the debate in architectural journals

The mid-19th century witnessed the implementation of studies and experimentations on air circulation and climatic control in indoor environments, in both public and private buildings. Such studies, initially developed in England (Richardson, 1837; Ritchie, 1862) found fertile ground for both scientific and entrepreneurial interests in United States, especially in those areas of the country where the climate affects the quality of life.

In winter 1866-87 engineer Lewis W. Leeds gave various lectures on ventilation at the Franklin Institute of Philadelphia (Leeds, 1868). In these lectures, like in his treatise published in 1871, the main focus was on hospital buildings, Leeds presented his studies also on public and residential buildings. In his treatise, an article on the Municipal Hall of Pittsburgh, Pennsylvania was republished, previously published in March 1869 in the Philadelphia monthly journal «The Architectural Review and American Builders' Journal». (Leeds, 1871) The journal was at that time directed by the architect Samuel Sloan (1815-1884), who had hired Leeds since 1868 as a Consulting Engineer of Ventilation and Heating, for a column named *Ventilation and Heating.*

Heating and ventilation studies shaping a building's plan layout found ample space in the journal directed by Sloane, whose objective was to educate and inform architects and professionals for forming an American identity in architecture, appropriating and surpassing European models (Ciranna, 2014). One of the main requirements was that these models had to adapt to different climatic needs and to the accelerated progress of technology.

James Riley Gordon's Texas courthouses: developing climate responsive typologies

In Gordon's technical correspondence, the architect specifically addresses the courthouse buildings' design challenges due to the Southern climate: "It is not difficult in the South to keep comfortably warm during the winter, but it is a monster problem to keep cool during the long hot summer" (Gordon, 1890-1937). He also describes behaviour and performances of ventilating shaft with tower, stating that 'acts upon the same principle as a fire place with good draft…. except this is larger', being able to 'draw thousands of cubic feet of air per minute', with the result of having "the most practical, simple, effective and inexpensive system of ventilation" (Gordon, 1890-1937, AAA).

In an affidavit the architect composed in 1895, Gordon also elucidates five distinct phases in the evolution of his climate-responsive approach to courthouse design (Meister, 2011). Gordon's first courthouse was built in Rockport, Texas (Aransas County, demolished). This masonry building featured a central ventilation shaft and tower. He then converted the shaft to an open court, complete with a fountain, for Fayette County. To this design Gordon added colonnades, taking advantage of large Roman arches for introducing breezes. The next chapter in Gordon's courthouse development was an anomaly, owing to the specific brief presented for Bexar County. The fifth phase of Gordon's courthouse represents what Meister calls the architect's "Signature Plan". (Meister, 2011)

Table 1. Steps characterizing the typological evolution of Gordon's Texas courthouses' design

	Plan layout	**Innovation/variation of the type**	**Location**	**Year**
1	Hollow plan	"ventilating shaft and tower combined in the center of the building of solid masonry,…. introducing colonnades.." (Gordon Affidavit, Meinster 2011)	Aransas County	1889
2	Hollow plan	"Open court in the center with fountain.... collonnades all around the side" (Gordon, *ibidem*)	Fayette County	1890
3	Hollow plan	Similar to Fayette, with "outside colonnades and changed the exterior of a plan" " (Gordon *ibidem*)	Victoria	1891
4	Hollow plan	Unification of " open court, tower and ventilating shaft and changed the exterior design" (Gordon *ibidem*)	Bexar County	1894
5	Signature plan	"arranging the stairway with two platforms between each story, in the combined tower, ventilating shaft and court, and arranged the entrance from corners, through colonades then into vestibules and a rotunda or colonade around the tower with a series of arches…."	Brazoria County Hopkins County Gonzales County San Patricio County Van Zandt County Ellis County Wise County Comal County Lee County Harrison County Callahan County	1894 1894 1894 1894 1894 1894 1895 1898 1898 1899 1900
6	Capitol Plan	Expansion of cruciform 'signature' plan	McLennan County	1900
7	Copiah Plan	Innovative plan to meet criteria of the Copiah County Courthouse building committee	Angelina County	1901

In Texas Gordon designed seventeen courthouses, twelve of which are still existing and functioning at this time. The typological metamorphosis in the design development of courthouses evolved over time to become more technologically sophisticated and climatically efficient. Table 1 shows the step by step evolution process of Gordon's Texas courthouse typologies.

In his patented cruciform plan ('signature plan'), Gordon incorporated the ventilating shaft with court, tower, and stairwell. In addition, Gordon placed entrances at each of the four corners, utilizing distinctive curved colonnades to capture the natural breezes. Historians and preservation scholars underline how this plan was devised to increase the building's ability to naturally regulate a comfortable environment (Juarez et al, 1996; Meister, 2011), as described by Salisbury: "as air strikes the building it gives off heat, forced through an opening it expands absorbing heat, and rising through a central atrium it gives off heat which then rises [and escapes] through the central tower".

Subsequent sections of this paper will use simulation tools to assess the effectiveness of some of these climate responsive buildings configurations focusing on the Fayette and Lee courthouses, which represent two main steps in Gordon's typology development process: the first featuring a hollow plan layout, and the second represents the 'signature plan' design of the last building Gordon designed in the Richardsonian Romanesque Style.

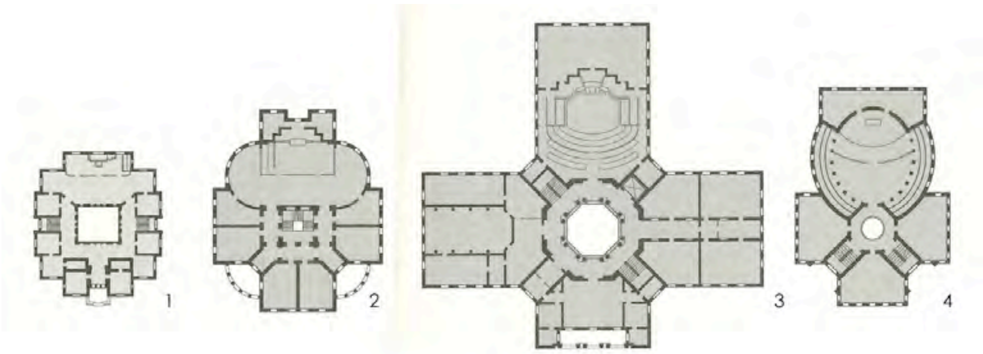

Figure 1. Overview of typological layouts adopted by James Riley Gordon: 1. Hollow plan; 2. Signature plan; 3. Capitol plan; 4. Copiah plan. (from Meister, 2011)

Figure 2 and 3. The Fayette courthouse, in La Grange, designed in 1890 and Lee County Courthouse, in the city of Giddings, designed in 1898

Climate responsive assessment in Fayette and Lee County Courthouses

Methodology

A qualitative assessment of air flows providing passive cooling effects is an essential tool for identifying the areas of the buildings most representative to study the performance of the structure in terms of passive cooling strategies. Following the preliminary qualitative analysis of the air flow patterns in the two buildings under analysis, this study utilizes CFD simulation as the main investigatory method. The CFD analysis utilized the software Design Builder. The modelling focused on the building core, where most ventilation flows took place. In order to compare the difference between the two buildings' performances in hot humid climate, San Antonio climate data was used as the bases for analysis in both situations. While there may be minor differences between the climates of the three cities: San Antonio, La Grange, and Giddings, all three fall in climate zone 2a of the international climate zone definitions, which is characterized by having between 6300 and 9000 CDD50◦F and an annual precipitation higher than 20" per year. This zone is typically dominated by cooling needs. The CFD simulations took into consideration both the incoming ventilation from the outdoor environment, based on the local climatic data, as well as air flow through indoor openings.

The Fayette Courthouse analysis and simulation

Building description: Gordon employed a hollow square floor plan, subdivided in five bays and characterized by a 30' x 30' spacious atrium or courtyard, with arrangement of offices and courtroom around it, with arched entrances located at the center of each side. Stairwells are located above these arched entrances starting from the second story. The load-bearing masonry walls for the exterior are made of four different types of native Texas stone.

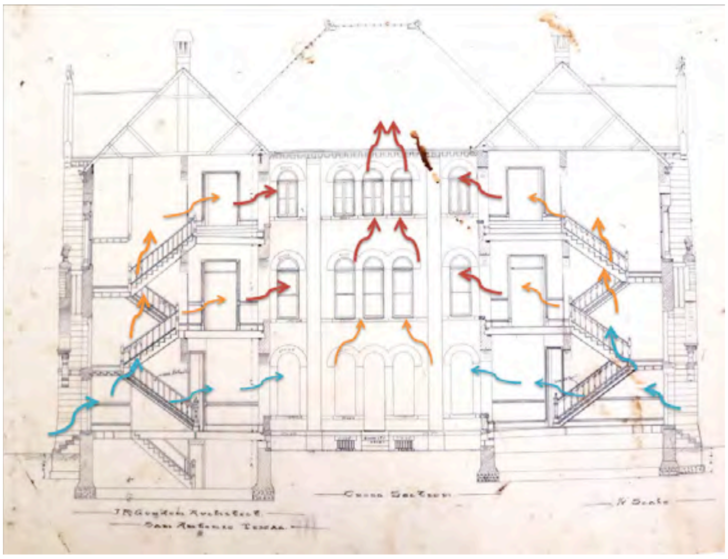

Figure 4: Section of the building showing air flows.
Blue: cool air; Orange: warm air; Red: Hot air

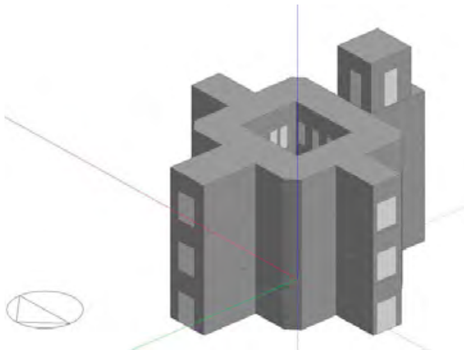

Figure 5 and 6: 3D modelling and axonometric section developed with software Design Builder

Air flow patterns: Air flow through the two stairwells from doors and windows located on the building's exterior facades, and, getting warmer, they rise through the vertical circulation spaces. Subsequently they are driven into the internal court, increasing convective air currents due to thermal gradients of air stratification and increasing the exhaust of warm air inside the circulation spaces which generates a pressure differential due to the vertical movement of warm air. The fountain, located by the architect in the center of the courtyard, has an important bioclimatic function as they can cool the air through evaporative cooling. The fountain therefore acts as air flow cooling point, contributing to improve comfort conditions in the spaces surrounding the courtyard. The CFD simulations conducted in this work do not take into account the presence of the fountain, therefore the below data may overestimate air temperature.

The Lee Courthouse analysis and simulation

Building description: The Lee County Courthouse, completed in 1899, is one of the last of Gordon's Texas Courthouses and is the last building he designed in the Richardsonian Romanesque Style. The building is an example of the architect's patented cruciform plan, 'ventilating shaft with tower', with integrated stairwell which serves the various building levels. It features rounded porticos between each wing of the building where entrances are located, bringing the visitor diagonally into a central stair hall, culminating in a clock tower, with openings on the four sides. (Henry, 1993).
Load bearing walls, with its high thermal mass, are made of red brick, contrasted, in the facade with white limestone trim.

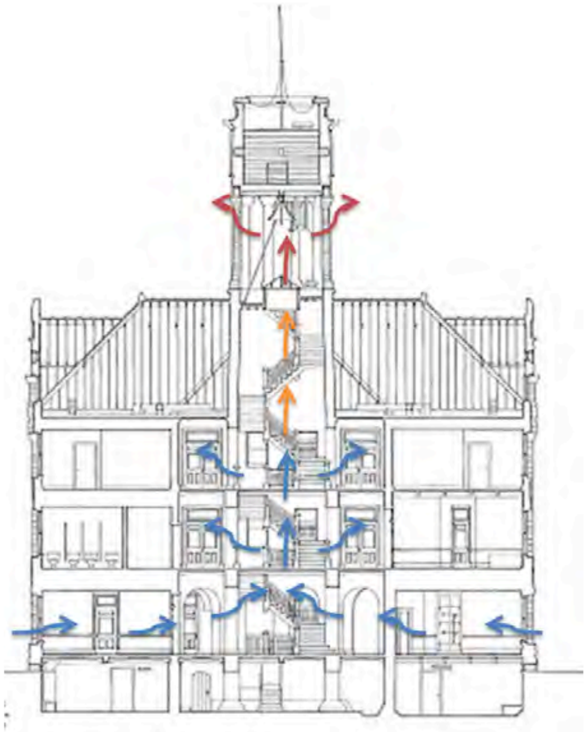

Figure 7: Building section with schematic air flows. Blue: cool air; Orange: warm air; Red: Hot air

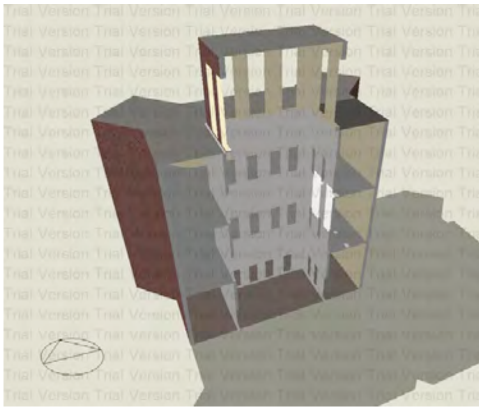

Figure 8: 3D axonometric section developed with software Design Builder

Air flows description: Air flows enter from the four entrances at the first floor, and it is channelled in the central ventilating shaft, increasing its temperature meanwhile rising. Airflows, in this way, are naturally expelled from the openings located on the top of the tower, which act as a ventilating chimney.

Simulation output

Table 2 shows average values of air temperature, radiant temperature and relative humidity obtained through the CFD simulation of both buildings. In case of the Fayette county courthouse, temperature data are high, while relative humidity is within the acceptable comfort parameters, demonstrating the thermal comfort performance of the building typology.

Table 2. Fayette and Lee Courthouses. Comparative simulation results showing Air Temperature, Radiant Temperature and Air Humidity.

	FAYETTE Courthouse Average Results during Summer Season (from May to September)			**LEE Courthouse Biweekly Average Results during Summer Season (from May to September)**		
Schedule	Air Temperature (°C)	Radiant Temperature (°C)	Air Humidity (%)	Air Temperature (°C)	Radiant Temperature (°C)	Air Humidity (%)
May 1-12	30.2	31.3	25.9	25.5	26.3	34.6
May 13-25	30.8	31.5	59.6	24.9	26.3	67.1
May 26- Jun 7	33.8	34.5	44.3	29.2	29.8	56.7
Jun 8 – 20	35.2	37.2	45.1	25.2	27.1	62.1
Jun 21- Jul 2	37.0	38.0	41.7	26.4	29.3	56.4
Jul 3-14	37.0	38.7	43.0	25.5	27.4	63.5
Jul 15- 26	36.4	37.7	42.4	25.9	28.1	58.5
Jul 26- Aug 6	37.5	38.5	41.2	29.0	29.1	67.3
Aug 7- 18	35.5	37.3	32.0	25.4	27.6	49.8
Aug 19 -30	37.4	38.4	45.8	31.0	31.2	66.7

Tables show biweekly average maximum values of temperature and humidity

In case of Lee county courthouse, temperatures are clearly lower, while relative humidity appears to be higher even if it is still considered within limits of the thermal comfort zone

Analysis of Results

The comparison of the two simulation results is undertaken through the insertion of the data shown in Table 1 and 2 in the psychometric comfort chart using online CBE Thermal Comfort Tool (CBE, 2017). The analysis was based on the following parameters: Air speed: 0.1 m/s (within acceptable parameters); Metabolic rate: 1 met (for sedentary activities, as suitable for courthouses); Clothing level: 0.1 clo (tropical clothing).

Table 3

	FAYETTE	LEE
Thermal sensation	**Hot**	**Neutral**
PPD (%) (Percentage of Person Dissatisfied)	100 %	7%
PMV (Predicted Mean Vote)	3.83	0.31

Figure 9. Psychometric chart showing CFD simulation results and comfort conditions.

As shown in figure 9, "input #1" data are related with Fayette courthouse, input #2 data are the ones for Lee Courthouse. In case of the Fayette Courthouse, the analysis shows that average comfort conditions fall well outside the comfort zone (in purple) mostly because of the high air temperatures. As discussed previously, the CFD analysis did not account for the potential impact of the fountain which will likely reduce this temperature resulting in the conditions being closer to the comfort zone. On the other hand, for the Lee Courthouse, the analysis shows the average conditions (in purple) to be within the acceptable range of thermal comfort. Therefore, we can conclude that the simulations shows the cruciform plan, patented by the architect, of the Lee Courthouse represents is more successful in achieving indoor thermal comfort conditions most likely due to the integrated ventilating shaft and tower, where the stairwell was also located.

Conclusions

This paper attempts to combine two methodological approaches to architectural research: historical analysis as carried out by preservationists and the use of performance simulation, to assess the work of a prominent architect: James Riley Gordon. Through historical analysis, the paper demonstrates that the architect consciously integrated climate-appropriate and responsive strategies into his court house designs in Texas. Mainly the use of natural cross and stack ventilation as well as evaporative cooling, and that he did so as a part of a wider movement in the US at the time. Through the use of CFD performance simulation, the paper assessed two major phases in the evolution of Gordon's courthouse designs from the point of view of their ability to achieve indoor thermal comfort conditions. The simulation showed that Gordon's signature plan, illustrated by the LEE County Courthouse, is more successful in achieving indoor thermal comfort conditions in the hottest time of the year than the earlier design, illustrated by the Fayette County Courthouse. This is consistent with the evolution of the architect's work and with his writings which contended that his signature plan represents an improvement with respect to passive design characteristics.

Thermal behaviour of urban semi-open spaces in the Mediterranean climate: the case of shopping arcades in the historic centre of Nicosia, Cyprus

Eleni Malaktou[1] and Maria Philokyprou[2]

[1]Department of Architecture, University of Cyprus, meleni@ucy.ac.cy
[2]Department of Architecture, University of Cyprus, mphiloky@ucy.ac.cy

Abstract: Urban public or semi-public, semi-open spaces formed, over time, focal points for trade, exchange, social interaction and political discourse. Such spaces, which are neither indoor nor outdoor, reduce the comfort expectations of users who are tolerant to a wider range of environmental conditions compared to the users of indoor spaces. Considering that thermally comfortable public spaces are essential for the social vitality of the urban realm, semi-open typologies may be (re)considered as positive design elements in sustainable urban planning practices. This paper investigates a particular semi-open typology, namely the shopping arcade, in Nicosia historic centre. It focuses on both the arcades' thermal behaviour and on the links between architectural form and environmental performance. Initially, on-site documentation and collection of geolocation data was undertaken, followed by a classification of the architectural characteristics of arcades. More than fifty arcades were identified and a sample of sixteen representative examples was selected for seasonal thermal monitoring. The findings suggest that arcades are well performing passive urban environments. Their variable architectural forms can provide microclimatic diversity and thermal adaptation to human nature, which can result in more frequent use and prolonged occupancy of the urban domain.

Keywords: semi-open space, arcade, summer thermal monitoring, thermal behaviour, Mediterranean climate

Introduction

Public or semi-public, semi-open spaces link private and public domains and have served, throughout the years, transitional, social, economic or political purposes. These covered passages —bordering a square, lining a street or passing through an urban block— form attractive places for dynamic (e.g. walking) and/or static (e.g. standing, sitting) activities. Such space types enable a gradual thermal transition between interior and exterior space and demonstrate a particular knowledge on how to achieve control over the microclimate by passive means. Semi-open spaces do not depend upon artificial thermal control and thus increase the thermal acceptability limits of the users. The positive thermal effects and benefits of such designs are thoroughly researched in vernacular architecture (e.g. Andreou & Axarli, 2012; Malaktou, et al., 2016; Sinou, 2007; Rudofsky, 1964), while such effects are less documented in the industrial era (e.g. Potvin, 1997) and the 20th century architecture (e.g. Tsiros & Hoffman, 2014).

In recent years, the wide use and dependence on artificial heating and cooling, the interiorisation of public space, hectic lifestyles, the automobiles effect and the development of telecommunications which enable social interaction in a virtual instead of a physical space, have changed the nature of the built form and led to the decadence and limited application of the semi-open type. Rudofsky (1969), in his book *Architecture without* *architects*, points out the fast disappearance of such typologies in vernacular architecture while Brown et al. (1998) and Wilson-Doenges (2001) identify a decline in the use of semi-open spaces in domestic architecture. Nowadays, the imperative need to tackle climate change effects, to mitigate the Urban Heat Island related problems and to achieve energy conservation, force us to re-visit and re-assess the potentials of semi-open spaces within a larger urban design context that would benefit contemporary society. In addition, since social attendance and interaction in semi-open or open spaces has proven to be strongly influenced by microclimatic issues (Nakano & Tanabe, 2004; Gehl, 2001; Nikolopoulou & Lykoudis, 2007), semi-open spaces, which form authentic bioclimatic design elements, can be reconsidered as tools for strengthening sociability and restoring a sense of community in the public space.

The present paper analyses a particular semi-open space type in Nicosia historic centre in Cyprus, namely the shopping arcade. According to Geist (1989), a *shopping arcade is defined as a covered passageway which connects two busy streets and is lined on both sides with shops*. This type was selected over other semi-open typologies because of the numerous examples found in Nicosia, because of their neglect within the urban fabric, their significant social role and the relatively scarce scientific data found in the literature related to their architecture and their environmental behaviour. In the case of Nicosia historic centre, this particular type appeared in the beginning of the 20th century, when in other major European cities it had already fallen into decline and was gradually replaced by department stores (Geist, 1989). The development of the arcade is a result of westernisation, modernization and urbanization processes in the island during this period. Historically, this type was quite popular during the 1960s; a time which coincides with a high building density construction in Nicosia following the demolition of many traditional structures for new developments. The 1980s marked a decline of the retail arcade concept which put a stop to its implementation within the urban fabric.

This study —which is a part of a wider research on the socio-environmental aspects of shopping arcades— focuses (a) on the summer thermal behaviour of these spaces and further (b) on the interrelation between the arcade architectural form and thermal behaviour. The aim of this research is to illustrate the thermal benefits of arcades over the external environment, to reveal opportunities for thermal comfort enhancement in the urban context through the application of the arcade type on the neighbourhood/district level and to provide design guidelines for such spaces based on environmental criteria.

Methodology

A three-fold methodology was followed, including (a) on-site identification and documentation, (b) archival research and (c) on-site thermal monitoring, in order to provide a holistic approach in the understanding of the shopping arcades in question. Initially, on-site collection of geolocation data, as well as description and classification of the architectural characteristics and bioclimatic aspects of arcades, was undertaken using photos, maps, sketches and notes (Malaktou & Philokyprou, 2016). Supplementary material to the on-site data, such as information about the year of construction, the architects involved in their design and architectural drawings, was acquired through the Municipal and Governmental archives. More than fifty arcades were identified and a sample of sixteen representative examples, as well as one reference indoor space, were selected for continuous air temperature and relative humidity monitoring. Additional data of outdoor climatic conditions was obtained by a VantagePro weather station, located at downtown Nicosia. Arcades were surveyed seasonally between August 2016 and May 2017. The last part of the methodology, which concerns the summer thermal monitoring, is the focus of this paper. Summer measurements of air temperature and relative humidity were carried out between August 1st to 31st, 2016, using Hobo UX100-003 type sensors. The sensors were carefully placed in order to ensure protection against direct solar radiation. The analysis of results included the presentation of mean minimum, average and maximum temperatures and temperature fluctuations of arcades with respect to the corresponding values of the outdoor environment, in order to estimate their potential cooling effect. In addition, a statistical process, i.e. a regression analysis, was performed to evaluate the dependence of the cooling effect of arcades on weather conditions. Finally, another statistical analysis was performed to demonstrate how the Degree of Enclosure (DoE), as called by Sinou (2007), affects the thermal environment of semi-open arcades. The Degree of Enclosure is defined as the ratio of the sum of all closed and open surface areas (A_{total}) to the sum of the open surface areas (A_{open}) (Steemers , et al., 2004). The purpose of this analysis is to demonstrate to what extent a particular architectural form of a space affects the microclimate within it.

Case studies description

Detailed information on case study spaces is provided in Tables 1 and 2. The majority of arcades under examination feature a linear straight passage (I-shaped), a type that is most commonly found in Nicosia. Other more complex types, such as L-shaped and U-shaped configurations, although sparsely applied, are also included in the sample. Due to the compact planning of the Nicosia historic centre, many arcades are built on land-locked sites; a fact that restricts the possibility of a through passage. Such design examples, are identified in Arc_4 and Arc_5. The DoE of the sample varies between 5.5 and 25.5. Given that the major commercial thoroughfares are mainly developed along the North–South axis,

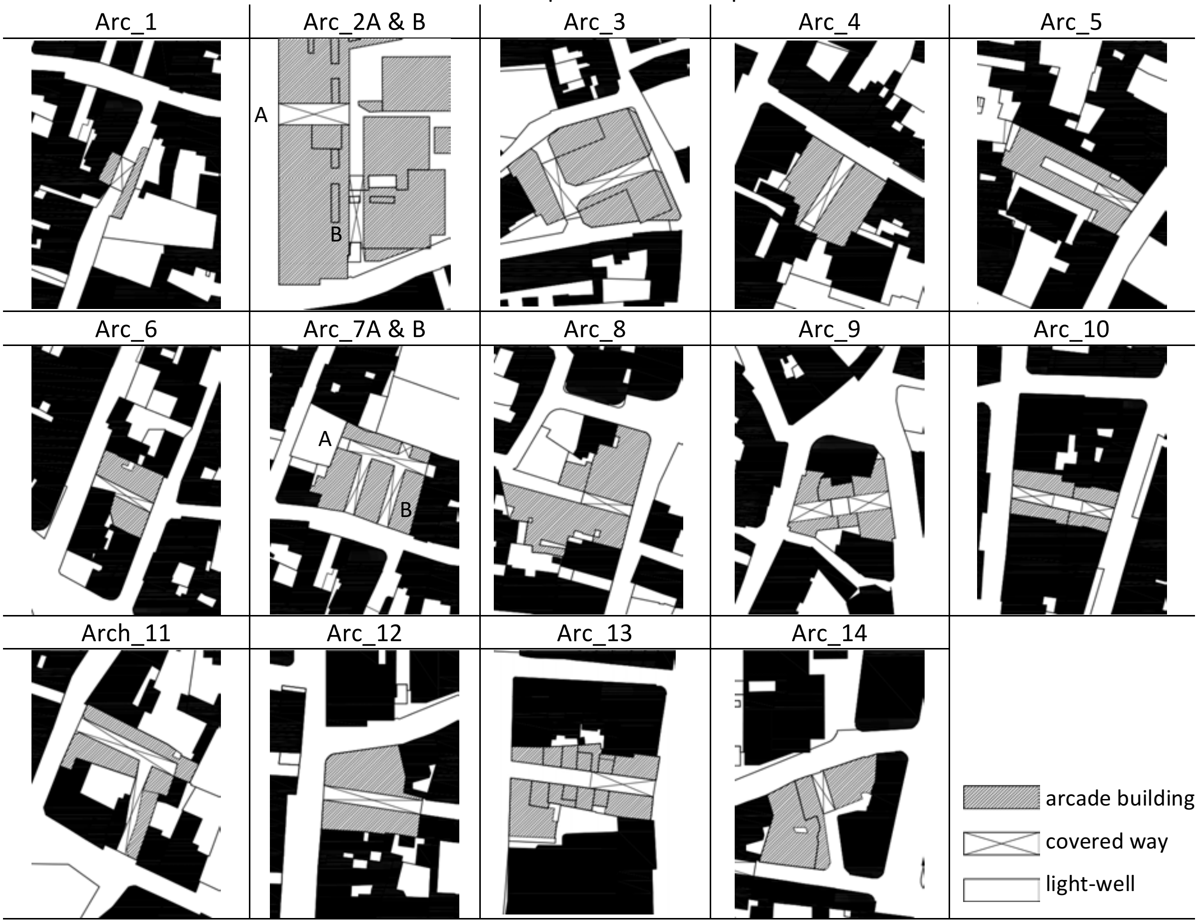
Table 2. Sample architectural plans



the majority of the sample is positioned along East–West axis. The arcades under examination, with the exception of Arc_12, are covered by high-mass roofs. High-mass roofs for this semi-open type are traditionally associated with low latitude countries, as opposed to high latitude countries where glazed roofs prevail.

Results and Discussion

Thermal behaviour assessment

The monitoring results of the entire summer experimental period indicate that, in principle, all arcades present remarkably lower mean maximum temperature values than the corresponding value of the outdoor environment (Table 3). More specifically, differences in mean maximum air temperature between the arcades and the outdoor environment vary from 1.0 to 3.9°C, while the peak reduction of maximum outdoor temperature reaches the 5.4°C (Arc_4). This cooling effect is attributed to the combined effect of compact urban morphology, orientation, shading and thermal mass. It is interesting to note that the maximum cooling effect for the majority of arcades under examination occurs during the hottest day of the monitoring period, i.e. 8/8/2016, when maximum outdoor temperature reaches 39.9°C. This indicates that maximum cooling effect in arcades is more associated with hotter days. To provide a better understanding of the cooling effect of arcades, a linear regression was performed between the outdoor daily maximum temperature, i.e. T_{max_out}, and the difference between the daily maximum temperature of the outdoor environment and that of arcades, i.e. $T_{max\_out} – T_{max\_arc}$ (Table 4). Table 4 shows a good degree of relationship in the patterns of variation between T_{max_out}

and $T_{max\_out} - T_{max\_arc}$ in the majority of case studies (R^2 = 0.46–0.81). This confirms that the outdoor air temperature has an impact on the level of cooling; i.e., the higher the maximum outdoor temperature, the stronger the cooling effect within the arcades. The values of the slopes are in a range of 0.16 and 0.49, indicating that maximum temperatures of arcades are always below the corresponding values of the outdoor environment. Applying the resulted regression, when outdoor maximum temperature rises by 5°C the cooling effect values of arcades are expected to be enhanced from 0.8 to 2.5°C. The above results are in line with the results of Tsiros & Hoffman (2014) carried out in the summer in semi-open spaces of Athens.

worst thermal condition; best thermal condition; 1, outdoor climatic conditions; 2, indoor reference space

In contrast to maximum temperatures, all arcades are always found to be hotter than the outdoor environment during night-time hours, when minimum temperatures occur (Table 3). Differences in mean minimum air temperature between arcades and the outdoor environment are at a range of -4.5 to -2.1°C, while maximum increase of minimum temperature against minimum temperature of the external environment is equal to 6.1°C (Arc_11). The warming effect observed in arcades is attributed to the narrow sky view of the case studies, resulting from the enclosure of the roof and side walls, which inhibits nocturnal radiative cooling. These results are in line with the findings reported in other studies (Malaktou, et al., 2016; Tsiros & Hoffman, 2014). The regression model between daily minimum outdoor air temperature, i.e. T_{min_out} and the difference between minimum outdoor air temperature and minimum temperatures of arcades, i.e. T_{min_out}-T_{min_arc}, shows mainly a weak to moderate degree of relationship in the patterns of variation (R^2 = 0.00–0.78) (Table 4).

[1] Regression is performed using daily data

Table 3 indicates that mean diurnal temperature fluctuation of arcades is significantly lower than the corresponding value of the external environment. It varies from 4.5 to 8.5°C, while in the case of the outdoor environment, it equals to 12.6°C. This dampening effect, which enables greater thermal stability, is attributed to the effective shading, the insulation of the arcade roofs, the high thermal mass materials and compact built forms of both the arcades and the surrounding urban environment. Table 4 shows the results of the linear regression between the daily air temperature fluctuation of the outdoor environment and the daily air temperature fluctuation of arcades. The model shows a good degree of relationship in the patterns of variation in most cases (R^2 = 0.33–0.88). Values of the slopes vary between 0.31 and 0.72, which means that every 5°C increase of daily outdoor fluctuation may correspond to a rise of daily fluctuation of arcades from 1.6 to 3.6°C.

Architectural form and thermal interrelations

This section investigates the relation between the architectural characteristics of arcades, i.e. the DoE, and their thermal behaviour (Figs 1A & B). The statistical analysis of the environmental data during the entire monitoring period, indicates a good degree of relationship in the patterns of variation between the DoE and mean maximum temperatures of arcades (R^2 = 0.76) (Fig. 1A). This implies that DoE affects the level of cooling inside the examined spaces; the higher the DoE, the stronger the cooling effect. The value of the slope equals to -0.12, which means that increasing the DoE by 10 units, mean maximum temperature drops by 1.2°C. At the same time, the regression analysis that was performed between the Degree of Enclosure (DoE) and the mean temperature fluctuations of arcades indicates a good degree of relationship in the patterns of variation between the Degree of Enclosure (DoE) and the mean temperature fluctuations of arcades (R^2 = 0.79) (Fig. 1B). The analysis demonstrates that semi-open spaces with higher DoE result in lower air temperature fluctuations and thus greater thermal stability. Interdependence of DoE and mean globe temperature fluctuation has been reported in the study of Sinou (2007) in two case study locations, i.e. Siphnos island in Greece and Cambridge in the U.K. These findings confirm that the architectural form is a significant aspect in governing and controlling the microclimate of semi-open environments as other studies have also demonstrated (Tsiros & Hoffman, 2014; Sinou, 2007; Chun, et al., 2004; Potvin, 1997). The analysis of the case studies shows that semi-open spaces with DoE lower than 5 will result high temperature fluctuation, the spaces in the group with DoE between 5 and 15 will present medium temperature fluctuation, while the spaces with DoE over 15 will demonstrate low temperature fluctuation.

It is interesting to note that although orientation is a determinant factor of thermal performance, its impact on temperature fluctuation and maximum temperatures of arcades is not clearly established (Figs 1A & B). Bearing in mind that arcades are located within a densely built environment, one could claim that the orientation effect is weak because arcades are protected from solar radiation by the surrounding urban fabric. Another explanation relates to the fact that increasing the DoE, the effect of orientation on thermal performance weakens.

A number of arcade spaces (Arc_1, Arc_5, Arc_10 and Arc_11) which have been excluded from the regression analysis, do not perform as expected. Arc_1, Arc_5 and Arc_10 lie below the line, representing the relationship between DoE and mean maximum temperature and below the curve, representing the relationship between DoE and mean temperature fluctuation. This means that at a given DoE, these spaces present lower temperature fluctuations and lower maximum temperatures compared to the rest of the sample. These discrepancies may be attributed to the surrounding urban morphology and thermal control systems. More specifically, Arc_5, which faces a compact, shaded enclosed backyard rather than a street, seems to benefit from its more favourable microclimatic conditions. Despite its low DoE, Arc_1 achieves considerable reduction of the undesirable solar heat due to the fact that is located on a narrow North-South, well-shaded street with limited openness to the sky. The thermal performance of Arc_10 may be explained by the operation of ceiling and standing fans that remove the stale, hot air from the arcade. Arc_11 showed the highest mean maximum temperature among the sample, despite the fact that it has a high DoE. This could be attributed to the significant heat absorbed by the roof, since Arc_11, does not have upper floors, as opposed to all other arcades, which would provide additional thermal insulation.

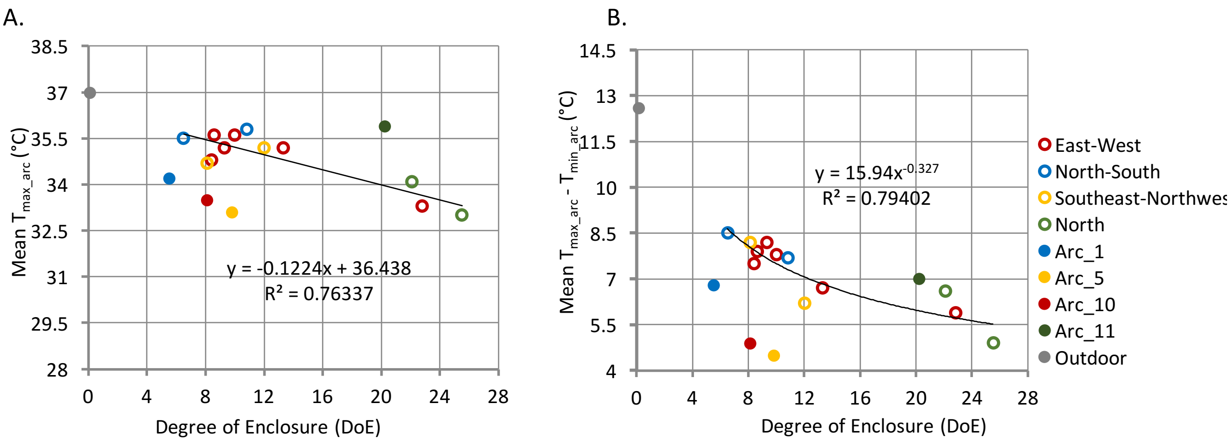

Figure 1. Linear regression results between DoE and A. mean maximum temperature (T_{max_arc}), B. mean air temperature fluctuation ($T_{max\_arc} - T_{min\_arc}$)

Conclusions

The present paper presents a quantitative examination of arcades' thermal behaviour in the summer and the links between architectural form and thermal behaviour. Arcades are found to be positive climatic elements in the summer Mediterranean climate. The low-tech, passive, climate-conscious design of such spaces may prove quite informative for contemporary architecture. Because of their environmental advantages, they can be exploited as models for the development of sustainable planning practices.

A strong cooling effect has been found to be associated with these spaces, indicating their importance in ameliorating summer climatic extremes. This cooling effect —estimated to have a maximum value of 5.4°C— was statistically evaluated and found to reach the maximum on extremely hot days. A strong cooling effect was also related to the Degree of Enclosure (DoE) and found to be greatest in spaces with high DoE; for every 10 units increase of the DoE, the mean maximum temperature dropped by 1.2°C. The assessment of the microclimate of semi-open spaces based on their architectural form, as presented in this study, could be used for the drafting of arcade design guidelines based on environmental criteria. For instance, a table providing a classification of semi-open spaces with regard to: orientation, materiality, degree of enclosure and obstructions, where information about the thermal impact of each parameter would be addressed, could provide a quick and simple tool for climate-conscious design proposals of urban areas. This would allow the creation of more thermally adaptive urban spaces which would encourage sociability and prolonged occupancy in the public domain.

Performance evaluation of climate responsive buildings in India: two case studies from hot-dry and composite climate zones

Sanyogita Manu[1], Gail Brager[2], Ann Dennis[2]

[1] CEPT University, Gujarat, India, SanyogitaManu@cept.ac.in
[2] Center for the Built Environment, University of California, Berkeley, CA, USA

Abstract: India has a rich tradition of climate responsive architecture throughout its five distinct climate zones. Designing climate responsive buildings is challenging, requiring an understanding of building physics, as well as the manner in which buildings are designed, constructed and operated in a given cultural context. The process becomes more difficult with the ever-increasing comfort expectations. This paper is based on a study that was initiated in 2013 to evaluate the thermal performance of climate responsive buildings in a quantitative way. Several modern institutional and office buildings in warm-humid, hot-dry, moderate and composite climate zones, where a wide range of passive and hybrid design strategies was deployed. Two of these case studies are presented in this paper to evaluate the performance of solar chimney with evaporative cooling and cavity walls. In addition to the measured variables, performance was compared using a calculated 'comfort exceedance' metric derived from the neutral temperatures calculated from the India Model for Adaptive Comfort (IMAC).

Keywords: Passive/ climate responsive buildings, Solar chimney, Evaporative cooling, Cavity walls, India

Introduction

Natural ventilation is a technique of passively-designed architecture that provides fresh air for occupants and reduces internal cooling load, improving occupants' comfort without the energy burden of mechanical systems. Solar chimneys are one method for utilizing buoyancy-driven ventilation. There are many contemporary examples of solar chimneys in commercial buildings, and some of the most frequently cited examples include the Inland Revenue Centre in Nottingham, UK, the DPR Construction Office in Phoenix, Arizona, the Waseda University Honjo Campus in Honjo City, Japan, and the Ocean City Comfort Station and Performing Arts Stage in Ocean City, Maryland

There are two buildings with solar chimneys whose performance has been analyzed and widely disseminated: the Building Research Establishment (BRE) in Garston, UK and the Building and Construction Authority (BCA) Academy in Singapore. BRE was completed in 1996 and has three-stories of a narrow floor plan with operable windows and stacks on the south facade. Riain et al. (1999) analyzed the BRE building with measurements of ventilation rates and environmental conditions. They found satisfactory comfort and air quality conditions, fulfilled ventilation requirements across occupied space, and increased air intake from chimneys during warm, still days. The results of the temperature difference across the stack were less than expected, a top-to-bottom gradient of 2°C. They also found the thermal mass of the stack releases its storage of daytime energy during the night. BCA was retrofitted in 2009 and is one of six interconnected three-story buildings awarded for zero-net-energy achievements. It has four solar chimneys and vertical ducts on the west façade. Tan and Wong (2012) analyzed the BCA building with air speed and temperature measurements. They found acceptable thermal conditions according to calculated PMV and PPD. On hot days, the chimney had a 17°C top-to-bottom temperature difference and was found to increase classroom airspeed up to 0.49 m/s slowing the heating up of the space and increasing the cooling down by 1-2 hours compared to a reference region

In addition to these field studies, several experimental studies have been conducted on solar chimneys over the past 3 decades from theoretical, mathematical models and simulations (Bansal *et al.*, 1993; Ong and Chow, 2003) to small-scale, fine-bubble modelling techniques (Spencer 2001) and full-scale mock-ups (Afonso and Oliveira, 2000; Khedari *et al.*, 2000; Arce *et al.*, 2009) . The main objectives of these studies were to validate predicted calculations with empirical measurements, determine the most optimal parameters for the design of the solar chimney, and document its effectiveness at providing ventilation.

Cavity walls are another passive design strategy, referring to a building enclosure constructed as two layers with a gap. With increased focus on energy conservation in the 1970s, the filled cavity wall gained value in its insulating properties (Hens *et al.*, 2007). Hens et al. found that ventilation in the hollowed cavity had no effect in managing moisture, concluding a filled cavity wall is an effective choice for its other insulating benefits. Van Belleghem et al. (2013) present the alternative that ventilation can have a negative effect on the walls' moisture tolerance in high humidity. The research on the performance of cavity walls has been conducted in the UK and differs in its conclusions. There has been minimal research on the performance of cavity walls in warm climates.

Since the application of passive design strategies is dependent on climatic conditions, it is important to study the performance of these systems unique to the region. This paper examines two buildings in India: one located in a composite climate, fitted with solar chimneys and a low-energy evaporative cooling system; the other located in a hot and dry climate and using cavity walls as the primary passive design strategy.

Case Study Buildings and Methods

Building 1 is a public office building located in Panchkula in the northern state of Haryana, very close to Chandigarh, which is classified as having a composite climate (Bureau of Indian Standards, 2005). The building is designed around a large courtyard, which is open to sky. The total built up area is around 4000m^2 of which approximately 470m^2 is air conditioned. The main façade faces south and has five identical solar chimneys that start on Floor 1 and go up to the terrace, to provide ventilation in some of the non-air conditioned (AC) spaces. Two similarly designed solar chimneys are located on the south-facing side of the courtyard. The façade has high performance double pane, low-emissivity glazing, and is broken by several elements similar to overhangs, which seem to have been designed to protect the south façade from direct radiation in summer. The courtyard has fixed ferro-cement louvers on top, angled to cut-off the high summer sun, and misters located on top to provide evaporative cooling in the hot and dry months. They are designed to work in conjunction with the solar chimneys, by drawing the cooled air from the courtyard into the rooms served by the chimneys.

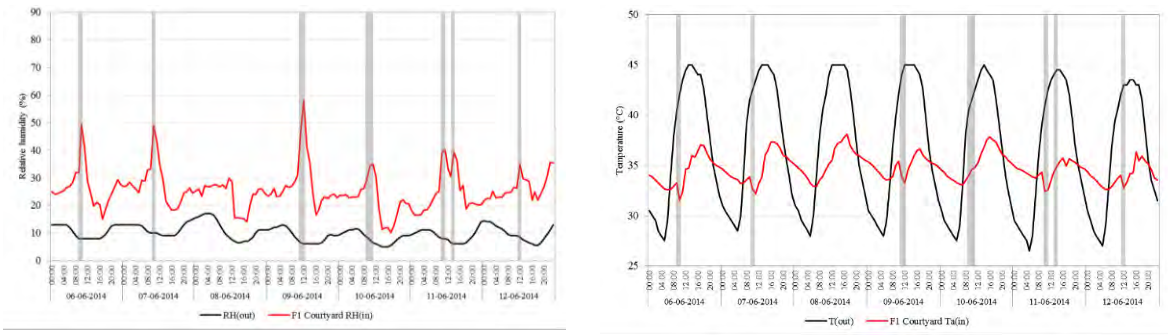
Building 2 is located on the outskirts of Ahmedabad in Gujarat, a hot and dry climate (Bureau of Indian Standards, 2005). The building has a total built up area of 2500m^2 with spaces such as classrooms, library and computer room, administration, multi-purpose halls and residential spaces for students and staff. The building is configured with more massing on the south-west, which provides shading to the open and semi-open activity areas located on the north-east. Parts of the building are subterranean and the ventilated cavity walls are constructed from load-bearing bricks, with the outer face left exposed (un-plastered). All spaces are naturally ventilated, with operable windows and ceiling fans.

Monitoring was done for a full year in each building. Air temperature and relative humidity were monitored using HOBO data loggers. Globe temperature was monitored in selected spaces. For Building 2, instantaneous measurements were taken using a Testo 410-2 anemometer (air velocity) and an Extech HT30 meter (air and globe temperature and relative humidity) measurements. Meteorological data for Chandigarh was requisitioned from an online weather source[1]. For Ahmedabad, data from a local weather station was used.

Results

Building 1: Solar chimneys & evaporative cooling

For brevity, only a sample of the full year of monitored data is presented here. Figure 1 shows temperature and humidity conditions for a week in June, representative of extreme summer conditions. The two most important passive strategies deployed in this building are the solar chimneys and the evaporative cooling from misters in the courtyard. In an ideal scenario, the misters would be turned ON during the hot and dry months. Figure 1(a) plots the relative humidity outdoors and in the courtyard, near the location of the misters. Except for Jun 8, which is a Sunday, one sees an increase in the relative humidity in the courtyard every day at around 9am, suggesting this is when the evaporative cooling starts. It then appears that the system is turned off 1-3 hours later, after the relative humidity reaches close to 50% or more. The periods when the misters are on are indicated using grey bands. Comparing these periods to the graph of air temperature outdoors and in the courtyard in Figure 1(b), an increase of 15% in relative humidity due to the misters leads to a reduction of 1.5°C in air temperature.



(a) (b)

Figure 1(a) plots the relative humidity outdoors and in the courtyard, (b) plots the air temperature outdoors and in the courtyard

Figure 2 plots the air and surface temperatures inside the solar chimney located in the courtyard. The black line is the outdoor temperature for those days, collected from an online weather source for that city (which admittedly could be somewhat different than the actual on-site outdoor climate). The red lines are from the solar chimney wall facing south – the wall that has the glazing intended to get heated up to enable stack ventilation. The blue lines are from the the solar chimney wall facing north. Solid lines are air temperature and dotted lines are surface temperature. Both air and surface temperature were higher on the south wall compared to the north, indicating the effect of at least some solar radiation. However,

[1] http://www.worldweatheronline.com/

on comparing the south-facing temperatures inside the chimney (red lines) with the outdoor air temperature, the former seems to be uncharacteristically low for an element that is supposed to work on the principle of catching radiation to move the warm air up the chimney. This may be attributed to the fact that all chimneys are covered with high performance glazing, perhaps limiting the degree of warming and hence the buoyancy-driven ventilation that might have otherwise occurred.

Figure 3 plots the air and surface temperatures inside one of the solar chimneys located on the south-facing façade of the building, with the red lines from data on the inside of the south-facing wall and the blue lines from data on the inside of the west-facing wall. In contrast to Figure 2, one does not see much difference between the red and blue lines here even though one might have expected that inside surface temperature of the south wall should have been higher. This might indicate that the solar chimney may not be very well designed. Solar chimneys on the façade have high performance glazing on the south, similar to the chimneys in the courtyard. However, the chimneys on the façade are also shaded by horizontal overhang type elements on the façade. The cumulative effect of the shading and high performance glazing decreases the efficiency of the solar chimneys.

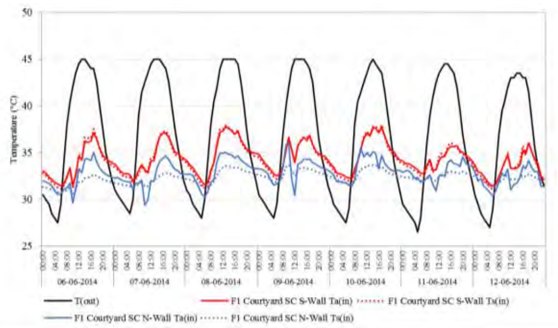


Figure 2: Air and surface temperatures inside the solar chimney located in the courtyard

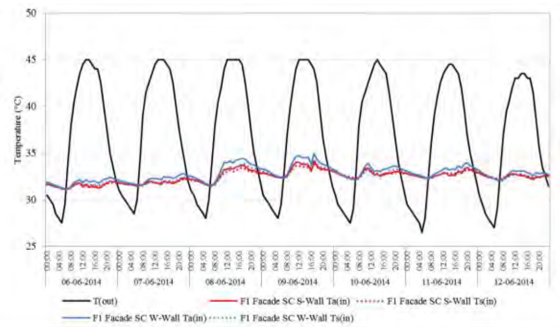

Figure 3: Air and surface temperatures inside the solar chimney located in the courtyard

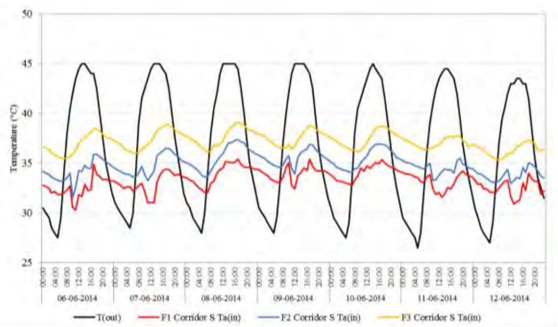

Figure 4: Air temperatures in the corridor on three floors

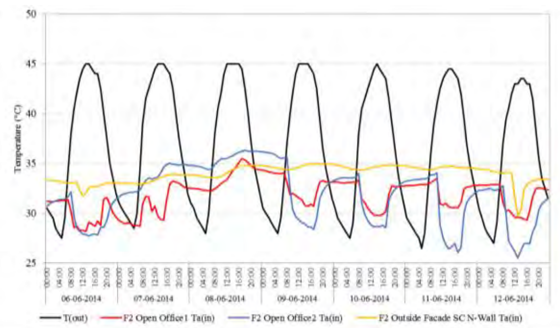

Figure 5: Comparison of air temperatures inside air conditioned and naturally ventilated rooms

Stack ventilation may be working in this building in two ways – (1) through the solar chimneys, and (2) through the courtyard. It is difficult to determine from the monitoring data alone what happens when both 'systems' interact. However, it is well known that for any kind of stack ventilation to work, there has to be stratification (or pressure differential). Figure 4 plots the air temperature in the corridor (open to the courtyard, as well as the rooms that have the solar chimney) at three heights (one on each floor of the building). As one might expect, corridor temperatures are higher as you move from Floor 1 to 3, indicating a considerable degree of stratification in extreme summer.

Figure 5 steps away from direct evaluation of the chimneys, and compares temperatures in rooms that have air-conditioning (AC) (red and blue lines) vs. one which is naturally ventilated and served only by the solar chimney (yellow line). The graphs suggest that AC in office 1 (red line) is on for all days except Sunday (June 8), while the AC in office 2 (blue line) is on for all days except Saturday and Sunday. While the outdoor air temperatures rise as high as 45°C, the temperatures in the naturally ventilated room served by the chimney (yellow line) remains below 35°C. The design problems with the façade solar chimneys were mentioned in the preceding paragraphs. It is possible, therefore, that the relatively low temperatures inside the space being served by the solar chimney are not a result of effective solar chimneys but the evaporative cooling system in the courtyard, as well as the thermal mass in the building.

Building 2: Cavity walls

Figure 6 shows the performance of the unshaded, exposed cavity wall in Building 2 (detailed section shown in Figure 8), for a week starting on May 16, 2015 (representative of extreme summer). Outdoor temperature is represented by both the black line (from a local weather station) and the solid red line (measured in the open courtyard). The dotted red line is the external surface temperature of the wall facing the courtyard, which receives direct solar radiation since it faces south. The blue dotted line shows the internal surface (adjacent to the classroom space) temperature of the same wall and the blue solid line shows the inside air temperature. The cavity wall is made of an interior layer of 230mm brick, a 115mm cavity and a 115mm external brick wall (Figure 8). The cavity space is naturally ventilated throughout the year but was not accessible for monitoring. The classroom is also naturally ventilated and has operable windows and ceiling fans. The external surface temperatures seem to be uncharacteristically high, even for a wall that receives direct solar radiation. What is noteworthy, however, is the dampening between exterior and interior air temperatures, ranging from 5.2-9.3°C. The thermal lag varies between 1-3 hours.

Figure 7 is a similar graph but for a shaded cavity wall. The red lines show the external surface temperature (dotted) of the wall and the air temperature (solid) near the wall. The blue lines show the internal surface (dotted) and air temperature (solid) inside the classroom. The wall construction is identical to that of the classroom shown in Figure 8; the space has operable windows and ceiling fans and is naturally ventilated throughout the year. The effect of shading is quite obvious when comparing Figures 6 and 7, in that the external surface temperatures for the shaded wall are lower than the outdoor air temperatures during the day. Interestingly, the interior classroom temperatures (blue lines) are very similar for both spaces, suggesting that the ventilated cavity is very effective at insulating against the effect of the solar radiation. The dampening for this room is comparable to what was found in Figure 6, and ranges from 5.4-9.9°C.

Figure 9 compares the indoor temperatures of spaces that have different orientations and exposures. All these spaces are naturally ventilated throughout the year, and have operable windows, ceiling fans and the same envelope (cavity walls). The dormitory and computer room are located on floor two (the top floor) and are therefore affected by the exposed roof. That may explain the higher air temperatures in these spaces. The admin building is exposed on the south, east and partially on the west. Direct solar radiation may lead to consistently high temperatures. The library has the same orientation as the admin building but is shaded on south and west, hence the lower temperatures.

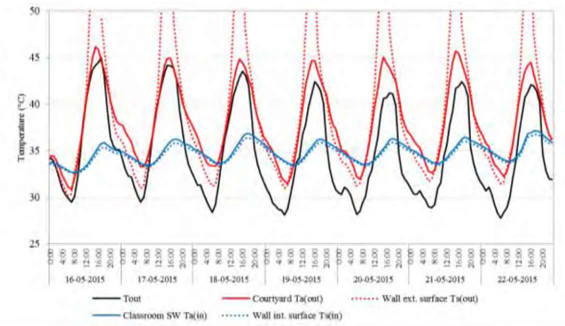

Figure 6: Air and surface temperatures of exposed cavity wall

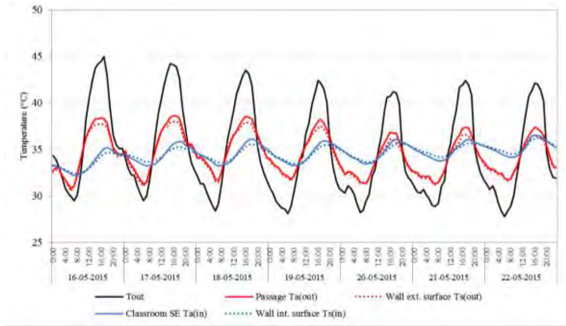

Figure 7: Air and surface temperatures of shaded cavity wall

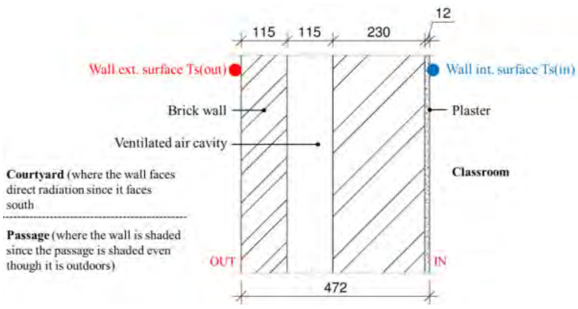

Figure 8: Cavity wall section

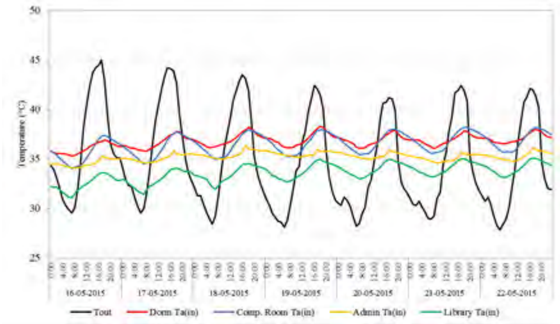

Figure 9: Comparison of air temperatures inside naturally ventilated rooms with different exposures

At 8 instances, we recorded instantaneous measurements for air and globe temperature, air velocity and relative humidity in three spaces – the classroom and library on the ground floor and the dormitory on the first floor. We then calculated operative temperatures (see Figure 10), which ranged from 22.7°C to 34.3°C. We compared these in Figure 10 to the acceptability limits (solid for 90%, dotted for 80%) from two different adaptive comfort models - black lines for IMAC (India Model for Adaptive Comfort) (Manu *et al.*, 2016) and red lines for ASHRAE Standard-55 (ASHRAE, 2013). For most instances, the operative temperatures were within the broader IMAC 80% acceptability limits. But they do not meet the narrower ASHRAE-55 adaptive model acceptability bands, except for a few data points from the classroom and library.

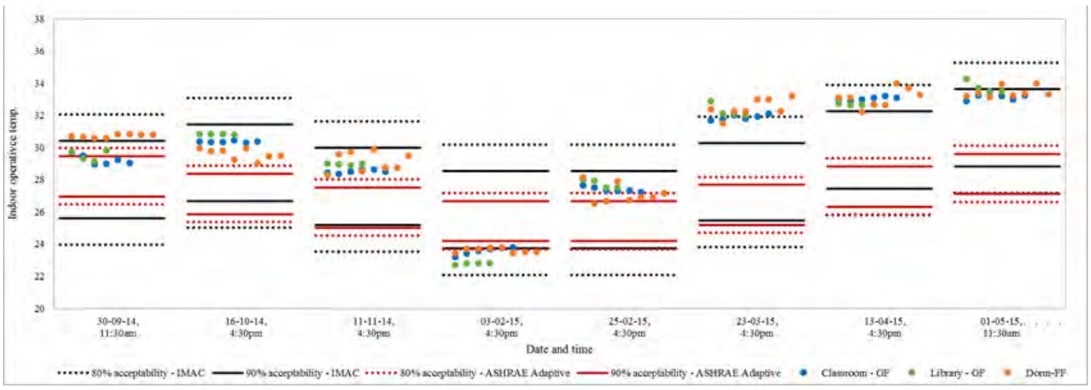

Figure 10: Evaluation of instantaneous indoor operative temperature based on the IMAC and ASHRAE-55 adaptive models

Comfort exceedance

The heats maps in Figures 12 and 13 were generated for the naturally ventilated spaces in buildings 1 and 2. The color coding indicates the "comfort" bin assigned to each hour based on the IMAC model for naturally ventilated buildings. The map for Building 1 was plotted from April 2014 to March 2015, and from August 2014 to August 2015 for Building 2. The wide "uncomfortably warm" bands in both figures are indicative of the days when the outdoor temperatures exceeded the applicability limits of the IMAC model for naturally ventilated buildings. That means the outdoor temperatures were too high for natural ventilation to mode to provide comfort conditions indoors. For that reason, the cells have been indicated as uncomfortable.

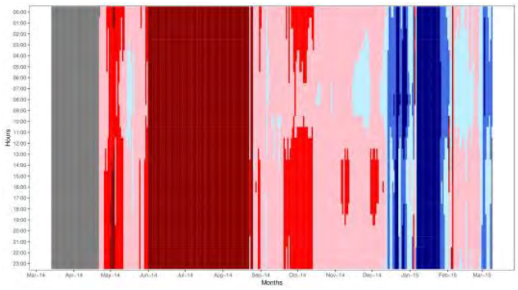

Figure 11: Heat map showing thermal comfort exceedance based on IMAC-NV model for Building 1

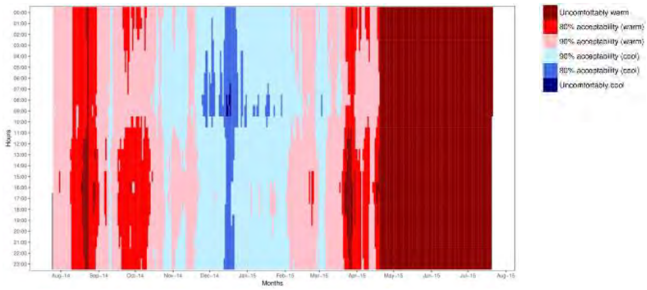

Figure 12: Heat map showing thermal comfort exceedance based on IMAC-M model for Building 2

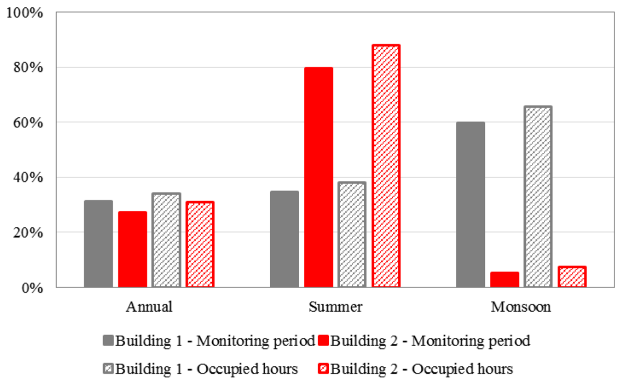

Figure 13: % Discomfort hours

The percentage of discomfort hours in each building were calculated for the duration of the monitoring period (Figure 13). Although the outdoor climate and building designs were quite different, the % discomfort was comparable in both buildings when looking across the whole year. There was slightly higher discomfort during occupied hours (31-34%), which is important since these are day-time use buildings. Binning the data into seasons revealed more interesting patterns. During the summer, Building 2 (cavity walls) exceeded the IMAC limits 88% of occupied hours compared to 40% discomfort hours in Building 1 (thermal chimneys). During the monsoon, the pattern was reversed and Building 1 had more than 65% of occupied hours being uncomfortable compared to only 8% in Building 2.

Conclusion

Two distinct buildings, located in different climate zones, were monitored for one year. In Building 1, the evaporative cooling system (misters in the courtyard) resulted in a reduction of 1.5°C in air temperature with a 15% increase in relative humidity during the extreme summer conditions. The stratification between floor 1 and 3 near the courtyard was around 3.5°C, a result of stack ventilation induced by the courtyard. The solar chimneys are covered with high performance glazing, with those on the façade having additional shading elements. It is suspected that these features keep the air inside the chimney from reaching the high temperatures needed to generate a powerful stack ventilation. This seems to be a lost opportunity due to poor design or execution. However, in spite of these flaws, the building is able to maintain a difference of 10°C between indoor (naturally ventilated spaces) and outdoor temperatures during extreme summer conditions. Comfort exceedance calculations for this hot and humid location showed that discomfort hours were less than 40% in summer, but exceeded 60% in monsoon. Results from Building 2 show that the cavity wall is an effective insulation against direct radiation. The building had very low discomfort during the monsoon, but that may also be explained by the predominantly dry weather of this location.

Ideal windows sizes for different orientation in a wind driven ventilated buildings

Talita Andrioli Medinilha-Carvalho[1] and Lucila Chabel Labaki[1]

[1] Department of Architecture and Building, State University of Campinas, Campinas, Brazil, talita.medinilha@gmail.com

Abstract: Wind driven ventilation is a passive cooling strategy that can be a powerful ally to reduce energy consumption in buildings, but it requires specialized knowledge and time investment. In order to make it more available to designers reliable and simplified guidelines are necessary. However, current ventilation standards require further developments since they only regulate minimal air change rate or percentages of window area, without considering other important parameters. In this regard, we verified the influence of different configurations of window systems on the thermal performance of a wind driven ventilated building. The object of this study is a residential building configured as a "double H" located in Piracicaba, São Paulo State (Brazil). Several configurations were simulated with the software Energy Plus coupled with CFD (ANSYS CFX) and the index Adaptive Comfort Degree-Days was adopted as a thermal performance indicator. It was shown that proper window dimensions depend on the window location and building orientation. The work provides simplified guidance to the windows design, thus, it stimulates the quality of the built environment and contributes to decreasing energy expenses with artificial conditioning.

Keywords: fenestration sizing, natural ventilation, wind driven ventilation, CFD analysis, thermal comfort.

Introduction

Design taking advantage of the wind driven ventilation is a recommended strategy to reduce energy consumption in buildings (Givoni, 1992; Lamberts et al., 2008; Rivero, 1986) . Nevertheless, to make proper use of this resource it is required an advanced knowledge in the field and time-consuming simulations. Thus, to allow greater applicability of this resource guidelines that simplify the process of dimensioning wind driven ventilation systems, as well as to approach the most relevant factors for natural ventilation are necessary. Such factors are the topography, the wind direction and velocity, the heat load, the proportion and shape of the building and window, the orientation, position in floor plan, type and area of the windows (Cóstola and Alucci, 2007; Lamberts et al., 2014; Toledo, 2006).

The current standards adopt a simplified approach to the topic, imposing a minimum number of air exchanges per hour, minimum ventilation area, or maximum air speed (Aflaki et al., 2015; Candido et al., 2010). These standards does not cover all the important aspects mentioned before and requires further study.

In addition to the standards, some researchers also address this issue by proposing methods for ventilation systems dimensioning for one face of a room (Khemlani, 1995; Suga et al., 2010), or hybrid ventilation and lighting systems in office buildings (Rupp and Ghisi, 2012), and different buildings proportion (Inanici and Demirbilek, 2000).

Other authors focus on the investigation of important parameters that indirectly lead to windows systems dimensioning guidance. The most investigated parameter in this regard is the WWR (window to wall ratio), which is mostly appropriated to evaluate its impact on the overheating, so that just a few researches explore the relation between the WWR and wind driven ventilation.

Zmeureanu (1988) relates WWR to the cost benefit of various types of thermal insulation and considers natural ventilation in the Montreal climate. Another case study evaluated air quality, thermal, acoustic, and visual comfort, in Nigerian hospitals(Stephen Nimlyat et al., 2015). Also, in Turkey, the ideal WWR for atrium and courtyards was analyzed (Tabesh and Sertyesilisik, 2016).

Although there is a discussion about some aspects of the windows design, it is noted that there are still some important factors related to natural ventilation that are not addressed, indicating the need for researches especially in the residential field.

In this regard, we investigated the ideal windows sizes for a low-rise building with wind driven ventilation considering different buildings orientations. The evaluated parameters are based on the previous research (Medinilha and Labaki, 2016), and are consistent with the scale of the models. A list of all parameters evaluated is presented: window area, the position of the windows on the floor plan, distance from the ground, and building orientation. To evaluate the best windows systems the building thermal performance was adopted, as recommended on Brazilian standard NBR 15220 (ABNT, 2005), instead of the wind speed.

Therefore, this study aims to contribute to reducing the deficit of information about sizing windows for the residential environment.

Method

The reference for this study is a residential building located in Piracicaba, São Paulo State (Brazil). It was modified by varying the area of the windows, and orientation. The data for this research were obtained through simulations, which occurred in two steps: the first one in CFD to obtain the pressure coefficients of the windows and then this information was fed to Energy Plus to perform the thermal simulation. This method improves the results accuracy because it allows considering different wind directions and intensity and building's heat load.

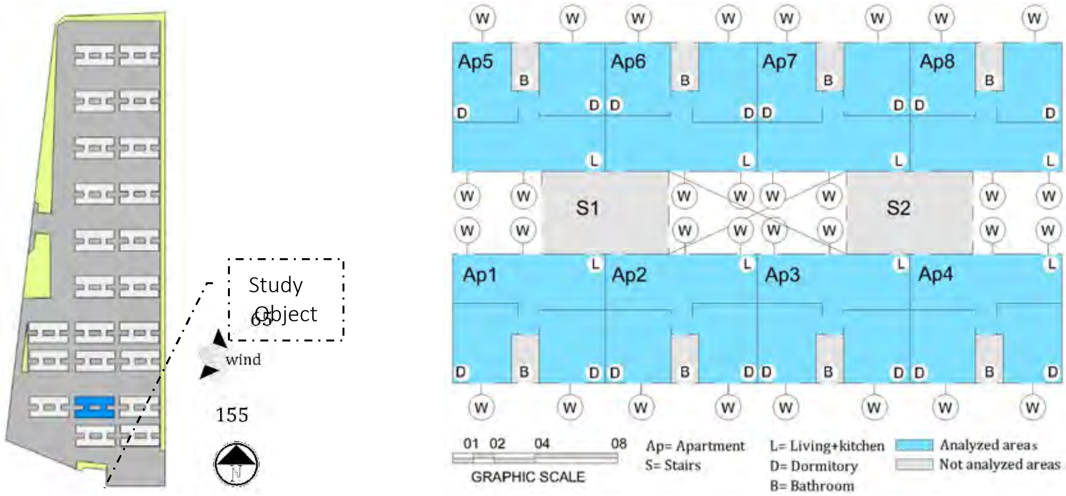
The city climate is described as humid subtropical - Köppen classification system (CEPAGRI, 2016). The average humidity is higher than 70% throughout the year; the maximum average temperature in the summer is 28,50°C and in the winter 26,19°C, the average minimum in the summer is 18,96°C and in the winter 12,48°C (Roriz, 2012a), which shows that even in the winter high temperatures are observed. Consequently, ventilation is needed throughout the year.

The wind speed varies from 4,80 to 0,44 m/s with an average of 2,46m/s (value used as the reference wind speed entry for the simulations). These data were extracted from Piracicaba climate archive (Roriz, 2012b) which were obtained at 10m above ground level. In order to consider the boundary layer effect a CCL (Common Command Language) expression (Cóstola and Alucci, 2007) was inserted on CFX, also the profile was considered neutral. After applying this correction, the resulted average inlet speed value were 1,06m/s and 2,27m/s, for the first and fourth-floor window level respectively. In addition, for Piracicaba, the wind prevailing direction is from 65° to 155°.

Model

For the selection of the reference building, the following conditions were considered: to have participated in a social housing program, to have an usual floor plan for the studied city, and to display uniform floor plan. Therefore Parque Piazza Navona residential complex was chosen not only because it meets those criteria but also it was the most populated. It is composed of 23 apartment blocks (as seen in figure 1-a). The location of the building at the residential complex (highlighted in figure 1-a) was selected for being the most obstructed one.

The reference case is a four-story building with typical materials and painted in light colors. As seen in the floor plan, shown in figure 1-b, the building is configured as a "double H" (two buildings shaped like an "H" positioned together) so that it forms a central courtyard and two side recesses. The apartments are composed of two bedrooms, a bathroom and a kitchen integrated to the living room. All rooms of the apartments were simulated except for the bathroom since it is of low relevance for thermal comfort.



(a) (b)

Figure 1. (a) - Location of the reference building at the residential complex; (b) - Floor plan of the Parque Piazza Navona residential complex.

Parametric variation

To determine the windows sizes to be tested, a calculation of window minimum (30% of the floor area) and maximum (60% of the floor area) area was performed by applying the currents Brazilian standards (ABNT, 2013, 2005) to the apartments. It was adopted the range from 0.6 to 4.0 m2 and the values were based on existing Commercial Brazilian windows and. The selected sizes are shown in table 1. Windows J60, J120 and J160 are the most common and inexpensive ones. In addition, the cases suffered variation on the parameters: orientation and window area, generating 24 case studies.

Table 1. Description of the simulated windows and ventilation areas.

NAME	N° OF SLIDING PANELS	ACTUAL HEIGHT [m]	ACTUAL WIDTH [m]	TOTAL AREA [m²]	VENTILATON HEIGHT [m]	VENTILATION WIDTH [m]	VENTILATION AREA [m²]
J60	2	1.00	1.20	1.20	1.00	0.60	0.60

J330	3	1.65	3.00	4.95	1.65	2.00	3.30
J400	3	2.00	3.00	6.00	2.00	2.00	4.00

Computer simulation

For computer simulations, two software were used: CFX Ansys 16.2 (CFD simulation) and the Energy Plus 8.4 (energy simulation). The settings are described as follows:

CFX

In order to obtain the pressure coefficients 8 simulations were performed with the software CFX Ansys 16.2 for different wind incidences (further input to the software Energy Plus). The simulations were carried out by rotating the wind attack angle every 45°, starting from 0° up to 315°. To represent the obstructed surroundings all buildings of the residential complex were modeled. All internal partitions for the first and last floor (evaluated floors in the study) were modeled. Therefore, 64 pressure coefficients were extracted from each model, considering the central point of each window present in the studied rooms (identified with a “W” in figure 1-b).

To enable the simulation of various wind attack angles it was adopted an octagonal domain with a 674,43m diameter (50 times the object height) and 77,40m height (5 times the object height), according to the recommendations of (Cóstola and Alucci, 2007). This configuration resulted in a blockage of 0.009%.

Mesh independence tests were performed to ensure the accuracy of the model and to define the mesh. Several simulations were carried out by refining the mesh each time, This process continued until a finer mesh did not present significant changes in results, as proceeded in other rehearses in the field (Cóstola and Alucci, 2007; Lukiantchuki and Caram, 2012; Morais and Labaki, 2013). Thus, the mesh and the model’s domain were configured as shown in table 2.

Table 2. Adopted configuration for CFX ANSYS 16.2 simulation.

Energy Plus

The models were constructed in SketchUp with the aid of OpenStudio plugin. The construction materials of the models were based on the reference building (listed in table 3), and the internal loads were established following recommendations (Pereira et al., 2013), see table 4.

Table 3. Materials used to compose the Energy Plus model.

	LAYER 1	THICKNESS [M]	LAYER 2	THICKNESS [M]	LAYER 3	THICKNESS [M]	TRANSMITTANCE [W/M2K]	ABSORPTANCE

Table 4. Internal loads used to configure the Energy Plus model.

TYPE OF LOAD	AMOUNT	UNIT

People	4	
Lighting	10.6	W/m²
Electric equipment	3.9	W/m²

Due to shape symmetry, it was possible to reduce the numbers of simulations by varying the orientation only at one-quarter of the circle (0°, 45°, 90°, and 135°). "Shading" objects were used to represent the surrounding's obstruction. The wind obstruction was already considered at CFD.

Natural ventilation was simulated in all studied apartments (see figure 1) using the object Airflow Network, with simulation control "Multizone Without Distribution", and pressure coefficients extracted from the CFD model. The maximum number of iterations was equal to 500 according to recommendations (Pereira et al., 2013). The windows were considered always open in order to understand the full potential to mitigate thermal discomfort through natural ventilation in different models.

Results and discussion

This study adopted as the performance indicator the Adaptive Comfort Degree-Days (for overheating) (McGilligan et al., 2011), which is calculated as the difference between the operative temperature and the adaptive comfort model of temperature for hot thermal sensation. This method allows to evaluate the intensity of discomfort throughout the day (Nico-Rodrigues et al., 2015); and is a well-known method for naturally ventilated environments.

Table 5 presents the best and the second best window sizes, which means the models with the lowest values of Adaptive Comfort Degree-Days. The ideal window size was also identified in the floorplan, in this analysis only the fourth floor was considered as the first floor had uniform results (table 5). These results were classified by window size, as follows: 0,60 to 1,20m² - small; 2,60 to 1,60m² - medium; 3,30 to 4,00m² - big.

By analyzing table 5, we notice that for all orientations apartments on the first-floor require small windows (from 0,60 to 1,20 m²). It is also clear that for apartments on the fourth-floor the ideal windows for orientation 0° was similar to the recommendation for the 135°, and the orientation 45° should have windows similar to the 90°. The dormitory of the fourth-floor presented similar needs for every orientation, and the most frequent window size was medium. Only at the orientations 45° and 90°, the dormitory of apartment one required small windows as the second best (1,20m²). The best window sizes for the living room and kitchen are different for each model. At 0° and 135°, the ideal windows are from 0,60 to 3,30m². The wide range of sizes presented in these orientations can be explained by the winds predominance, as it becomes more clear in figure 2-c.

By observing the floor plan shown in table 5, it is clear that the courtyard does not influence the ideal window size, since all the windows with view to the interior (the ones on the recess and those on the courtyard) show similar behavior. Nevertheless, it is relevant to notice that this situation provides unreliable and poor quality ventilation because the airflow from cross the neighbour's apartments before arriving at the apartment located leeward on the courtyard.

Subtitle: small 0,60-1,20m² medium 1,60-2,60m² large 3,30-4,00m²

*Average of the two bedrooms

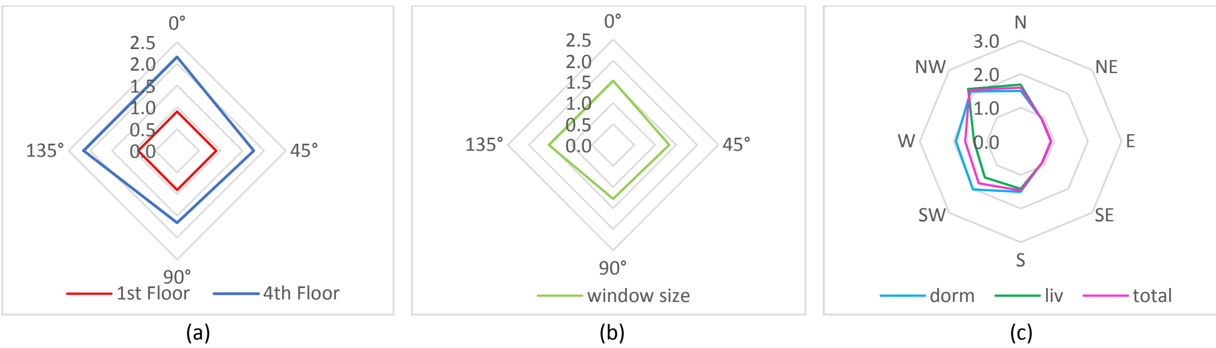

Figure 2. (a) – average ideal windows area of the rooms on the first and fourth-floor [m²]; (b) -average ideal windows area for different buildings orientations [m²]; (c) – average ideal windows area for different window orientations [m²].

Figure 2-a shows that window sizes for the first-floor are smaller than for the fourth-floor since apartments on the first-floor need less ventilation to reach the ideal temperature due to contact with the ground. In addition, windows on the first-floor do not show any influence of the building orientation, which was not the model for the fourth-floor. In the first-floor, the influence of the wind attack angle is reduced because at this height the wind speed is low for all directions.

In respect to the results concerning orientation, figure 2-b shows that for building orientations 0° and 135° the windows should be bigger. This phenomenon is better explained through figure 2-c, where it is clear that apartments oriented to northeast, east and southeast require smaller windows. These orientations coincide with the prevailing wind and also receive less solar radiation. It is worth of noting that the behavior of the living room and the bedroom are very similar.

Conclusion

Thus, it was possible to evaluate the sizing of openings from the viewpoint of thermal comfort in naturally ventilated buildings, indicating those models with the best thermal performance, therefore contributing to improve the knowledge of the openings design and consequently to reduce energy costs.

For the Piracicaba climate, the wind does not blow predominantly from a single direction but from a range of angles, thus we considered the range of wind predominance to evaluate its influence on different window dimensions. Therefore, at the process of designing windows in different climates, it is recommended to observe if this is a similar model or not. Even when the occurrence of prevailing winds is low, this direction influences the ideal window size, which means that windows oriented to the prevailing wind can be smaller than the leeward ones.

Analyzing the window size with respect to the floor height, it is noted that at the first-floor the optimal windows were smaller than for the fourth-floor and the ideal windows on this floor show little influence of their orientation. This happens because at the first-floor temperatures are milder due to contact to the ground and its lower exposure to the sun; on the other hand at the top floor the heat gain through the roof causes increased temperatures, thus requiring higher wind speed.

In addition, even if the courtyard has no influence on the size of the windows, it has not a reliable ventilation.

The sun exposition plays an important role on window dimensioning because window that receive direct sunlight tends to overheating, and consequently window size must be reduced, but with shading it is possible to have large windows improving the airflow. In some situations, when more ventilation is desirable but the large windows would cause overheating, shading devices should be considered. In this regard, future work could evaluate the influence of window shading devices on the ideal window sizes.

It is worth noting the strong influence of the climate on the results, so it is necessary to be very careful in applying these conclusions about the temperature ranges to other climates. Although this study only addresses one building geometry, the same methodology can be applied to other formats thus expanding the scope of the results.

Analysis of sustainable collective housing in Jijel, Algeria: evaluation of resident satisfaction

Mia Mehibel[1] and Adrian Pitts[2]

[1] Researcher, School of Art, Design and Architecture, University of Huddersfield, UK, correspondence email Mia.Mehibel@hud.ac.uk;
[2] Professor, School of Art, Design and Architecture, University of Huddersfield, UK, email A.Pitts@hud.ac.uk;

Abstract: Worldwide, 40-percent of all energy used is consumed in the buildings sector. In this context, most developed countries have orientated their research and design to encourage energy efficient or green buildings; however comparable sustainable architecture is still in its early stages of exploitation in many developing countries. There are many pressures that can reduce emphasis on sustainable design in developing countries; for instance over one billion people worldwide still lack adequate shelter and suffer poverty, and Algeria is one example facing a pressing housing shortage. The socialist government that came to power after Algerian independence in 1962, considered this problem to be the major issue and this resulted in the initiation of major building programmes for social multi-storey housing estates. This research described in this paper reports on the quantitative and qualitative analysis of collective contemporary houses built in the city of Jijel. Detailed questionnaires were used with 30 residents in Jijel. The results showed that residents were more concerned with space issues while thermal comfort was neglected. Another interesting finding was that most of the interviewed residents would prefer to participate in the design of their houses; a process that would enable them to improve space and thermal comfort.

Keywords: Green buildings, sustainable dwellings, housing shortage, Algeria.

Introduction

In addition to enhancing human life and comfort, urbanisation and industrialisation have serious negative impacts on the environment. Global warming, industrial waste, and air pollution adversely affect the ecological balance (Memon, 2008). The most common definition of sustainability is 'meeting the needs of the present without compromising the ability of future generations to meet their own needs'. This definition was first used in 1987 in the Brundtland report entitled "Our Common Future" published by the United nation's World Commission on Environment and Development (WECD, 1987).

Worldwide, 40-percent of all energy used by humans is consumed in buildings sector. The increasing need to make buildings more energy-efficient can be explained by the limits of natural resources, national security, environmental concerns, climate change, social justice, and rising costs (Ramsdell et al.). In this context, most developed countries were oriented to research and design of 'energy efficient' or 'green' buildings since the energy crisis of 1970 (Zhu and Lin, 2004). However, there are many pressures that can reduce emphasis on sustainable design in developing countries; for instance over one billion people worldwide still lack adequate shelter and suffer from poverty (United Nation, 2012). Algeria is one example of a developing country facing a pressing housing shortage. The problem threatens cities with the spread of informal settlements and slums around all Algerian cities. The main causes of this dilemma were the acute rural exoduses to cities which took place in two different periods. The first was after independence in 1962 when people grouped in urban areas in order to ameliorate their living conditions(Benmatti, 1982). The second was during the Algerian civil war between 1990 and 2000 when people escaped from rural areas to live in more secure urban areas. However, not all new informal settlements are created by rural migrants as there has also been population growth. Consequently, Algeria witnessed a large spread of multi-storey housing after independence in 1962 (Daara, 2009).

Housing policy in Algeria

The new national housing policy adopted by the Algerian government since the five year plan of (2000-2004) aimed to improve living conditions for all social groups with special emphasis on low income groups in order to achieve better space occupancy and slow down rural exodus. This policy was based on diversifying housing types according to households' incomes(MHUV, 2012). Consequently, new housing types were established in order to meet the needs of intermediate income households who were not allowed to benefit from the social rental houses designated to low income families and could not afford to buy the expensive promotional (luxurious) houses. However, this policy failed to respond to the real demand of residents. Table 1 shows the ratio of demand and offer for different housing programmes in the province of Jijel. It indicates that there is a deficiency in housing offer in comparison with the number of demands, the number of demands is more or near double the cumulated programmes excluding Promotional public houses (LPP).

Table 1:*The demand and offer of collective housing programs in Jijel until 31/12/2016. (Source: Based on data from Housing department, Jijel)*.

Housing Programme	Cumulate (Offer)	Demand Number	Ratio Demand/Offer
Social Rented (LPL)	16981	40972	2.41
Promotional assisted (LPA)	6727	14700	2.18
Rent to sell (LV)	3600	7074	1.96
Public Promotional (LPP)	1000	426	0.42
Total	28308	63172	2.23

In fact, citizens are unable to benefit from government assisted houses due to households' low incomes and sometimes unemployment. Also, there is a big gap between salaries and housing prices. The ratio between the price of a house and the average annual income of a middle-income family is 9, which means that the family has to save her annual income for 9 years to be able to afford an LPA house (Bellal, 2009).

Survey for the evaluation of residents' satisfaction

Collective housing dominated the urban fabric of the city of Jijel without any consideration to the aspects of sustainability such as comfort, climate adaptation, the use of construction materials, and the respect of social and cultural values of the Algerian society. In fact, occupants' needs must be combined with modern technologies and sustainability potential in traditional architecture in order to create new sustainable cities that suit present and future expectations of the inhabitants (Mehibel et al., 2014). Consequently, the research project, of which this paper reports a part, is involved in assessing potential residents' satisfaction and integrating their views process. This research included quantitative and qualitative analysis for collective contemporary houses in Jijel using comparative analysis through descriptive, qualitative and spatial analysis for the case studies. Therefore, a number of detailed interviews have been carried out with thirty residents from three different collective housing estates in the city of Jijel, and the results are reported here.

The qualitative survey is divided into four different parts: Exterior environment, spatial comfort, thermal comfort and housing preferences. Each part contains a number of closed ended questions and open ended questions in order to evaluate the inhabitants' satisfaction of the design of their dwellings. The three case studies are governmental housing estates which are: Site 1 is the 400 social houses estate (400 LS) this kind of houses is entirely financed by the government; it is designated to low income households living in very bad conditions or those who don't own a suitable house. Site 2 is the 170 social participatory houses estate (170 LSP); this type of houses is designated to households with intermediate income who are eligible to a governmental non- refundable financial aid. Site 3 is the 375 promotional (Luxurious) houses estate (375 LP); this kind of houses is intended to comfortable households or individuals who are not eligible for any type of governmental financial aid.

Exterior environment

When the residents of the three estates were asked for the perception on the presence of green spaces, children playgrounds and squares for inhabitants where they can be gathered; most of the inhabitants considered that there is very little. Some inhabitants of the ground floors enclosed the surrounded areas adjacent to their blocks and plantedthem which created some sort of private external green spaces (Figure 1). In fact, this act is not permitted by the local municipality as such places should be public and shared between all residents. Also, the majority of respondents in the three estates claimed that there are no play areas and the children are playing in car parks and undesignated areas between blocks (Figure 2).

Figure 1: Public areas enclosed by residents of ground floor to make private green spaces in: a) 400 LS site and b) 375 LP site.

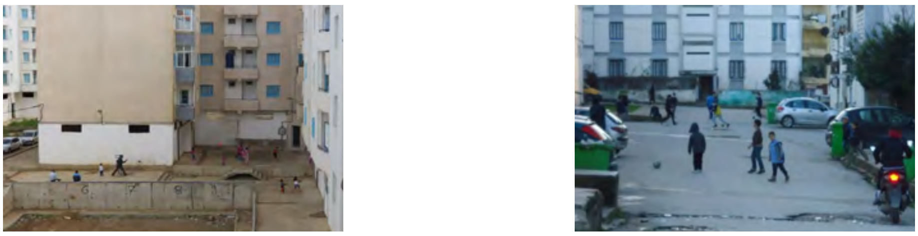

Figure 2: General and street views: a) 170 LSP and .b) 400 LS site.

Figure 3 shows children's playgrounds in the 375 LP estate which are in a poor state, this problem can be seen in many other collective housing estates in the city of Jijel. Residents can be blamed for such behaviour and the government should take action for the destruction of public places.

Figure 3: Destroyed children playgrounds in the375 LP estate.

The majority of respondents considered that there are no squares or areas where residents and neighbours can gather. When asked if they preferred having such areas, most residents agreed; only 20% in the 400 LS and the 375 LP estates disagreed; they were women who for cultural reasons prefered not to have such areas close to their houses in order to have more privacy in using the balconies.

Spatial comfort

Housing organisation preferences

All the apartments are organised around a corridor. However, The vast majority of respondents in the three estates (80% in 170 LSP and 70% in both 400 LS and 375 LP estates) preferred to have the dwelling organised around a central space rather than a corridor. They justified their answers that this organisation provided more space, better air circulation and more accessibility to the other parts of the house.

Size of the house

In the two social estates (170 LSP estate and 400 LS estate), the majority of respondents (70%) found the size of their apartments too small for their family needs, and all of them preferred to have one or two extra rooms to be used as a room for children and a dining room. Interestingly, 60% of respondents in the third estate (375 LSP) considered that the apartments are of the right size for their family needs 20% of them stated that the apartment is big and only 20% considered their apartment small. Just 20% of the respondents desire to have an extra room to receive guests. Table 2 represents the total living area of houses in the three estates. It is obvious that total living areas of the promotional flats is similar to social houses. However; residents in the promotional estate are more satisfied with the size of their houses.

Table 2: Area of the houses.

Estates	Living area (m²)				
	F3 (Living + 2 bedrooms)			F4 (Living + 3 bedrooms)	F5 (Living + 4 bedrooms)
170 LSP	70,39	68,45	69,99	-	-
400 LS	65,21			76,68	88.15
375 LP	68,66			80,95	93,40

Size of the different rooms

The majority of respondents from 170 LSP and 400 LS estates find the size of the living room and the other bedrooms small and all of them find the shape inconvenient to accommodating the furniture. In some cases they had to swap between the bedrooms and the living room in order to get more space area for children room or to get more space by rearranging the furniture in parents' room.

Conversely, in the 375 LP estates, the majority of respondents stated that the bedrooms have the right size and they can arrange the furniture the way they want. Also, just half of respondents find the size of the living room small and the other half find it about the right size. However, 70% of respondents find the shape inconvenient to arrange the furniture. Table 3 shows the area of the living room in the estate of 375 LP (16.99m^2) which is very small for a promotional house and even smaller than the area fixed by the Algerian regulations for social rented housing which is 18 m^2. That explains the fact that most residents close the loggias in order to gain more living area in the living room.

Table 3: Area of the living rooms.

Estates	Living area (m^2)		
	F3 (Living + 2 bedrooms)	F4 (Living + 3 bedrooms)	F5 (Living + 4 bedrooms)
170 LSP	19.66	-	-
400 LS	14.96	14.96	14.96
375 LP	16.99	16.99	16.99

Residents of the three estates where asked if there are any other activities they cannot do in their houses because there is not enough space. In 170 LSP estate, the number is more significant than the other estates (70 % in 170 LSP versus 40% in 400 LS and 375 LP estate) which mean that residents in 400 LS and 375 LP estates are more satisfied in terms of space and this can be related to the number of bedrooms. Some respondents answer that they cannot practice sport, or have family gatherings during social and religious occasions or receive guests. Table 4 shows that the areas of bedrooms in the three estates are very close even with the promotional apartments. However, people in this site are more satisfied in terms of spatial comfort as they have more number of bedrooms. So it can be concluded that residents do not need bigger areas of bedrooms but they want a larger number of bedrooms.

Table 4: Area of the bedrooms.

Estates	Living area (m^2)			
	Bedroom 1	Bedroom 2	Bedroom 3	Bedroom 4
170 LSP	12.31	12.74	-	-
400 LS	12.25	13.30	11.47	11.47
375 LP	11.02	13.34	13.80	12.45

Size of the kitchen

The vast majority of respondents in the three estates find the size of the kitchen small and they don't have enough space for work and to arrange different equipment. In some cases, residents in the three estates have to use bedrooms, corridor, bathroom and balconies in order to put the rest of their electrical equipment. Table 5 shows the area of the kitchen in the three case studies, it also shows that the kitchen in the 400 LS estate is smaller than the other sites.

Table 5: Area of the Kitchen.

Estates	Area of kitchen (sqm)		
	F3	F4	F5
170 LSP	10.41	-	-
400 LS	07.56	07.56	07.56
375 LP	08.29	08.29	08.29

Importance and use of the kitchen's loggia

The majority of apartments in the three estates have a loggia connected to kitchen. The loggias are used as an arrangement space, a place to dry clothes, put water tank, washing machine, the fridge and tabouna which is a cooker for traditional bread; some of them have been closed in order to gain more space to the kitchen (Figure 4), which shows one of the inconvenient consequences of closed loggia; the resident had to use the corridor to dry the clothes in rainy days (Figure 5).

Figure 5: Closed loggia in 400 LS estate.

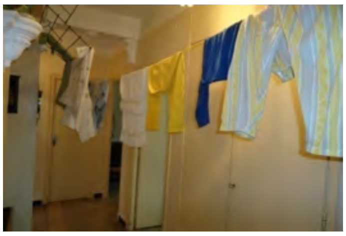

Figure 4: Drying the clothes in the corridor in a rainy day(closed loggia in the 400LS estate).

Thermal comfort

In this section residents were asked of their feeling of comfort in both summer and winter periods.

Summer comfort

More than half respondents in the three estates answer that they feel comfortable in their houses in summer. However, in 400 LS and 375 LP estates mainly all respondents are using air conditioners which opposite their feeling of comfort. On the other hand, just 10% of respondents in 170 LSP estate are using air conditioners which make their feeling of comfort more correct.

Winter comfort

In 170 LSP estate, all the interviewees don't feel comfortable in winter due to cold and the lack of natural gas to use heaters. Contrary to the other two sites where nearly all respondents stated that they feel comfortable in their houses during winter but all of them are using heaters.

Energy consumption

The results found in thermal comfort analysis help explain the energy consumption:

- The consumption of electricity in the 400 LS and 375 LPestates is approximately doubled in summer in comparison to winter as they all use air conditioners. However, the consumption of gas is much higher in winter than in summer as they all use heaters.
- In the 170 LSP estate, the price of electricity is similar between summer and winter as the majority of them don't have air conditioners.

Housing preferences

When residents were asked about their housing preferences:

- The majority of respondents wanted to change the house to an individual villa with a garden.
- More than half respondents wanted to participate in the design of their houses.
- In the three estates residents suggested to build cities with small number of houses, bigger apartments with green areas and children playgrounds.

Results

- The only different criteria between the studied social and promotional estates is spatial comfort; as people in the promotional estate are more satisfied in terms of space than the others; however, people want extra rooms to gain more comfort.
- Thermal comfort is not considered in the design of houses. However, residents were not concerned about it as they can afford their comfort with energy consuming appliances.
- Although, people are satisfied by their apartments in the example of the promotional estate, they prefer to have an individual villa with a court or a garden; and most of the interviewed residents prefer to participate in the design of their houses.

Conclusion

Housing policy in Algeria fails to respond to residents needs in both quantitative and qualitative levels. In fact, many problems are facing the housing sector and the most important issue is the serious imbalance between housing demand and the available supply. Unfortunately, a significant increase in the number of houses being produced is not possible, particularly after the economic crisis declared in the country in 2015 caused by the sharp decrease of oil prices. Also, the slowness of administrative procedures in most cases is one of the important causes that delay the completion and then the delivery of new projects.

In order to reduce the cost of projects the government can:

- Make better use of local workers, developers and professionals rather than importing them from overseas, an example of Rent to sell houses projects in Jijel; a total of 2000 houses are under construction by an international company using more than 200 foreign workers. The government could train local workers and professionals and this will reduce the rate of unemployment and also reduce the cost of houses.
- Integrate and encourage sustainable behaviours such as the use of recycled materials and renewable energies which can reduce energy consumption in different phases of housing projects.
- Integrate the new technologies and techniques in all fields of work in order to speed the administrative procedures in all stages of projects: Choice of land plot, design, and construction in order to deliver the houses in their deadlines.

In terms of qualitative issues; certainly it is not always possible to satisfy all people's needs but the government can find a method of work to integrate civic society in the process of design such as by surveys to assess the needs and preferences of future inhabitants.

- In terms of design; the exterior environment should be provided with green spaces, secure children playgrounds and squares for residents to be gathered, also, the state should penalise and strictly prohibit any behaviour that damages the exterior environment.
- The design of houses should consider bioclimatic parameters in order to build passive, low energy consuming buildings.
- The form of social LPL and LPA houses has been fixed by the government to a three-room apartment (living+ 2 bedrooms) with a little increase in the living area of the house from 68 m^2 to 70 m^2 ± 3%; this initiative aimed to avoid the increase in assisted

Abstract: The demands for cooling in non-domestic buildings are rising throughout the world. This paper is concerned about the environmental performance of primary schools in hot climate, which affect the pupils' health, education and productivity. The study focuses on the thermal comfort within classrooms and the improvement of the building fabric by provision of a passive cooling system, as well as other passive ways that improve the classroom's thermal performance. It is common for school classrooms often to have poor thermal comfort and poor indoor air quality (IAQ).Computational fluid dynamics (CFD) simulations have been performed in order to examine the behaviour of the cooling wall system in reducing the effect of outside air temperature under different wind velocities in the summer period. Furthermore, different reductions in heat flux with air velocities have been examined by comparing the performance of the wall fabric system, both with and without passive cooling, and with the same geometry and the same physical characteristics and parameters. The results demonstrated that the proposed passive cooling, in conjunction with outdoor air, could significantly reduce the temperature and enhance the thermal comfort inside the classrooms. The performance of the natural wall ventilation with passive cooling system is an improvement in terms of cooling the classroom compared with the non-passive cooling wall system, since it allows the peak air temperature to decrease the temperature inside the classroom zone from 35-44C° range to just 26-22C° (5–18% to 50–61%) compared with peak temperature at 46-48C°

Keywords: Building Fabric, Passive and Low Energy Architecture, Ventilation, Thermal comfort.

Introduction

Constructions, buildings and, in particular, school buildings in developing countries such as Sudan are normally designed with little consideration to the effects of the climate. It has been established that the most significant purpose of a building is to deliver thermal comfort to its occupants. This becomes more important when it comes to the construction of school buildings, where the pupils need thermal comfort for their health, learning ability, and productivity. School buildings are among the most important buildings, and the majority are not given enough care and consideration. Children at primary level are very vulnerable to the indoor environment; this will affect their health and will not help them improve their skills. The climate is hot in summer and cold in winter. Classroom temperatures on a summer afternoon day can reach over 37C°-42°C. According to ASHRAE, the recommended thermal comfort for the dry "bulb" room temperature is around 22°–23°C with 50% relative humidity. The building envelope is the interface between the outdoor and indoor environment, and the amount of the energy required to maintain thermal comfort in buildings can be determined. One of the best options for saving energy in retrofitting the project and existing is through designing the building envelope in an energy conscious way. Educational buildings, i.e. school buildings, have particular concerns and the issues around energy require more attention because of their specific characteristics compared with other buildings. In fact, educational buildings represent a special case, mainly because of their specific occupants, activities and occupancy patterns, and knowing the students/children spend 25% of their time at school building Calautit and Hughes (2016) ,Barrett, Davies et al. (2015). Educational building is a good opportunity to promote building energy efficiency and environmental quality towards the pupils or occupants (P.O. Fanger 1970, Barrett, Davies et al. 2015). The most effective way to increase thermal comfort and energy efficiency in buildings is by means of acting on the element which constitutes the exterior–interior exchange system, controlling the heat transfer through the envelope (Dominguez et al. 2012.). The basic principle of the evaporative cooling wall system is achieved by the exploitation of the latent heat of evaporation of water to reduce the sensible heat of air and consequently its temperature. Based on this method, both direct and indirect evaporative cooling can be developed. When adapted, this principle dramatically decreases and sometimes even cancels out the cooling load in hot and warm climates (Carbonari et al. 2015). This paper addresses the potential of introducing passive technique to control the temperature and thermal comfort inside school buildings in hot dry climate. Moreover the develops and produces a base case design concept for passive cooling to reduce the temperature inside the classrooms, to identify and explore the possible effectiveness of adding passive cooling in the classroom fabric, in terms of reducing the temperature and enhancing.

Methodology

Description of the proposed concept

In the base cases design for the porous ceramic design, the ceramic itself is closed and the system is designed to have openings at the top and bottom of the wall. The schematic geometry of the system is shown in figures 1. The structure on the left is the wall with the inlet, the middle part is the porous ceramic and the part on the right is the indoor wall structure with the outlet in the bottom of the wall. The inlet should allow ambient air to enter, while the outlet should allow airflow directly into the classroom or the building. Air coming from the outdoors passes through the porous ceramic evaporator where it is cooled by evaporative cooling, and is drawn downwind by the bouncing effect and then enter into the indoor spaces where the cooling effect is required

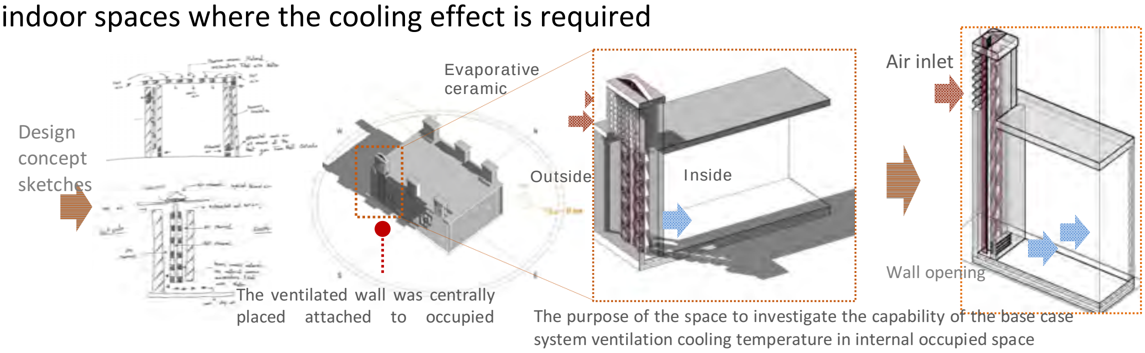

Figure 1-The base case primary design 3D perspective added to occupied space [classroom].

CFD Analysis -Design Detailed of the Geometry

The ventilated wall structure of (2.5 m) height with top and bottom opening with attached cooling wall is, centrally placed and attached a small occupied space with height, width and length of 1.5m, 2.5m and 1m. The purpose if this was to investigate the capability of the base case design in cooling and ventilation of the occupied space. The ventilated wall consists of environmental inlet on one side of the domain and opening at the top and bottom of the wall. The wall of occupied wall has an outlet opposing boundary passive cooling wall. The computational grid used for calculating the airflow and the heat flux within the ventilated cavity had a quadrilateral mesh with dimensions 0.5cm by 1.0cm within all the domains which contain air channels, the PCW [passive cooling wall], the outer layer of the subject facade, the inner wall space and the outer classrooms. A three-dimensional simulation model was developed to establish the natural ventilation flow path and the temperature distribution throughout the space of the classroom as demonstrated in figures 2. Passive cooling using a ceramic wall can be described as the heat flux in the fluent software. It is located between the external wall and the internal wall of the classroom

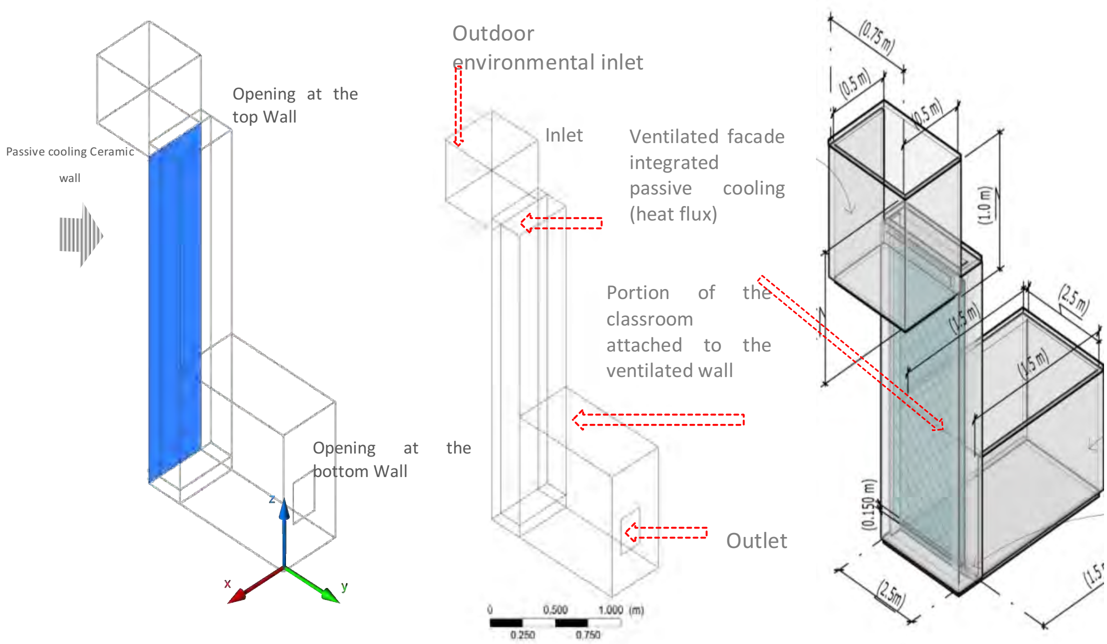

Figure 2-The 3D geometry of the ventilated facade integrated cooling wall used in the simulation.

Mesh description

The 3D CFD simulation model was built using meshing tools within ICEM. The meshing strategy was used to create conformal structure mesh that was considered as hexahedral cells. The benefit of using the hexahedral mesh was that the iteration run more smoothly and convergence could be reached more quickly, figure 3.

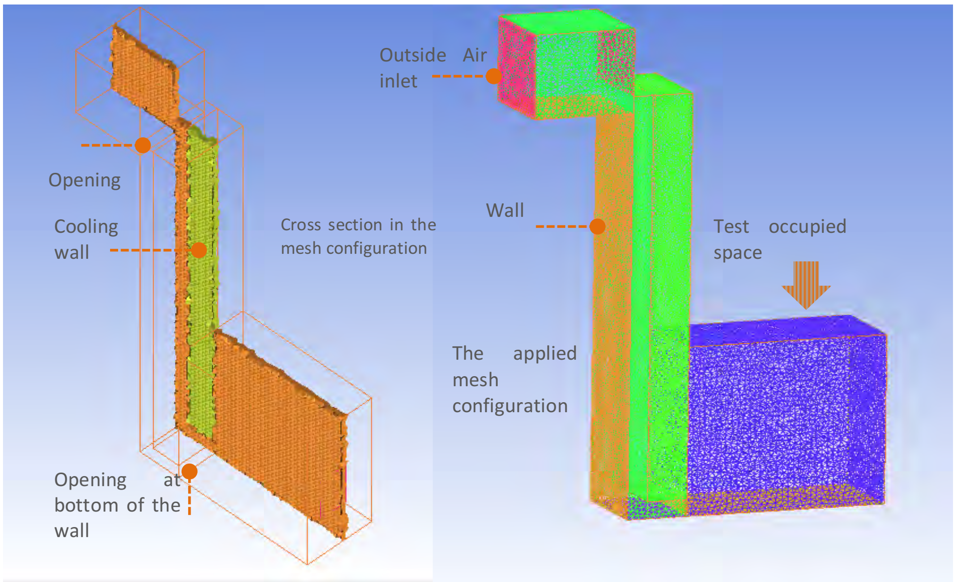

Figure 3: reduced scale perspective view of the base case geometry in its computational domain

Description of Boundary conditions

Cooling wall effect

The CFD is able to prescribe the surface heat flux inside the wall system of the classroom, as well as specifying the generated volumetric cooling rate of the cooling wall (Ibrahim Elfatih et al.2003). An equivalent heat flux of -5W/m2 was set to represent the 5, 10, W/m2 in their experiments.

Air temperature boundary condition

A velocity boundary condition of 0.2m/s, 04m/s, 0.6m/s and 0.8m/s were defined at the environment air inlet attached to the wall. The base case based on the air temperature of 36 C, determined by the local weather of Khartoum. The aim is to evaluate the local comfort environment of the corresponding occupied space of the class room with the reference to the local temperature and velocity distribution The table(1) below demonstrates air density, specific heat and thermal conductivity, for the temperatures values of 36° defined at fluent software

Table 1-The boundary conditions of the air properties at 36 Temperatures (Engineering Box 2016)

Temperature °C	Density	Specific Heat	Thermal Conductivity
	- ρ -	- c_p -	- k -
	kg/m^3	kJ/(kg K)	W/(m K)
36	1.127	1.005	0.0271

Simulation Results and discussion

Temperature variation

The effect of the incoming hot outside air on the cooling source resulting from PCW also had to be taken into account, and which was defined in the Fluent software as the heat flux. Figures 12 and 13 illustrate the behaviour of the temperature inside the wall at five different planes and locations parallel to the wall. The maximum temperature of 39.9°C was observed at the top of the wall. The surface temperature at the interior reference plane inside the classroom was set to a slightly lower value, while the lower temperature occurred at the bottom region of the plane, as seen in the figures. (Horizontal and vertical) .As can be seen in the results of the whole system, stratification of the temperature was identified, with higher temperatures externally at the top and lower temperatures at the bottom of the cavity in the wall. The results show the influence of the passive cooling air from the wall. The effect of the temperature horizontally and vertically in different positions are shown in Figures 4 and 5, and there is well-defined change from hot air to cold air indicated by the arrow in Figures below which demonstrated the occupied zone in the range in the comfort temperature

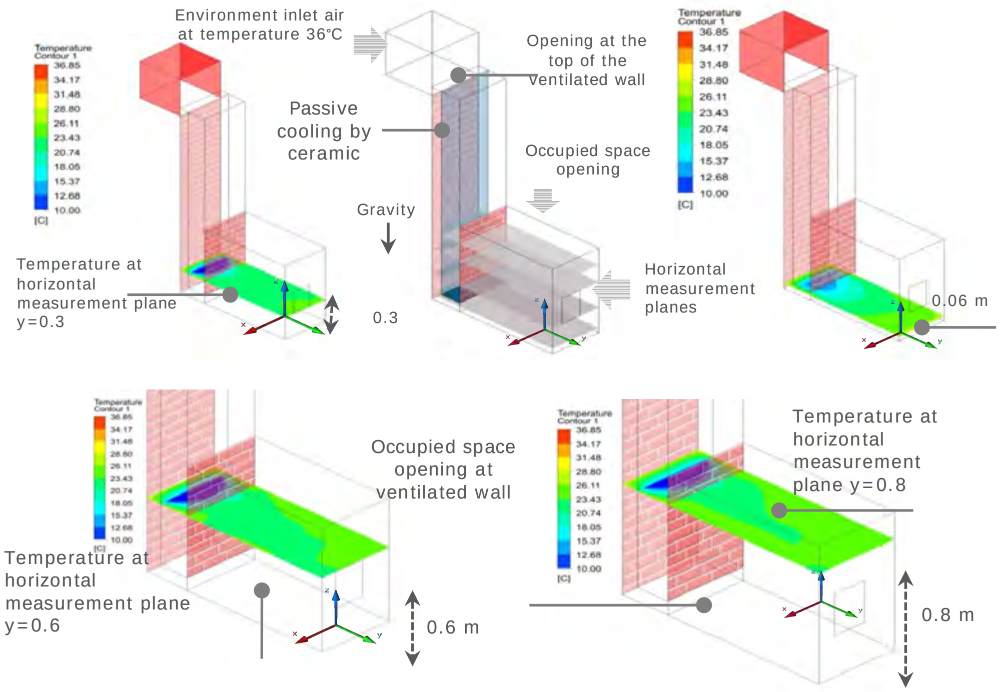

Figure 4-Temperature profile for ZX section through the classroom at different

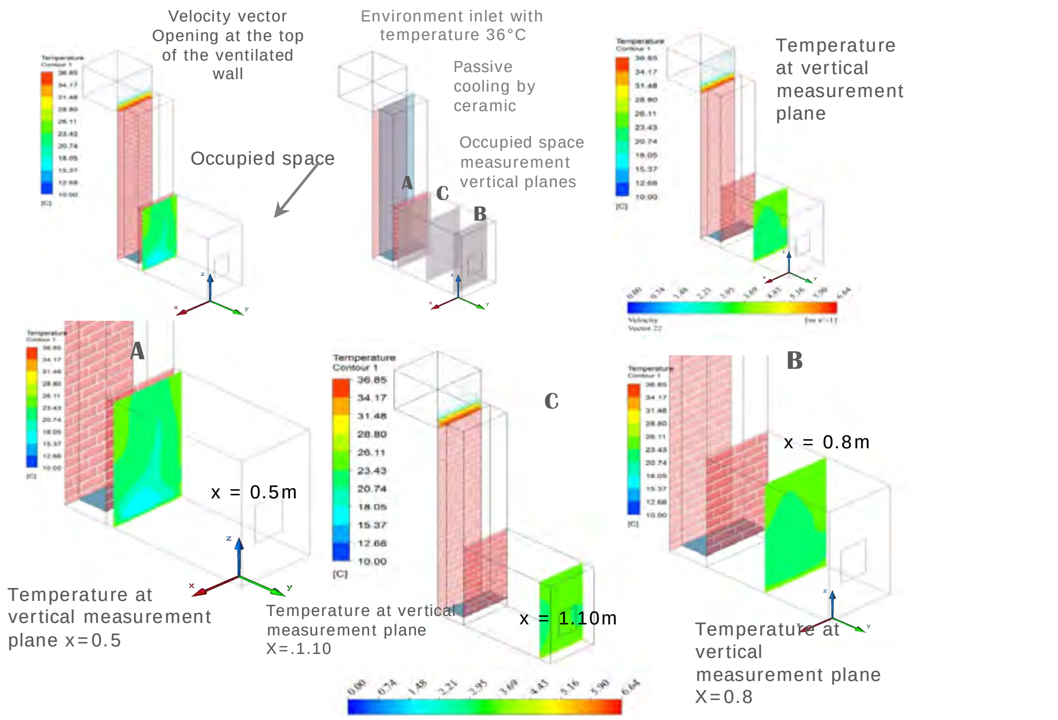

Figure 5-Temperature profile for YZ section plane through the classroom at different dimensions – demonstrates how the temperature decreases with passive cooling compared with the air entering the wall

The maximum temperatures are recorded with the ventilated wall without passive cooling reached values up to 40C° in the measurement plane, while the ventilated wall with passive cooling and have reached values close to the comfort temperature of 22C°-25C° as shown in the figure 6 and 7below with regards to the air movements within the system, the external wind flows normally, within the ventilated wall, with cool wall, from the top to downstream. It means that the air velocity within ventilated wall is mainly affected by the external wind. It is possible to highlight that when the wind velocity increases, the air velocities within the ventilated wall and in the space increased too.

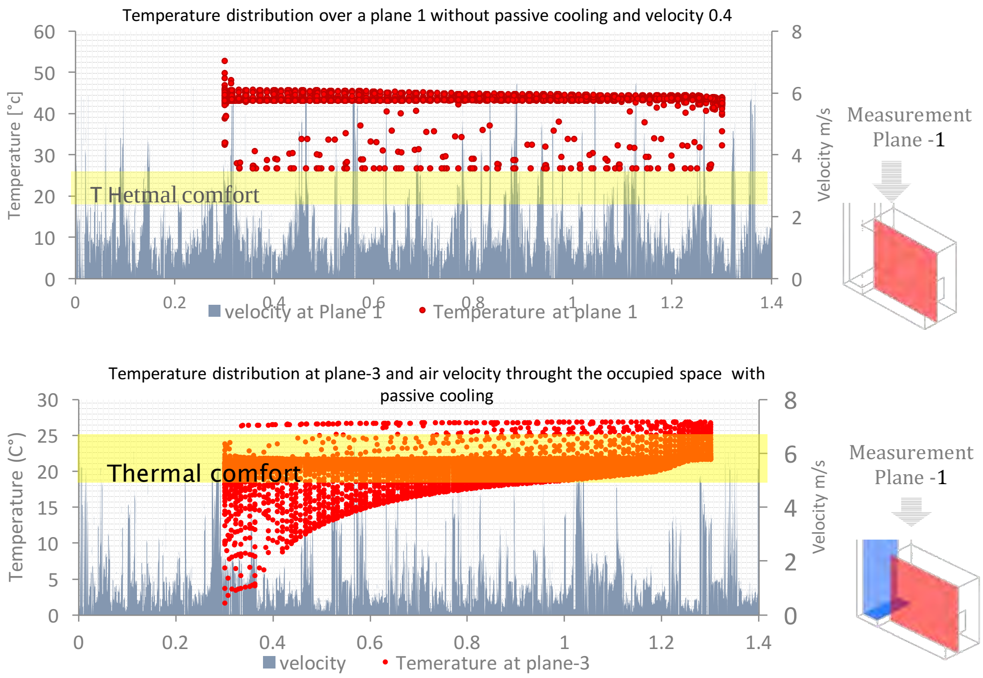

Figure 6: The temperature and velocity results in the measurement planes 1 at the occupied space with and without passive cooling at the ventilated wall

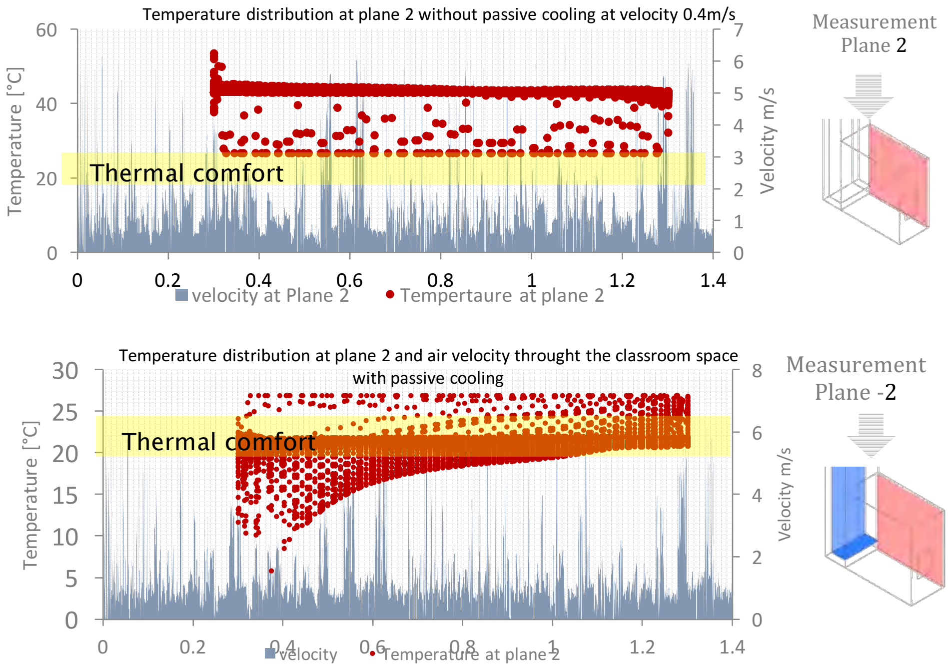

Figure 7: The temperature and velocity results in the measurement planes 2 at the occupied zone with and without passive cooling at the ventilated wall attached the base case design.

The analysis of the results indicated that cooling effectiveness improve with decreased when adding passive cooling to the wall fabric. It has also shown that ventilated cooling wall has higher performance by reducing the temperature by 61 % at 0.2m/s air velocity compared with other air velocity values. So a certain amount of air will pass by without contact the cool surface, figure 8. The results agree with (Jomehzadeh et al. 2016), stated that at low air velocity om 0.2 and 0.4 m/s the temperature gradient is high and decreases when air velocity increases.

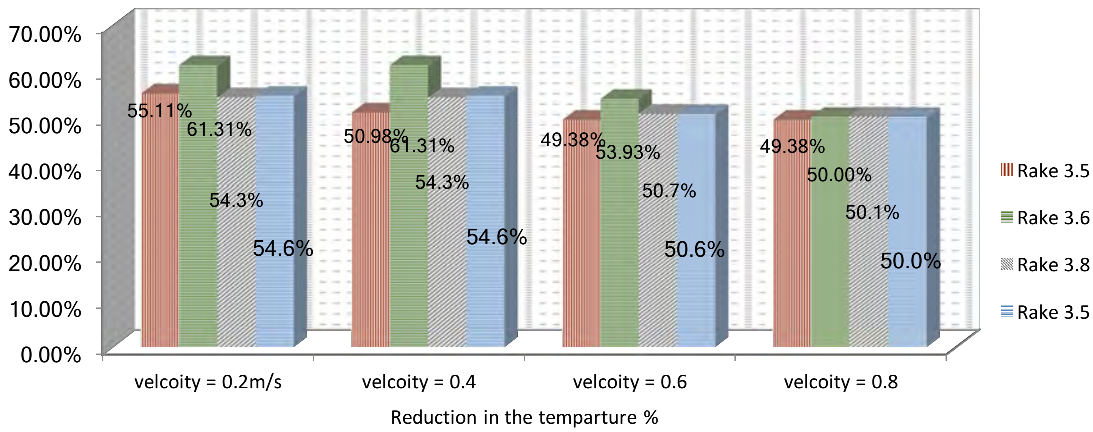

Figure 8: measurement rakes at the occupied space. (b) Temperature distribution at the measurement rakes along with air velocities (c) Reduction in the temperature at measurement rakes

Conclusion

The base case of the PCW was examined to assess the influence of cooling wall when added to the building fabric. The system has been assessed under varying inlet air speed. It was found that the PCW (passive cooling wall) was able to reduce the occupied room temperature compered to ventilated wall without passive cooling. For the base case with ventilated wall without adding passive cooling, the maximum temperatures are recorded in the measurement planes along with the width of the classroom space, are 39C°-41C°, compared with ventilated wall with passive cooling reach values at comfort temperature vary between 22C°-25C°.Overall, when comparing the effect of passive cooling wall PCW at envelope, we can observe a reduction in the temperature and consequence reduction in the classroom zone, which achieved thermal comfort level. The maximum total reduction in the temperature inside the occupied zone decreases between 49%-to 61 % at measurement rakes and plane, compared with only between 8%-18% reduction has been recorded in the temperature distribution at the measurement planes and rakes at the classroom space. Moreover such a comparison allows pointing out that, the PCW not only reduce the outside air temperature, but also shift the thermal wave that occurs in the envelope. The results showed the capability of the system in reducing air temperatures and deliver cooling following the addition of supplying recommended fresh air rates at the occupied space. As a final point, ventilated wall with Passive cooling process remain one of the least expensive technique, environmentally clean, fresh supply air and natural fragrance of air to bring dry bulb temperature to a move comfortable range particular in hot and dry climate.

Principles and Tools for Bioclimatic Building Design - an applied review and analysis in cold climates –

Maria Coral Ness[1]

[1] Energy and Environment Group, Department of Architecture and Technology, Faculty of Architecture and Design, NTNU, Trondheim, maria.coral.ness@ntnu.no

Abstract: The comparison between climate and comfort represents a fundamental step for the implementation of energy efficiency in buildings. It determines the design strategies that are best suited for a specific climatic context, as well as the level of architectural complexity. In cold climatic contexts, this would suggest the use of compact shapes and extremely airtight and well-insulated envelopes, in order to minimize heat losses. However, when combined with high internal gains, these measures might cause overheating problems in the warm and transitional seasons. That is especially the case of office buildings, where mechanical cooling is included as default even in cold climates (Norway), drastically increasing their energy use. It is therefore becoming a necessity to consider there the adoption of passive strategies for cooling, traditionally identified with warmer climates. The aim of this paper is first to revise the existing methods and tools for bioclimatic building design, and then reflect on how these could be applied to assess the suitability of different passive strategies in relevant building cases. The first part of this research will be conducted through literature review. The second part will analyse relevant buildings in cold climates with especial focus on passive design, to reflect on how they could have been affected by the use of these bioclimatic building design tools.

Keywords: bioclimatic building design, passive strategies, thermal comfort, psychrometric chart, pre-early design stage

Introduction

As Reyner Banham postulated in his *Architecture of the well-tempered environment* (Banham, 1984), indoor comfort can be provided passively by the building, or actively by the use of energy. However, in order to design energy efficient buildings, passive strategies must be considered during the early design phase (Lechner, 2009). It is important as well to have a close collaboration between architects and engineers throughout the building design process in what is called "Integrated Energy Design" (Heiselberg, 2007). This is fundamental to ensure their mutual understanding of the project and the means to reach their common goals, making use of their different competencies and ways of thinking and working.

Problem statement

Traditionally, the choice of passive design strategies for climatic control in buildings was based on experience (vernacular architecture). Even today, the most common methods in use in many countries are experience-based (rules of thumb, building standards and norms, etc.). However, new building morphology, typologies (e.g. office buildings), elements and materials are challenging these pre-design methods to move towards research-based approaches.

This is the case of the Building Bioclimatic Charts that were developed in the second half of the 20th century. The most extended one is the Givoni-Milne bioclimatic chart (Milne and Givoni, 1979), that studies how to reach thermal comfort within the psychrometric chart. It considers as well the potential for extending the comfort zone by means of different passive design strategies for climate regulation. However, being developed primarily for warm climates, this method seems to be insufficient for identifying the correct measures for climate adaptation in energy efficient buildings in cold climates, under specific conditions (Finocchiaro et al., 2010). The use of extremely stringent envelopes, in combination with the high internal gains characterizing office buildings, is implying here the use of strategies for passive cooling, natural ventilation and solar control, once identified with warmer climates.

Purpose and methodology

In the first part of this paper, it will be offered a short review of the principles and tools for bioclimatic building design, reflecting on their suitability for cold climates. This section relies primarily on literature review.

The second part studies how these methods and tools could be adapted and applied to assess the suitability of different strategies for climate control in office buildings in cold climates, with especial focus on passive design. This is explored in two different case analysis.

Principles and tools for bioclimatic building design

The term *bioclimatic building design*, combining *biology* and *climate*, refers to the design of buildings in accordance to the local climate (Olgyay, 1963). Thus, the architectural design is linked to the physiological and psychological need for health and comfort. It also implies maximizing the utilisation of the available natural resources, prior to any energy supplement by active means.

Climate classification

The most widely used system is the Köppen-Geiger climate classification (Köppen and Geiger, 1930), based on temperature and precipitation. Following this scheme, a *cold climate* (represented by the letter D, also called *snow*) would be represented by an average temperature of ≥ 10°C for the warmest month and ≤ 0°C for the coldest month (-3°C according to some authors). The discrepancy in the temperature range for this type of climate is due to the fact that this classification is done according to the natural vegetation systems that are associated to each climatic zone (to represent long term mean climate conditions). The correspondence between these and the monthly mean temperature of the coldest month differs in some cases, e.g. for North America and Europe (Wilcock, 1968).

In the last years, a more specific climate classification for analysing the performance of energy efficiency measures in buildings was developed for the ASHRAE (Briggs et al., 2003b). Primarily designed in the United States for the implementation of energy codes and standards in buildings, it may also be applied in design guidelines and energy analysis in buildings. It uses SI units and climate indices based on the Köppen-Geiger system (Strahler, 1969), so that it can be adopted anywhere in the world. According to this system, a *cold climate* would include those regions with heating degree days (HDD) 18°C > 3000 (Briggs et al., 2003a).

The ASHRAE climate classification seems more adequate for energy analysis in buildings in general, which makes it more suitable for the present study.

Thermal comfort

An internationally-accepted definition of thermal comfort is ”that condition of mind which expresses satisfaction with the thermal environment” (ISO, 2006)

The evolution of indoor thermal comfort theories follow a continuous line from the first studies on thermal neutrality (static approach) conducted by Fanger (Fanger, 1970), to the ones on adaptive thermal comfort (de Dear and Brager, 1998, Humphreys and Nicol, 1998), to the newest developments towards transient thermal environments with the theory of thermal alliesthesia (De Dear, 2011).

The *static approach* is an analytical method derived from the assumption that the combination of skin temperature and core temperature of the body provide a sensation of thermal neutrality. The heat produced by the metabolism should be equal to the heat loss from the body. This approach to thermal comfort is based on the Predicted Mean Vote (PMV) and the Predicted Percentage of Dissatisfied People (PPD). It is used mainly for mechanically ventilated buildings, where thermal neutrality is an achievable demand.

The *adaptive approach* considers that contextual factors and past thermal history modify thermal expectations and preferences of the occupants in the building, through behavioural adjustment and psychological adaptation. It is a numerical method, used for natural or hybrid ventilation in buildings, where the occupants are tolerant of a significantly wider range of temperatures, according to seasonality.

The *transient approach* investigates thermal pleasure derived from environmental or metabolic transients. The thermal alliesthesia studies how thermal comfort in buildings can improve by allowing a broader variety of thermal solutions in different spaces, or in the same space in different moments in the year (seasonality) or the day, to mimic natural environments. This theory is still in an early stage of development.

Being this research focused mainly on the implementation of passive strategies for climate control, the adaptive approach seems to be the most relevant one here. Nevertheless, since its range of application is for mean monthly outdoor temperatures between 10°C and 34°C, which are not that common in cold climates, the static approach to thermal comfort will be considered in this study.

Building bioclimatic chart

The concept of constructing buildings in accordance to the climate is as old as humanity, but bioclimatic architecture was not recognised as a science until the Olgyay brothers started publishing their studies on climate-conscious design. They created the first Bioclimatic Chart in the early 50s and developed it in their book *Design with climate* (Olgyay, 1963). It was based on a Cartesian system with dry bulb temperature and relative humidity as coordinates, and shows the potential of wind and solar radiation on human thermal comfort. This method is suitable for application outdoors or for lightweight buildings in warm and humid regions, where there is little difference between indoor and outdoor conditions (Givoni, 1969), since it uses outdoor temperatures directly in the chart.

Soon after, Baruch Givoni adapted those concepts in his book *Man, climate and architecture* (Givoni, 1969), to create the first Building Bioclimatic Chart (BBCC). He used an Index of Thermal Stress (ITS) to evaluate the human requirements for the indoor environment to which the building design should respond. He also changed the graphical representation by using the psychrometric chart, to better show the hygrometric relations between the different parameters, and in a way that was already accepted and widely used by engineers since 1904, when it was first published by Willis Carrier (Gatley, 2004). In addition, he plotted into the chart the comfort zone and the areas of influence of different passive strategies (Milne and Givoni, 1979). This BBCC is still today the most widely used around the world, and it has been constantly updated according to new studies on the field. However, being developed for residential buildings with relatively light construction in warm climates, it does not take into consideration the effect of highly insulated and airtight envelopes in cold climates, especially when combined with high internal gains (office buildings).

There have been developed several computer programs to help analysing the building bioclimatic chart for its application onto energy efficient design. Amongst them, Climate Consultant© seems to be the most complete, up-to-date and user friendly. Developed by the UCLA Energy Design Tools Group, it is based on the theoretical work by Givoni and Milne (Givoni, 1969, Givoni, 1994, Milne and Givoni, 1979) and intended to support the book Climatic Building Design by Watson and Labs (Watson and Labs, 1992). It uses weather data in EPW format (Energy Plus Weather, exhaustive selection of weather stations around the globe, freely available) and can analyse it according to four different comfort models in the Psychrometric Chart. Yet it was designed to be applied on residential or small non-residential buildings in mild climates (Milne, 2015).

Case analysis

With the increased consciousness of living on a finite planet, there has been a proliferation of low-energy buildings, passive house, net zero emission buildings, zero emission buildings or even plus energy buildings. However, this number becomes drastically reduced when limiting the sample to office buildings in cold climates, with a special emphasis on energy efficiency through passive design strategies.

The cases chosen here for their level of innovation and integration, while offering a very different approach to energy efficient design in cold climates are: Manitoba Hydro Place (new built, Winnipeg, 2008) and Powerhouse Kjørbo (refurbishment, Bærum, 1979-2014).

This analysis will focus first on the local climate, to then study the spontaneously created microclimate (because of the stringent envelope and high internal gains) and the selection of passive strategies for climate control. The results will be then compared to similar conventional solutions, to understand the effect of the choices made under the design process.

Manitoba Hydro Place

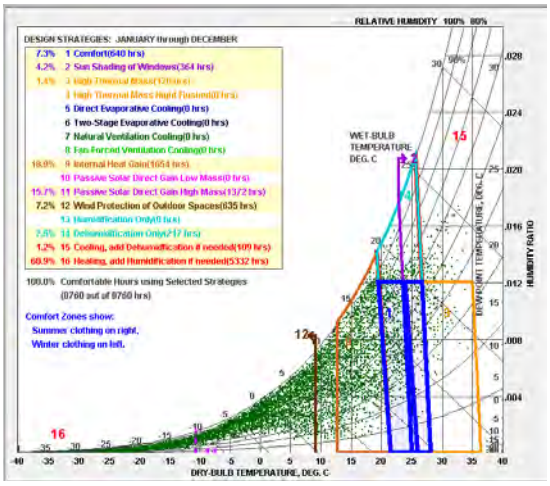

Figure 1. Left: bioclimatic chart for Winnipeg, from Climate Consultant© (Milne, 2015). Right: Manitoba Hydro Place, Winnipeg (Canada). Image: AIA top ten.

This office building is located in Winnipeg, Canada. It was designed by KPMB Architects in cooperation with Transsolar KlimaEngineering. The Köppen-Geiger climate classification for Winnipeg is Dfa: cold (T_{hot}>10, T_{cold}≤0), without a dry season and with hot summers (T_{hot}≥22). In the ASHRAE climate classification, it corresponds to zone 7: *very cold,* with an average of 5703 HDD (5000 < HDD 18°C < 7000). According to the BBCC and the 2030 Palette (Milne, 2015), the most relevant passive design strategies for this location are aimed at maximizing solar gains in combination with interior thermal mass, and minimising heat losses (low mass envelope, compact, airtight, super insulated and protected from the wind). See Figure 1.

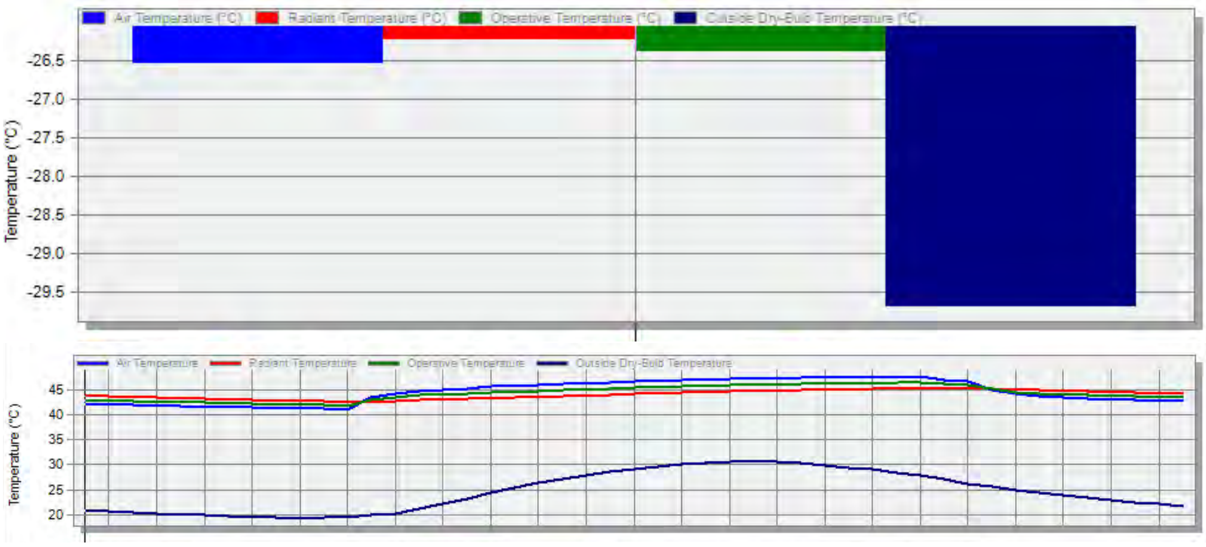

Figure 2. Winter and summer design temperature for the office block to the west, without environmental control systems (Energy Plus). We can appreciate that the indoor air temperature is respectively 3°C and 17°C higher than the outdoor air temperature. This is due to the effect of the solar gains and envelope alone in the first case, and in combination with the internal gains in the second case.

If we consider though the temperature increase indoors due to the effect of the solar gains plus envelope and internal gains, prior to the implementation of environmental control systems, it becomes quite relevant the incorporation of those two factors (envelope and internal gains) into the BBCC. For the west office block, the solar gains and envelope alone help increasing the temperature in just 3°C compared to the outdoor values in winter, while together with the internal gains produce a difference of +17°C in the summer. The indoor temperature becomes -26.5°C in winter and 47°C in summer, far away from comfort. See Figure 2.

The design of this building includes in fact several passive cooling strategies. It relies on a tempered buffer respiratory system with double-glass curtain walls to the east and west, and a series of three-floor-high atria to the north and six-floor-high atria to the south, to preheat the incoming air, minimising also the need for insulation materials. This system provides for fresh air all year round, in combination with a solar chimney for air extraction by stack effect, and elevated floors for air intake by displacement ventilation. In addition, each south atrium includes a water feature to humidify/dehumidify incoming air depending on the seasonal needs. It also utilizes a geothermal heat pump system for radiant heating and cooling via the exposed overhead concrete slab. Besides, it allows for operable windows and includes automated solar shading to prevent overheating. The U-values for the envelope are very low, ranging between 0.02 and 0.23 W/m^{2}K, and it is very airtight and relatively compact ($C=4.836*V_t^{2/3}S_G=0,63$ (Florensa and Roura, 2001)).

Due to its climate responsive design, its total energy consumption was of 138 kWh/m2 in 2011 , which implies a 66% of energy savings, compared to the Canadian Model National Energy Code for Buildings (Kuwabara et al., 2013).

Powerhouse Kjørbo

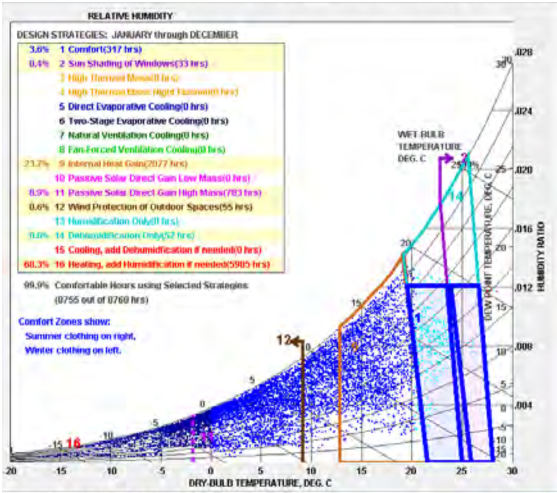

Figure 3. Left: bioclimatic chart for Oslo, from Climate Consultant© (Milne, 2015). Right: Powerhouse Kjørbo, Oslo (Norway). Image: Norwegian Green Building Centre.

This case is a refurbishment of two office blocks linked by the elevators and stairs. It is a pilot project for the Zero Emission Building Centre and was developed by the Powerhouse consortium as a ZEB. It is located in Bærum, near Oslo (Dfb), with a cold climate, without dry season and with warm summers ($T_{mon10} \geq 4$). Classified in ASHRAE as zone 5: *cool*, with 3700 HDD (3000 < HDD 18°D < 4000). The recommendations from the BBCC and the 2030 Palette are very similar to the previous case, though with a lower efficiency for thermal mass because of the higher cloud coverage throughout the year. See Figure 3.

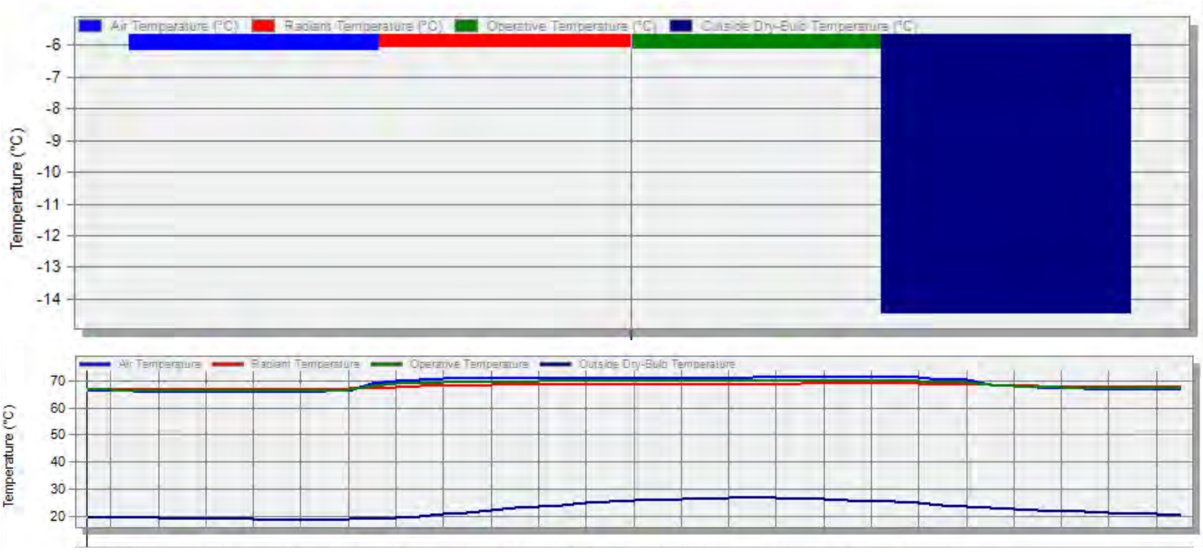

Figure 4. Heating and cooling design temperatures for the open landscape office without environmental control systems (Energy Plus). In this case, the difference between the indoor and outdoor air temperature is of around 9°C in the first case (envelope) and 40°C in the second (envelope and internal gains).

This office building is the case with highest compactness (0.76) and most stringent envelope, with an infiltration rate of just 0.23 ach and U-values between 0.08 and 0.8 W/m^{2}K (corresponding to the Norwegian Passivhaus Standard). This makes it possible to have a temperature increase in the winter of around 10°C indoors, compared to the outdoor conditions. See Figure 4. On the other hand, it also explains the extremely high air temperatures that could be reached indoors in the summer without environmental control systems. Then the highly insulated and airtight envelope does not allow the solar and internal gains to escape the building, creating a cumulative effect and reaching a temperature increase of around 40°C. This is due to the long summer days and the low angle of the sun that helps its penetration through the windows.

On the contrary, this building makes extensive use of thermal mass, leaving the concrete slabs exposed for thermal regulation in combination with the ventilation system (air intake from the façade on the top, distributing it in the central core, next to the concrete slabs for cooling of the structure). It maximizes daylighting as well, in conjunction with effective exterior solar screening to prevent overheating. Its building integrated ventilation solution makes use of the stairs and corridors for air distribution, allowing as well for opening the windows for natural ventilation in the warmer periods. Natural and hygroscopic materials with low emissivity help also in lowering the ventilation needs.

Together with the installation of sensors and a control system for lighting, equipment and installations, the total delivered energy was lowered to 45 kWh/m^{2}a including the operational energy for office equipment and server. As a reference, the Norwegian Building Code TEK-10 sets the total energy consumption for office buildings to 150 kWh/m^{2}a, so it achieved a reduction of 30% (Throndsen et al., 2015). If we exclude the consumption for the server and equipment to appreciate better the effect of the building envelope, it becomes around 20 kWh/m^{2}a, 80% lower than the typical case (Jensen et al., 2015).

Discussion and conclusion

As seen in the cases analysed, the very stringent envelopes used in cold climates have a very relevant effect in the indoor temperatures, especially in the summer. This is due to the fact that they are optimised for heat conservation in the winter, but it has a similar effect in the summer, when we need to dispose of the unwanted heat. When adding the high internal gains that are typical of office buildings, as well as the long days and low angle of the sun characteristic of high latitudes, these tend to create overheating problems.

It is also interesting to see the effect of these two different approaches to a similar problem. In the Manitoba Hydro Place, the main element for environmental control consists of a series of buffer zones along the façades. These allow for a higher flexibility in the regulation of the indoor conditions prior the use of mechanical systems, with the pre-heating or pre-cooling of the incoming air. On the other hand, it has a very limited effect in the winter (+3°C temperature increase), unless it is combined with other heating systems. The summer temperatures obtained in the energy simulations also confirm the need for the combination of natural ventilation with evaporative cooling in the south atria for the pre-cooling of the incoming air.

On the other hand, the Powerhouse Kjørbo is a more typical case, relying on a highly insulated and airtight envelope, together with a very compact shape. This is reflected on an improved behaviour in the winter, with a temperature increase of almost 9°C. However, it also means that the unwanted heat produced or stored in the summer has it more difficult for escaping the building. This could cause severe overheating problems without environmental control systems, which supports the use of different passive strategies to avoid them.

Consequently, this research underlines the need for updating the existing methods for bioclimatic building design (BBCD), in order to consider the spontaneously generated microclimate, as a result of the use of stringent envelopes in combination with high internal gains in cold climates office buildings.

Refurbishing Houses to Improve Energy Efficiency - Potential in Vietnam

Phan Anh Nguyen[1], Regina Bokel[1] and Andy van den Dobbelsteen[1]

[1] Department of Architectural Engineering and Technology, Faculty of Architecture and Built Environment, Delft University of Technology, Delft, Netherlands, p.a.nguyen@tudelft.nl

Abstract: The housing stock in Vietnam faces the challenge of becoming sustainable, provide a healthy living environment and reduce its energy consumption. The challenge lies not only in new buildings but also in existing houses. Nevertheless, little is known whether the new tube houses, the most dominant housing typology in Vietnam, can be renovated to offer adequate living conditions for the occupants, can tackle the issue of energy shortage, and can adapt to climate change. This paper introduces the potential of refurbishment design for energy efficiency. Although both passive and active approaches are encouraged, traditional bioclimatic design strategies, including solar control, natural ventilation and thermal insulation, are more popular because of their low cost and high efficiency. This paper concludes that solar energy has large potential in Vietnam because it can be used passively in sun space or actively in photovoltaics and solar thermal collectors. However, as these refurbishment measures require investments and careful design, the actual benefit in Vietnamese context has not yet been verified.

Keywords: refurbishment, energy efficiency, comfort, houses, Vietnam

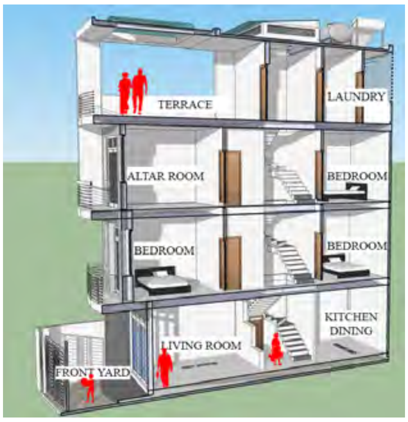
Introduction

Vietnam has undergone a lot of changes in its history. This includes different wars against Eastern and Western invaders as well as the development of a socialist society. As a result, Hanoi, the capital city of Vietnam, is therefore very rich in architectural styles and typologies which are reflected in its urban pattern. Most recently, the economic reform of 1986 called "Doi moi" has had a huge impact on the Vietnamese society. The rapid economic growth and privatisation of the market has resulted in the appearance and significant development of the "new tube house" which soon became the most dominant housing type in Vietnam. The spontaneous development of this housing type helped to solve the housing shortage in the context of urbanization and modernization. However, they also take major responsibility for a more sustainable housing stock in Vietnam.

The tube houses

New tube houses

A new tube house layout and spatial composition of a traditional one are presented in figure 1. A new tube house is normally built in a rectangular plot with the width of 3-6 meter and the depth of 10-20 meter; 3 to 5 storey high. Within this narrow plot of land, courtyard is often limited. The typical structure type is concrete frame and brick masonry.



New tube house Traditional tube house

Figure 1: Layout of a typical new tube house a traditional tube house in Vietnam

Several features of the traditional and new tube houses were compared as shown in table 1 (To, 2008). Traditional tube houses are more sustainable both in terms of spatial composition and climate responsive architecture elements.

Table 1: Comparison of the traditional tube houses and the new tube houses

	Traditional tube house	New tube house
Average plot size	3.5m x35m	4.5m x 20m
Inner courtyard	Yes	Limited
No. of storey	1-2	3-5
Building materials	Ceramic roof tiles, wood beams, brick walls, plaster	Reinforced concrete bearing frame, brick walls, plaster

Climate design in traditional tube houses

There are 3 main climatic regions in Vietnam from North to South, but there are some common climatic features that most houses have to deal with. Firstly, the high annual solar radiation result in great unwanted heat gains in building. Traditional tube houses applied double layer windows, with wooden shutter to block the direct sunlight and at the same time provide natural ventilation. The roofs are usually high and ventilated since the sun position is very high in the summer. Shading is provided by eaves and trees, while the later also benefit the houses with evaporative cooling. The houses were usually painted light colour to reflect the radiation. The high temperature and humidity make natural ventilation a mandatory design strategy in almost every house. Popular measures are high ceiling, large openings and the use of inner courtyard. Thermal mass is not applicable due to the low diurnal and seasonal temperature different. Most houses use local lightweight construction instead. Finally, most traditional houses have pitch roof because of the high annual rainfall. However, rain water harvesting is not yet considered though it has a huge potential to reuse this resource. Figure 2 below illustrates some of the bioclimatic techniques in traditional houses.

Energy efficient design strategies

Both passive and active measures for refurbishment can reduce energy consumption in houses and provide better living conditions. Passive design, or similar strategies such as bioclimatic design or environmental design, uses architectural measures and considers the local climate, such as air and sun, in providing thermal and visual comfort without using additional energy. Active measures, on the other hand, consume a certain amount of auxiliary energy. This paper discusses both active and passive measures for Vietnamese context.

The Trias Energetica, introduced in the late 1980s (Lysen, 1996), lists sustainable measures for buildings according to their significance to sustainability. The concept includes three steps. The first step is to reduce energy by improving thermal performance, reducing heating and cooling loads. The next step involves generating and using renewable energy sources as much as possible. Finally, when non-renewable energy use is inevitable, this step consists of exploiting the non-renewable energy efficiently.

Introduced in 2002, Cradle to Cradle (C2C) is a new concept of sustainability (McDonough & Braungart, 2002). It focuses on closing material cycles and using waste as food for new lifecycles. Although the applications of this philosophy were mainly for materials and products, there are great opportunities that it can also be used for sustainable buildings and urban planning (Dobbelsteen, 2008).

Inspired by the C2C approach, Dobbelsteen (2008) proposed a new strategy with three main steps for sustainable building (figure 3). Basic idea is to create loop cycles of energy and material flows so that no waste is dumped in nature. The first step is similar to the first one of the Trias Energetica, reducing energy demand. It is the most important step in all strategies and is often referred as passive design or bioclimatic design. The next steps, inspired by C2C, are to recycle the waste flows both internally and externally. The final step is to supply the house with sustainable energy sources and let waste be food. In terms of energy efficiency, these new strategy steps consider the use of waste energy in the cycles of energy, materials and water.

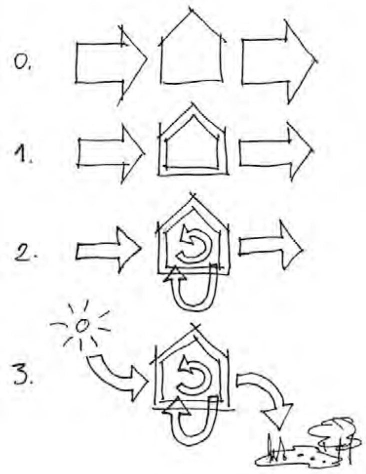

Figure 3: The New Stepped Strategy: 1. reduce the demand, 2. reuse and recycle, 3a. supply the resulting demand sustainably and 3b. let waste be food.(Dobbelsteen, 2008)

In Vietnam, the National Technical Regulation on Energy Efficiency Buildings (NTREEB) provides mandatory technical standards to achieve energy efficiency in the design, new construction or retrofit of civil buildings (MOC, 2013). These standards apply to 6 categories, i.e. building envelope, ventilation and air-conditioning, water heating, interior lighting, and auxiliary energy. These standards cover both active and passive measures and also align with the Trias Energetica. Table 2 below summarizes potential design measures for refurbishing new tube houses. Application of these design strategies in Vietnam context will be discussed in the following parts of this paper.

Table 2: Potential refurbishment design strategies for housing in Vietnam

Design strategies	**Detail measure**	**Potential**	**Involving Building Element**
Solar control	Orientation, massing Natural control (trees)	Limited	
	Shading devices	High	Opaque envelope
Natural ventilation	Cross ventilation	High	Windows Internal dividing
	Stack effect	Low	Inner courtyard
Evaporative cooling (EC)	Direct EC (trees, pond)	Moderate	Courtyard Envelope
	Indirect EC	Limited	Envelope
Passive solar gain	Direct gain (windows, envelope)	High	South Façade
	Indirect gain (sun space)	Limited	South Façade
Thermal mass	High thermal mass walls	Limited	Building envelope
Daylight	Side Windows Light well/ Courtyard	High	Windows Courtyard
Thermal Insulation	Highly insulated envelope	High	Roof
Solar energy	Photovoltaics (PV cells)	Moderate	Roof
	Solar collectors	High	Roof
Biomass	Algae/Bio waste	Limited	
Active heating/cooling	Ground source heat pump	Limited	Underground
	Air source heat pump	Moderate	Wall
Lighting and appliances	Energy efficiency equipment Automation system	High	Equipment

Passive design strategy

Avoid overheating

Located in a subtropical climate region, the main climate characteristics of Vietnam are a high annual temperature and high solar radiation. Therefore, overheating becomes the biggest problem in houses that passive design needs to deal with. There are several techniques that are used to prevent this phenomenon, such as solar control, natural ventilation and green building envelope. In order to achieve highly efficient cooling in a building, generally more than one system is applied.

Solar control (orientation/ shading device)

In Vietnam, the most preferable orientation is south and south west because it helps to catch the prevailing cool winds and easily avoid direct solar gain. High solar radiation and the low sun position make the west the least favourable orientation. However, for tube houses, where orientation options are limited, this principle only applies when the house has more than one façade. In refurbishment projects, changing orientation is usually not possible.

When the house has an unfavourable orientation, for example west, an additional shading solution can control the solar access. Firstly, shading can be achieved through architectural massing. A service space that does not require high thermal comfort can be used as a protective layer for the internal living space from the heat gain. This measure requires intensive refurbishing, usually when extra space is needed. Natural elements such as trees or shrubs can shade the building from sunlight and provide additional evaporative cooling of both indoor and outdoor environments (McGregor & Trulsson, 2001). As tube houses usually are built on the whole plot, there is lack of space to allocate additional trees in an existing project. Green facade, however, is an alternative. Finally, a shading device is the most efficient element to block solar radiation. Apart from being more efficient, external shading devices are easier to retrofit than an internal one (Almusaed, 2011).

Natural ventilation

Natural ventilation is the most popular and most important measure to deal with overheating in the hot and humid climate. First, it helps cool the human body by the effect of evaporation of sweat and by convection. In this case, the air speed needs to be at least 0.2 m/s for the cooling to be effective (A. T. Nguyen, 2013). Furthermore, building structures with high thermal mass, heated during daytime, can be cooled down using night ventilation provided that the temperature at night is within or below comfort zone. Finally, it helps prevent condensation in the high humidity environment.

Natural ventilation can be classified as three main types: cross ventilation, single side ventilation and stack ventilation (CIBSE, 1997). In Vietnam, stack ventilation is not efficient due to the small different temperature between indoor and outdoor temperature. Therefore, wind-driven ventilation is the main ventilation strategy (A. T. Nguyen, 2013).

In Vietnam, there are different kinds of monsoon winds. Good understanding of the monsoon wind can help supply the buildings with a fresh cool breeze in summer as well as avoid cold winds in winter. However, natural ventilation requires good control of air quality. In big cities, for example Hanoi or Ho Chi Minh City, sometimes air quality is very poor. The air quality index of these places can sometimes be very high, and there are dust and pollutants in the air. Therefore, no matter the ventilation system, there should be always an option to control the amount of air allowed into the buildings. Filtering layers such as greenery systems are recommended.

Evaporative cooling

Evaporative cooling is not efficient in hot and humid climate area because high humidity level increases thermal discomfort (Almusaed, 2011).

Passive solar use

In winter time, where the outdoor temperature can drop to a very low level, heating is needed to ensure a comfortable living space for occupants. The heating season occurs in the northern parts of Vietnam which are affected by the cold monsoon wind. The winter climate of northern Vietnam is not that severe compared to the winter in temperate climates as in the Netherlands. However, traditional Vietnamese architecture tends to mainly solve the problem of hot summers, maximizing opening, using lightweight structures. Therefore, the indoor temperature in wintertime can be very cold and require a lot of heating.

Passive solar strategies are widely used in the temperate climate, making use of the energy from the solar radiation to heat the internal space without mechanic equipment. Solar gains can be achieved directly (through glazed area) or indirectly (sunspace and thermal mass). Passive solar gains are mainly achieved on the south façade of a building (or north façade if the house is in the southern hemisphere). It is also a limitation of this strategy. Passive solar design is not feasible if the house is shaded by other buildings or trees, or, in case of the tube house, if the south façade is not available.

Sunspace
